TRANSACTIONS

OF THE

AMERICAN SOCIETY

OF

CIVIL ENGINEERS

(INSTITUTED 1852)

VOLUME 93

1929

Edited by the Secretary, under the direction of the Committee on Meetings and Publications.

Reprints from this publication, which is copyrighted, may be made on condition that the full title of Paper, name of Author, and page reference are given.

NEW YORK
PUBLISHED BY THE SOCIETY

1929

Entered according to Act of Congress, in the year 1929, by the AMERICAN SOCIETY OF CIVIL ENGINEERS, in the office of the Librarian of Congress, at Washington.

NOTE.—This Society is not responsible for any statement made or opinion expressed in its publications.

	GEORGE GIBBS	648
1709	**FLOOD CONTROL WITH SPECIAL REFERENCE TO THE MISSISSIPPI RIVER: A SYMPOSIUM**	655
	INTRODUCTION.	
	By Edgar Jadwin	657

No. PAGE

RESUME OF THE MISSISSIPPI RIVER FLOOD PROBLEM.
By C. McD. Townsend 659

RAINFALL CHARACTERISTICS OF THE MISSISSIPPI DRAINAGE BASIN.
By H. C. Frankenfield 675

RUN-OFF CHARACTERISTICS OF THE MISSISSIPPI RIVER DRAINAGE BASIN.
By Nathan C. Grover 690

THE WORK OF THE MISSISSIPPI RIVER COMMISSION.
By C. W. Kutz 697

FOREST COVER AS A FACTOR IN FLOOD CONTROL.
By E. F. McCarthy 716

RESERVOIRS FOR MISSISSIPPI VALLEY FLOOD PROTECTION.
By William Kelly 724

THE BASIS OF THE CASE AGAINST RESERVOIRS FOR MISSISSIPPI FLOOD CONTROL.
By Arthur E. Morgan 737

LEVEES AS A MEANS OF FLOOD CONTROL FOR THE MISSISSIPPI RIVER.
By J. F. Coleman 755

IMPROVEMENT OF NAVIGATION IN RELATION TO FLOOD CONTROL.
By Stuart C. Godfrey 762

THE FLOOD PROBLEM OF NEW ORLEANS, LOUISIANA.
By Marcel Garsaud 782

THE RELIEF OUTLETS AND BY-PASSES OF THE SACRAMENTO VALLEY FLOOD-CONTROL PROJECT.
By C. E. Grunsky 791

RECLAMATION AS AFFECTING FLOOD CONTROL.
By Elwood Mead 812

POWER AS AFFECTING FLOOD CONTROL.
By F. W. Scheidenhelm 815

THE EFFECT OF AGRICULTURAL DRAINAGE UPON FLOOD RUN-OFF.
By Sherman M. Woodward and Floyd A. Nagler 821

Discussion:
By J. P. Snow 840
Frank B. Maltby 841

PAPERS AND REPORTS OF SPECIAL COMMITTEES PUBLISHED IN PROCEEDINGS, AM. SOC. C. E., JANUARY, 1928, TO MAY, 1929, INCLUSIVE, NOT PUBLISHED IN TRANSACTIONS, VOL. 93.

Number of *Proceedings*.

STREAM FLOW IN GENERAL TERMS.
By Melvin D. Casler ..... January, 1928

FOUNDATIONS AND DRAINAGE OF HIGHWAYS.
By Albert C. Rose ..... January, 1928

DESIGN AND CONSTRUCTION OF CONCRETE PAVEMENTS.
By Clifford Older ..... January, 1928*

THE ROLE OF THE CIVIL ENGINEER IN POWER DEVELOPMENT.
By I. W. McConnell ..... January, 1928*

GENERAL CONTRACT SYSTEM VERSUS SEGREGATED CONTRACTS.
By Ward P. Christie ..... February, 1928

CROWN STRESSES IN A SKEW ARCH.
By J. Charles Rathbun ..... February, 1928

INLETS ON SANDY COASTS.
By Earl I. Brown ..... February, 1928*

THE COMPRESSIBILITY OF SAND-MICA MIXTURES.
By Glennon Gilboy ..... February, 1928*

* Published in *Proceedings* only.

	Number of *Proceedings.*
THE DESIGN OF AIRPLANE WING-BEAMS. By Joseph S. Newell	March, 1928*
CHEMICAL-ELECTRIC MEASUREMENT OF WATER. By Angelo Barbagelata	March, 1928*
FLOOD CONTROL ON THE RIVER PO IN ITALY. By John R. Freeman	April, 1928
ONE HUNDRED FIFTY YEARS' ADVANCE IN STRUCTURAL ENGINEERING. By H. M. Westergaard	April, 1928
IMAGINATION IN CITY PLANNING. By Stephen Child	April, 1928*
QUALIFICATIONS OF CONTRACTORS ON PUBLIC WORKS. By Frank T. Sheets	April, 1928*
EVALUATION OF WATER RIGHTS. By John E. Field	April, 1928
ADMINISTRATIVE WATER PROBLEMS: A SYMPOSIUM	April, 1928

NEW THEORY FOR THE CENTRIFUGAL PUMP*

By Allen F. Sherzer,† Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. J. W. MacMeeken, Thomson Kingsford, Sanford A. Moss, P. L. Reed, Max M. Munk, Elmo G. Harris, O. Gruenberger, Elmer G. Hooper, F. Theodore Mavis, Mario Medici, A. H. Blaisdell, Morrough P. O'Brien, R. T. Liddicoat, Lloyd H. Donnell, S. Timoshenko, A. B. Cox, and Allen F. Sherzer.

Synopsis

This paper presents an outline of a program of research and experiment on centrifugal pumps conducted in the Hydraulic Laboratory of the University of Michigan. This study has resulted in:

1.—The discovery of a number of errors in present accepted theories;
2.—The development of an entirely new theory; and
3.—The successful application of the new theory in increasing the efficiency of the centrifugal pump.

Introduction

It is a matter of common knowledge among those intimately connected with the design and manufacture of the centrifugal pump that most of the literature on this subject is of little assistance in their work. The actual design of a centrifugal pump is based largely on the known performance of similar pumps, and the designer determines empirically the various dimensions, constants, etc. An English writer on hydraulics, John Perry, makes the following significant statement:

* Presented at the meeting of October 5, 1927.

† Associate Prof., Mech. Eng., Univ. of Michigan; Cons. Hydro-Mech. Engr., Ann Arbor, Mich.

"In this subject of flowing water there are more misleading hypotheses, due to perverted ingenuity, than in almost any other; and unfortunately the logical conclusions drawn from these hypotheses when known to be untrue are said to be the statements of theory as opposed to practice."

A careful examination of the centrifugal pump theory will show, it is believed, that he has hit the nail squarely on the head.

Notation

In this paper, the following symbols are used:

1 or e	= point on entrance edges of runner vane.
2 or a	= point on discharge edges of runner vane.
r_1	= radial distance to Point 1.
r_2	= radial distance to Point 2.
V_2 or U_a	= peripheral speed of the runner at its outer diameter.
V_1 or U_e	= peripheral speed of the runner at its inner diameter.
C_2 or W_a	= absolute velocity of the water discharged from the runner.
C_1 or W_e	= absolute velocity of the water at entrance to the runner.
W_2 or V_a	= relative velocity of the water to the runner at discharge.
W_1 or V_e	= relative velocity of the water to the runner at entrance.
g	= acceleration due to gravity.
γ	= weight per unit volume of the liquid, in pounds.
H_{at}	= height of water column supported by atmospheric pressure.
D_3	= outer diameter of the vortex formed in the pump casing.
V_3	= peripheral speed of outer diameter of the vortex.
C_{p2}	= tangential component of C_2.
C_{p1}	= " " " C_1.
α_2 or δ_a	= angle between C_2 and V_2.
α_1 or δ_e	= " " C_1 and V_1.
β_2 or β_a	= " " W_2 and V_2.
β_1 or β_e	= " " W_1 and V_1.
ω	= angular velocity, in radians per second.
A_1, A_2, A_3	= areas of Orifices Nos. 1, 2, and 3. (See Fig. 8.)
H_1, H_2, H_3	= decreases in pressure head due to flow through Orifices Nos. 1, 2, and 3.

The Present Theory

From among many references setting forth the usual theory of the centrifugal pump, three are selected as typical:

(1) "Pumping Machinery", by A. M. Greene, Jr. His treatment is similar to "Die Zentrifugalpumpen", by Fritz Neumann, and is typical of the German method.

(2) "Centrifugal Pumps", by Lowenstein and Crissey.

(3) "Centrifugal Pumps", by R. L. Daugherty. This derivation of theory resembles that found in British texts.

A review of these and similar works indicates that the theoretical working equations may be derived, in general, from two distinct lines of approach. One of these seems to be held in especial favor by European writers, particu-

larly in Germany, and is based on the application of Bernoulli's theorem to the flow through the pump. The other is often found in works of British and American origin and is based on the laws of angular momentum.

Present literature on this subject as typified by these authorities appears to be incorrect both hydraulically and mathematically. Further, the fundamental laws of action of the centrifugal pump seem never to have been explained properly, and many misconceptions exist, even among those supposedly familiar with the hydraulics of these pumps.

Derivation by Application of Bernoulli's Theorem.—To simplify matters, the discussion will be confined to the derivation of Lowenstein and Crissey.* This corresponds closely with that given by Greene, and usually the same remarks may be applied to both.†

This derivation contains a most important and interesting error which contributes largely to the defects in present pump theory. One derivation reads, as follows:

$$h_a + \frac{W_a^2}{2g} = h_l + \frac{W_l^2}{2g} + p_l h_n \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (A)$$

This is merely the application of Bernoulli's theorem to the problem, since h_a is the pressure head in the fluid at Point a, and W_a is the absolute velocity of the water discharge from the impeller at Point a; while h_l is the pressure head at l, the entrance to the guide-vanes (a short distance from Point a), and $\frac{W_l^2}{2g}$ is the absolute velocity head at l. The term, $p_l h_n$, represents the hydraulic losses occasioned by the flow from Points a to l. This expression is Bernoulli's theorem in its usual form.

It is commonly considered that the total head at a is composed of a pressure head, h_a, and, in addition, a velocity head, $\frac{W_a^2}{2g}$. When the pump discharge is approximately zero, the pressure head, h_a, is very nearly $\frac{U_a^2}{2g}$ as is well known. Under the same conditions the relative velocity, V_a, becomes practically zero and, hence, the absolute velocity, W_a, approaches the peripheral speed of the impeller at a, or U_a. The velocity head is, therefore, $\frac{U_a^2}{2g}$, or nearly so. As will be shown, this theory would logically lead to a discrepancy between theory and practice of about 100 per cent.

Current Fallacies.—The usual explanation of this discrepancy indicates a serious misconception not only of the action of the centrifugal pump, but of one of the fundamental laws of hydraulics. The error is due to a misapplication of the well-known Bernoulli theorem.

When water flows in a pipe it is customary to say that the total head is obtained by measuring the pressure head by a piezometer at right angles to the flow, and adding the velocity head. This is a correct application of the theorem. The pressure and velocity exist as separate and distinct factors. However, water being set in rotation in a cylindrical vessel by the action of

* "Centrifugal Pumps," p. 7.

† See Appendix II for derivation in full.

a paddle or impeller, there is a pressure created by centrifugal force which is equal to $\frac{U_a^2}{2g}$ and which is part and parcel of the velocity itself. The total head may be regarded as either, but not both. The pressure exists merely because of the velocity in the circular path, but certainly not in addition to it.

It would be as logical to say that the "hammer", swung around by the athlete, has a total energy equal to the sum of the kinetic energy of the ball and the tension in the wire. Clearly the tension is not energy, but merely a force existing because of the tendency of the ball to fly off on a tangent. The energy is entirely kinetic. The act of letting go of the wire (destroying the tension) does not change any of the original energy, and the hammer flies off at a tangent with a velocity, U_a, which is the same as its former peripheral velocity. Therefore, the total energy is $\frac{U_a^2}{2g}$.

It is clear that the pump gives a head of only $\frac{U_a^2}{2g}$ at "shut off", instead of $\frac{U_a^2}{g}$ as required by all present theories, for the very simple reason that the energy imparted is only $\frac{U_a^2}{2g}$ and naturally the water can have no more energy than is given it by the impeller.

One of the reasons that might be advanced as to the cause of this error in the pump theory is the widespread failure to distinguish properly between pressure and energy. Pressure may measure potential energy and may serve to transmit energy, but it is not in itself energy any more than force is work.

Derivation by Principle of Angular Momentum.—In order better to understand this derivation, refer to Fig. 1. The value, $C_2 \cos \alpha_2$. represents the tangential component of the absolute velocity leaving the impeller, and $\frac{1}{g} C_2 \cos \alpha_2$ is the tangential momentum per second for each pound of water passing through the impeller. Momentum per second is force, and, therefore, $\frac{1}{g} C_2 \cos \alpha_2$ represents a force acting on the impeller in a direction opposite that of rotation. This force may be conveniently regarded as concentrated at Point 2. The moment of this force is $\frac{1}{g} C_2 \cos \alpha_2 r_2$, in which, r_2 is the radial distance from the center of the shaft to Point 2. In a similar manner, $\frac{1}{g} C_1 \cos \alpha_1$ represents a force concentrated at Point 1 which, if α_1 is less than 90°, will assist in rotating the impeller. The moment of this force is $\frac{1}{g} C_1 \cos \alpha_1 r_1$. The total turning moment on the wheel is the difference of these two moments, or,

$$\frac{1}{g} C_2 \cos \alpha_2 r_2 - \frac{1}{g} C_1 \cos \alpha_1 r_1$$

or,

$$\frac{1}{g}\,(C_2 \cos \alpha_2\, r_2 - C_1 \cos \alpha_1\, r_1)$$

If this torque be multiplied by the angular velocity, ω, the result is the work done by the impeller on the water, or,

$$\text{Work} = \frac{1}{g}\,(C_2 \cos \alpha_2\, r_2\, \omega - C_1 \cos \alpha_1\, r_1\, \omega)$$

but $\omega\, r_2 = V_2$ and $\omega\, r_1 = V_1$. Hence,

$$\text{Work, or head} = \frac{1}{g}\,(C_2\, V_2 \cos \alpha_2 - C_1\, V_1 \cos \alpha_1) \ldots\ldots\ldots (B)$$

This is exactly the equation obtained by the application of Bernoulli's theorem to the flow of water through the pump.*

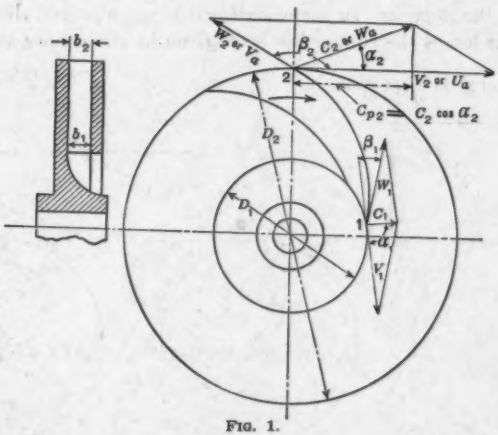

FIG. 1.

If the water approaches the vane at entrance in a radial direction, as is often assumed, obviously, the runner can receive no angular momentum from that source; hence,

$$C_p\, r_1 = 0$$

and,

$$H = \frac{1}{g}\left(C_{p2}\, r_2\right) = \frac{1}{g}\left(C_2\, V_2 \cos \alpha_2\right)^{\dagger} \ldots\ldots\ldots\ldots (C)$$

Evidently, as far as the final results go, one method is equivalent to the other.

Reasons for Observed Discrepancies.—Equations (*B*) and (*C*) form the basis of all present theories. They do not, and cannot, furnish a rational basis for the analysis and design of centrifugal pumps.

* See Equation No. 15, p. 12, in "Centrifugal Pumps," by Lowenstein and Crissey. Also, see Appendix II.

† This is identical with Equation No. 36, p. 62, in "Centrifugal Pumps," by Daugherty.

The reasons for this fallacy, as before, involve a misconception of the true action of a centrifugal pump. The increase in angular momentum of 1 lb. of water in passing through the impeller is,

$$\frac{1}{g}\,(C_{p2}\,V_2 - C_{p1}\,V_1)$$

On the assumption that the water approaches the entrance edge of the vanes in a radial direction and, hence, $C_{p1} = 0$, the work done on 1 lb. of water is found to be $\frac{1}{g}\,(C_{p2}\,V_2)$. This is nearly correct, but not for the reason given.

The water probably never approaches the vanes in a radial direction, but rotates with the impeller at all rates of flow. Hence, C_{p_1} is probably never zero. The error lies in the assumption that the water had some energy as it approached the runner which it received from some outside source. Naturally, if this is so, this should be deducted from the final energy to obtain that given by the impeller. In the centrifugal pump, however, all the energy in the water as it leaves the runner has been given by the runner and, hence, the increase in energy is $\frac{1}{g}\,(C_{p2}\,V_2)$.

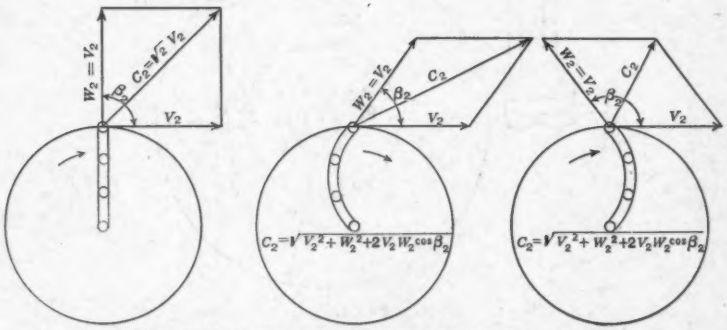

FIG. 2.—DISCHARGE DIAGRAMS FOR THE ASSUMED CONDITION OF FREE RADIAL ACCELERATION OF THE WATER.

NEW CONCEPTIONS OF PUMP ACTION

Imagine a circular disk with a radial groove from the center to the outer circumference (Fig. 2). Suppose that this disk revolves in a horizontal plane and that a very smooth round ball is introduced into the groove at the center. If there are no losses due to friction and the only forces acting are those of centrifugal force and inertia, the ball will cross the outer circumference in a radial direction relative to the moving disk with a velocity in that direction equal to its peripheral velocity, V_2*. The absolute velocity of the ball, therefore, will be the resultant of these two velocities, or $\sqrt{2} \times V_2$, in a direction inclined 45° to the tangent. The kinetic energy is clearly,

$$\frac{1}{2}\,M\,V_2^2, \text{ or } \frac{2\,V_2^2}{2\,g} = \frac{V_2^2}{g}$$

* See Appendix I for proof.

The energy given to the water, however, is only about one-half that obtained by this process. The reason is that the disk and ball and the centrifugal pump are by no means equivalent, as has been commonly supposed. For the similarity to hold, it would be necessary (1) that the vanes or grooves be radial; (2) that the particles be free to accelerate radially; and (3) that the particle be introduced at the center.

Real Action of Centrifugal Pump.—None of these conditions is fulfilled in the centrifugal pump. The water contained in the impeller rotates with it and owing to centrifugal force has a tendency to move out from the center. Outside the runner is the spiral casing filled with water. The pressure in this casing acts to retard the flow from the runner. If the discharge valve is opened the pressure falls in the casing and more water flows from the runner. In the same way if the discharge valve is closed the pressure rises in the casing, thus reducing the discharge.

Thus, the flow from the runner is due to the difference between the force tending to throw the water out (centrifugal force) and the pressure in the casing tending to hold the water in the runner. This, of course, entirely prevents the free radial acceleration necessary to obtain the theoretical $\frac{V_2^2}{g}$ so often given in texts. A runner without a casing and discharging into the air might approximate this condition, but such a machine would be of no practical importance in engineering. In addition, it would be impossible to introduce each particle of water at the center of the shaft.

The result, $\frac{V_2^2}{g}$, would obviously be true only for radial vanes, at least at the discharge tips, which is only one special case. The slot in the disk might be curved forward in the direction of rotation and hence discharge the ball with an absolute velocity greater than V_2 (Fig. 2), or it might be curved backward in the opposite direction, in which case the absolute velocity is less than V_2.* If these vanes were curved forward in such a manner as to be tangent to the outer circumference the final absolute velocity would be $2\ V_2$ in the direction of the tangent and the energy per pound would be,

$$\frac{4\ V_2^2}{2\ g} = 2\ \frac{V_2^2}{g}$$

On the other hand, if the vanes were curved backward and tangent, the absolute velocity and, hence, the kinetic energy, would be zero. Thus, the energy put into the ball may vary according to the curvature of the vanes from zero to $2\ \frac{V_2^2}{g}$, with a mean of $\frac{V_2^2}{g}$ for radial vanes. All this presupposes that the ball is free to accelerate radially, which is never true of the water in the pump. The fact that the present pump theory is purely kinetic and depends on the previous assumption of free radial acceleration seems to have been overlooked completely. This theory would be more applicable to a pump without a casing and discharging freely into the air. Under such conditions the

* See Appendix I.

energy given to the water is entirely kinetic and can be readily obtained from the vector diagrams.

Assuming free radial acceleration, the relative velocity at discharge, regardless of the direction of the vane (forward, radial, or backward), is always equal to the peripheral speed of the vane at its outer diameter, V_2. The only factor that could make it less would be friction in passing through the impeller. In such case the kinetic energy at exit is not the sole measure of the work done on the fluid, as that done in getting it to the outer circumference should also be included. This error is commonly made in drawing the vector diagram at the discharge from the impeller.

The implied loss due to friction in the impeller passages is the hidden assumption that causes much of the difficulty in fitting theory to practice. In Fig. 3 the correct and incorrect values of the relative velocities, W_2 and W_2', and of the absolute velocities, C_2 and C_2', are shown. If the fluid is free to accelerate radially without friction loss in the impeller, the relative velocity, W_2, must equal the peripheral speed, V_2. The direction of W_2 is that fixed by the vane angle, but its magnitude is constant and equal to V_2 under the assumptions. Actually, the value of W_2 is often much less than V_2, as W_2'; but in such cases the original assumptions are not realized.

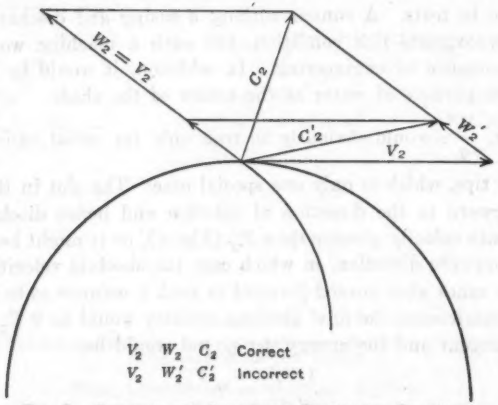

FIG. 3.—CORRECT AND INCORRECT DISCHARGE DIAGRAMS.

The restriction of the relative velocity, W_2, by the pressure in the casing is accomplished very efficiently, whereas an equal restriction caused by friction in the impeller passages would be very wasteful of energy. Similarly, the flow of water from a long pipe might be regulated very efficiently by a weir of variable height at the discharge end, but if the regulation was by a valve placed in the line, energy would be lost in friction.

EXPERIMENTAL VERIFICATION

Theoretical vs. Actual Heads.—In Fig. 4(*a*) is represented graphically the generally accepted theory of the centrifugal pump. Here the ideal quantity-head curve is shown beside the actual quantity-head curve for comparison.

Similar curves may be found in numerous works of reference.* There is an obvious inconsistency between the equations representing the head imparted to the water and their graphical representation as in Fig. 4(*a*). For example, the ideal quantity-head curve is seen to pass through a point representing more than double the head actually developed at the point of zero discharge—an obvious impossibility as the pressure is caused only by centrifugal force.

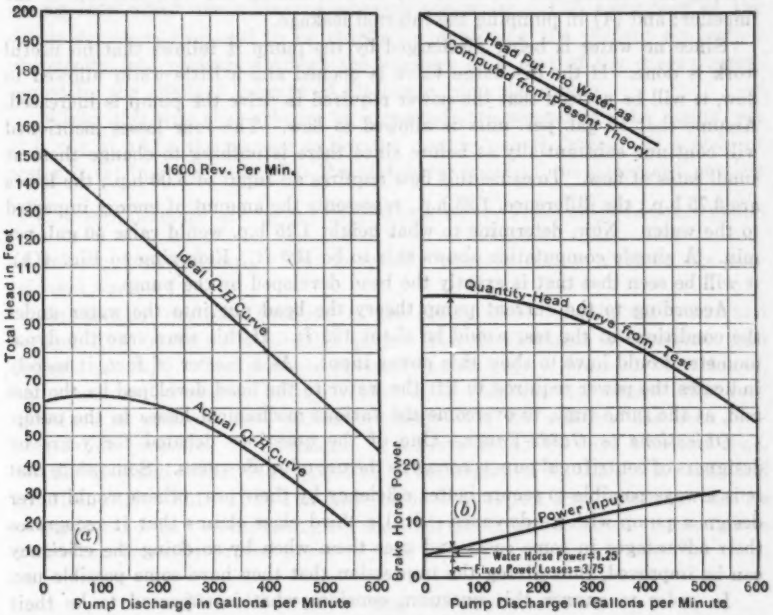

FIG. 4.—GRAPHICAL COMPARISON OF THEORETICAL AND ACTUAL HEADS IN CENTRIFUGAL PUMPS.

According to the present theory the total head is considered to be composed of two items, pressure and velocity. A measurement of the pressure indicates an average value of about $\frac{U_a^2}{2g}$ at or near the point of zero discharge. Discharge diagrams of runners show that at small rates of flow the absolute velocity, W_a, is nearly equal to U_a and, hence, the energy represented by it is nearly $\frac{U_a^2}{2g}$. This would apparently mean that the total head is approximately $\frac{U_a^2}{2g} + \frac{W_a^2}{2g}$, or very nearly $\frac{U_a^2}{g}$. As a matter of actual experience only a head of about one-half the ideal is developed by the pump. The difference is commonly said to be due to shock losses and many elaborate formulas have been developed to account for it.

* "Centrifugal Pumps," by R. L. Daugherty, pp. 76-77, Figs. 58-59.

Test Determination of Power Expenditure.—Fortunately, it is possible to settle this question beyond any doubt by a simple test in the laboratory. Referring to the characteristic curves obtained from a test of a centrifugal pump, as in Fig. 4(*b*), it will be noticed that at the point of zero discharge the power required to drive the pump is the minimum (3.75 h.p.). This power is consumed as follows: (1) In overcoming the bearing friction; (2) in overcoming the stuffing-box friction; (3) in overcoming the disk friction of the impeller; and (4) in pumping the internal leakage.

Since no water is being discharged by the pump it follows that no useful work is done. If the discharge valve is opened and a little water allowed to flow, it will be noticed that the power required to drive the pump is increased. Assume that 50 gal. per. min. is allowed to flow. The four losses mentioned will continue substantially as before since there is nothing to change them at small rates of flow. To cause this flow requires an input of 5.00 h.p.; the losses are 3.75 h.p.; the difference, 1.25 h.p., represents the amount of energy imparted to the water. Now, determine to what height 1.25 h.p. would raise 50 gal. per min. A simple computation shows this to be 100 ft. Referring to Fig. 4(*b*), it will be seen that that is exactly the head developed by the pump.

According to the current pump theory the head put into the water under the conditions of the test would be about 195 ft. If this were true the dynamometer would have to show this power input. As a matter of fact, it merely indicates the power required to lift the water to the head developed by the test and, at the same time, to overcome the various mechanical losses in the pump.

Objections to Guide-Vanes.—One of the questions debated for years by designers of centrifugal pumps concerns the use of guide-vanes. Some state that it is always possible to secure better efficiency by their use; others would never design a pump with guide-vanes. Still a third class claims that it recognizes their advantages in some cases and uses them when by so doing the efficiency can be improved, thus giving the impression that they have some possible use.

In order to answer this question, consider what is supposed to be their function. It has been shown in the various theories that at the discharge from the runner the water has a pressure head, $\frac{P_2}{\gamma}$, as well as a velocity head, $\frac{C_2^2}{2g}$. It is often stated that this velocity head, $\frac{C_2^2}{2g}$, will be lost in shock, friction, etc., unless suitable provision is made for its recovery. The commonly accepted idea has been that at very small rates of flow this energy is about equally divided between pressure and velocity and that the entire velocity head under these conditions was apt to be lost unless special provision was made in the form of guide-vanes or diffuser vanes. Such vanes were designed so as to receive the absolute velocity of the water. By increasing the area of the water passages between them, the velocity was expected to be converted most efficiently into pressure.

Evidently, from the previous discussion, the use and benefits of guide-vanes are founded on a misconception of the theory. In a centrifugal pump it is absolutely wrong to assume that the total energy is represented by the pressure in the casing plus the kinetic energy of the absolute velocity of discharge.

As the water is confined to a circular path, its kinetic energy is necessarily converted into pressure without any assistance from the guide-vanes. In fact, they often serve to obstruct the natural flow of water, which entirely defeats their purpose and renders them useless. From the point of view of practice equal or better efficiency can be obtained with a properly designed volute.

Purpose of Casing.—What has just been said with regard to the use of guide-vanes may also be extended to include the so-called volute or spiral casing into which the runner discharges the water. The advantage of the volute casing is supposed to lie chiefly in permitting the efficient conversion of velocity into pressure thrdugh the recovery of a part of the energy represented by the absolute velocity of discharge from the runner.

While it is true that velocity is converted into pressure in the casing, yet it is not at all in the manner or for the reasons usually given. If a body of water is set in rotation so that the peripheral speed of the outermost particle is V, then a pressure will be developed equal to $\frac{V^2}{2g}$, a case of perfect conversion of velocity into pressure. This is exactly what is taking place in the centrifugal pump.

Apparently, the only function of the casing is to restrain the water and compel it to move in a circular path. The development of pressure then follows naturally. The pressure obviously exists only because of the velocity, and one may be said to be equivalent to or measure the other. The very existence of pressure here indicates clearly that the velocity has been converted into pressure. It is difficult to see how it can be done a second time, yet this is exactly what is supposed to be accomplished by the guide-vanes and spiral casings. This shows how hopeless it is to expect any gain from the use of guide-vanes and spiral casings, since their advantage is based on conditions which can be easily proved never to have existed.

New Analysis of the Centrifugal Pump

The Impeller and Its Action.—A pump is fundamentally a device for increasing the energy of the fluid passing through it. In the centrifugal pump this energy is first in the kinetic, and, later, in the pressure form. The conversion of velocity into pressure takes place in the casing as will be shown. For the present, however, consider the action of the runner quite apart from that of the casing.

Imagine a runner arranged so as to receive the water at its suction entrance and discharge it into the air—a device resembling a lawn sprinkler.

A particle of water, initially at rest at the level of the source of supply, soon leaves the runner with high velocity and, therefore, possesses kinetic energy. All this energy must necessarily have come from the impeller. Numerically, it is equal to $\frac{C_2^2}{2g}$ per lb. of water, neglecting any slight static head which might be present in addition to the velocity head, $\frac{C_2^2}{2g}$. The

design of the vanes at the discharge from the runner determines the amount of energy given to the water. This can be seen by reference to Fig. 5. If the vanes are curved forward in the direction of rotation the kinetic energy given to the water will increase as the discharge from the pump is increased. On the other hand for backward curved vanes the reverse will be true.

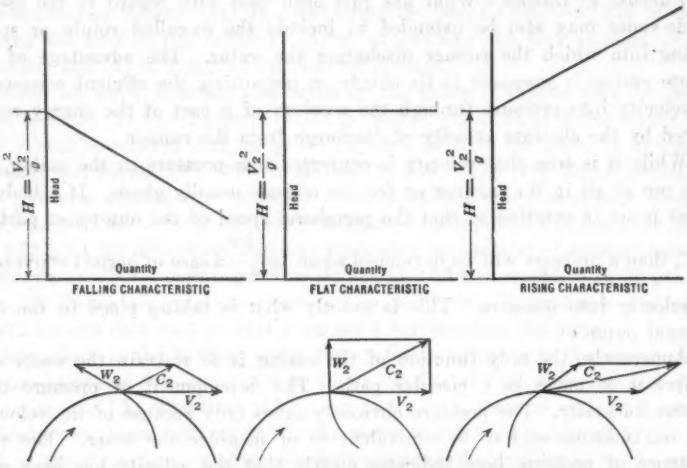

FIG. 5.—EFFECT OF THE VANE ANGLE, β_2, ON THE PUMP CHARACTERISTIC ACCORDING TO PRESENT THEORY.

In remarking on this, texts usually add that if the vanes are radial the energy given to the water is independent of the rate of discharge.* This is obviously incorrect as may be seen from Fig 5. All that can safely be said for such a condition is that the energy imparted is less affected by the rate of discharge. The relation between these elements is called the quantity-head curve, or often the pump characteristic (Fig. 5). In the case of forward curved vanes the head increases as the rate of discharge, and the runner is said to have a rising characteristic. If the vanes are radial it is usually (incorrectly) assumed that the head is independent of the discharge, and such runners are said to have a flat characteristic. When the vanes are curved backward the head decreases as the rate of flow, and the characteristic is said to be steep or falling.† All this, with some exceptions, would be substantially correct for a pump without a casing, but textbooks fail to state that qualification.

As a matter of fact in centrifugal pumps as built commercially the vane angle is only one of several factors that determine the pump characteristic. It does not, as many imagine, entirely control the shape of the quantity-head curve. If there were no casing and the water were free to discharge into the

* See "Centrifugal Pumping Machinery," by DeLaval, p. 58, Fig. 56.
† "Centrifugal Pumps," by R. L. Daugherty, p. 63, Fig. 55.

air the total energy imparted to the water could be measured by the work done on it in giving it its absolute kinetic energy, $\frac{C_2^2}{2g}$ per lb. of water.

Effects of Casing.—As a matter of fact pumps always have a casing, generally spiral in design, which completely encloses the impeller. The water in this casing between the runner and the side-walls and also in the volute is set in rotation by the impeller. The water discharged from the runner with an absolute velocity, C_2, has a relatively large tangential component. Mingling with that circling in the casing, it assists in maintaining the revolution. As the water is confined to a somewhat circular path a pressure is created in the casing due to centrifugal force.

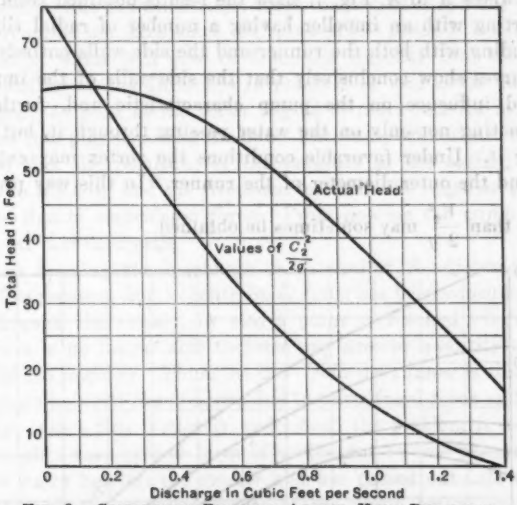

FIG. 6.—COMPARISON BETWEEN ACTUAL HEAD DEVELOPED AND THAT COMPUTED FROM VALUES OF THE ABSOLUTE VELOCITY OF DISCHARGE FROM THE RUNNER, OR C_2.

To use a very homely illustration this might be compared to a paddle stirring the water in a cylindrical tank assisted by a jet of water applied tangentially. The final velocity of rotation is the result of these two causes; but it is difficult to separate the effect of each. Basing the theoretical power input on the value of the absolute velocity of discharge from the runner (C_2) much less power is obtained than is actually supplied as determined by an accurate test. In Fig. 6 the value of $\frac{C_2^2}{2g}$ has been plotted as a function of the discharge. The actual quantity-head curve is also shown for comparison. Actually, much more energy has been imparted to the water than can be accounted for on the basis of the absolute velocity head, $\frac{C_2^2}{2g}$. It seems more

nearly to approach the constant value, $\frac{V_2^2}{2g}$, but probably is actually some intermediate value yet to be determined.

The runner acts not only on the water passing through it, but also on that outside, between it and the side-walls of the casing. The water in this space is set in rotation by the dragging action of the side-walls of the impeller. As a result, a vortex is formed within the case quite independent of whether or not the pump is actually discharging any water.

The nature of the side-walls of the impeller and case determines the extent to which this vortex may be formed. A number of experiments were performed to determine the effect of various conditions of the side-walls of the impeller. Curves *A* to *E*, Fig. 7, show the results obtained from a succession of tests starting with an impeller having a number of radial ribs cast on its sides and ending with both the runner and the side-walls entirely smooth.

These curves show conclusively that the side-walls of the impeller have a very marked influence on the pump characteristic and, further, that the impeller is acting not only on the water passing through it, but also on that surrounding it. Under favorable conditions the vortex may extend into the casing beyond the outer diameter of the runner. In this way pressures somewhat higher than $\frac{V_2^2}{2g}$ may sometimes be obtained.

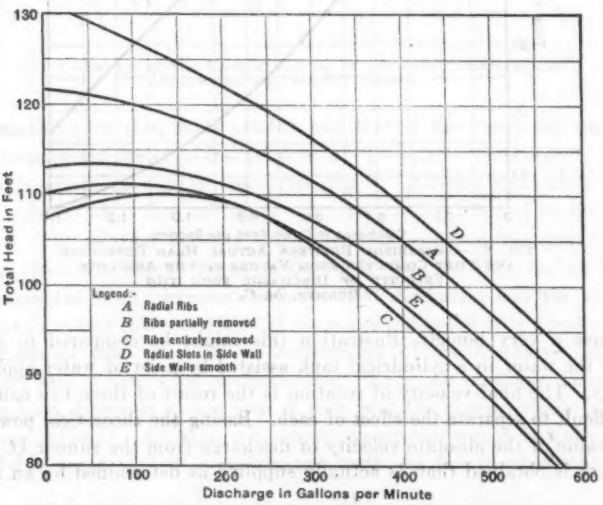

FIG. 7.—CHARACTERISTIC CURVES OF A 4-INCH CENTRIFUGAL PUMP AT 1 750 REVOLUTIONS PER MINUTE, SHOWING VARIATION IN THE CHARACTERISTIC CAUSED BY DIFFERENT SIDE-WALLS OF IMPELLER.

The absolute velocity of the water as it leaves the impeller will assist in maintaining this rotation and the vortex results from their combined action. The outer diameter of this vortex, which determines the pressure developed by the pump, will be called D_3 and the peripheral speed of the water at that

point, V_3. It is likely that D_3 and, hence, V_3 will vary somewhat with the pump discharge. Owing to the fact that the water is confined to a circular path, this velocity, V_3, is converted into pressure and causes the water to rise to a height, $\frac{V_3^2}{2g}$.

Action After Flow Begins.—Consider a pump running at a certain speed, but with its discharge valve closed. The water in the impeller and the casing is set in rotation, creating a pressure in the pump, but flow from the runner is prevented owing to the pressure of the water in the casing. Now, assume that the discharge valve is opened a trifle to permit a slight amount of flow. The pressure in the casing falls, and the pressure opposing the flow from the impeller decreases, but the centrifugal force tending to throw the water out of the impeller remains the same since the speed of the pump is constant.

Consequently, water will flow in from the impeller into the casing, the quantity depending on the difference in pressure as well as on the area of the water passages. As soon as the water begins to move relative to the impeller friction comes into play opposing the flow. The pump will adjust itself to these conditions so that the resultant of the pressure in the casing, the drop in pressure due to the flow, and the frictional losses in the impeller will equal the total pressure due to centrifugal force. From now on the pump will operate continuously at this discharge.

On further opening the discharge valve similar re-adjustments continue until the entire pressure due to centrifugal force has been consumed in forcing the water through the runner, or else a point is reached where the atmospheric pressure is no longer able to force any greater quantity of water into the suction of the impeller. Thus, the flow from the runner is simply governed by the difference between the pressure due to centrifugal force and the pressure in the casing. Once this is clearly understood the problem is merely that of the flow through a very special form of orifice due to this pressure difference.

After the water has left the runner and has passed out into the casing, it must flow through the so-called throat of the pump before passing the discharge flange. This throat is merely the point of maximum cross-section of the volute. All the water discharged from the runner passes through this, a third orifice.

Pump Considered as Three Orifices.—Hence, the entire problem of the centrifugal pump is that of flow through three orifices in series. The first is at the suction entrance to the impeller; and this determines the maximum capacity of the pump. The second is at the discharge from the runner, and, the third is at the throat of the pump. Each of these orifices or points of restriction has its own characteristics and their combined effect determines the pump characteristic.

Consider that the pump is running at a constant speed. The pressure developed by centrifugal force, tending to force the water out of the impeller, is constant and is quite independent of the flow or the amount of it. Centrifugal force is equal to $\frac{M V^2}{r}$; evidently, neither V nor r is greatly changed

by the flow of water and the mass, M, need not be considered in determining the energy input per pound of water. In other words, if there were no loss of pressure in the impeller and casing, the pump would deliver any quantity of water within the limit of the suction capacity at a constant pressure of approximately $\frac{V_2^2}{2g}$. A drop in pressure at the discharge flange is necessary if any water is to flow from the impeller.

The quantity that will flow depends on the area of the water passages, and its velocity, on the pressure difference established. The velocity is, therefore, quite independent of the quantity being discharged. The quantity is the product of the velocity and the area of the water passages measured perpendicularly to it.

The amount the pressure at any point falls below the horizontal line tangent to the quantity-head curve at "shut-off" is very nearly that required to force this quantity of water through the pump. The total drop in pressure is (1) that required to cause the given quantity of water to flow; and (2) that required to overcome the hydraulic losses. These are fundamentally different in their nature and yet produce similar effects on the pump characteristic.

Analogy Between Pump and Electric Generator.—The drop in pressure required to produce flow is an example of a loss in pressure without any loss in power. A similar instance occurs in the field of electricity. An electric generator would deliver a constant voltage at its terminals were it not for two principal losses. These are the drops in pressure due to armature reaction and to internal resistance. The drop in pressure due to armature reaction causes no loss of energy, whereas that due to resistance wastes energy in the form of heat. A loss of pressure that does not involve a loss of power is called a pressure drop, while a loss of power is called a pressure loss. These same terms might apply to the pump theory. In fact, many close analogies exist between the centrifugal pump and a separately excited shunt generator.

In the pump the drop in pressure without loss of power merely means that a greater pressure drop is required to discharge a given quantity of water through a small orifice than for one of larger area; or that for a given pressure drop, more water will flow through a large orifice than a small one. This does not mean that the large orifice is necessarily more efficient than the smaller one for both may have a coefficient of nearly 100 per cent.

When water flows through the runner it has to overcome the frictional losses. These produce a drop in pressure, which is also a loss of power. Since the length of the path of the water in the impeller is short and the water ways are smooth, this loss of power due to friction usually is not large.

Application of Theory to Determine Pump Characteristic

To make the new theory clear and indicate its application to practice, three characteristic curves, showing the relation between the capacity and

head, at constant speed, have been worked out for different typical pumps. These machines are of usual design and construction and of well-known makes. Fig. 8, showing typical views, serves to illustrate the three points of control or orifices. The first is at the entrance to the impeller-vane passages, and its area is equal to the product of the dimensions, B and D, and the total number of vane passages. The second is at the discharge from the impeller-vane passages; its area is the product of the dimensions, A and C, and the total number of vane passages. The third is at the throat of the pump; its area is usually that of a circle of diameter, E (Fig. 8).

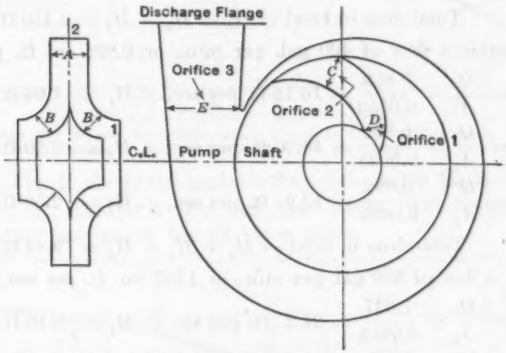

FIG 8.—VIEWS OF SHELL AND RUNNER, SHOWING LOCATION OF THE THREE ORIFICES.

Analysis of the Characteristic of a 4-Inch Double-Suction Centrifugal Pump.—For Orifice 1 at entrance to the impeller vanes:

$$\text{Area } A_1 = B \times D \times \text{number of vanes} \times 2 = 0.0553 \text{ sq. ft.}$$

For Orifice 2 at discharge from impeller:

$$\text{Area } A_2 = A \times C \times \text{number of vanes} = 0.0625 \text{ sq. ft.}$$

For Orifice 3 at the throat of the shell:

$$\text{Area } A_3 = \frac{\pi E^2}{4} = 0.0694 \text{ sq. ft.}$$

The velocity through the orifice is equal to $\frac{Q}{A}$, hence the velocity through Orifice 1 is,

$$\frac{Q}{A} = \frac{Q}{0.0553} = C_1 \text{ ft. per sec.}$$

the velocity through Orifice 2 is,

$$\frac{Q}{A_2} = \frac{Q}{0.0625} = C_2 \text{ ft. per sec.}$$

and the velocity through Orifice 3 is,

$$\frac{Q}{A_3} = \frac{Q}{0.0694} = C_3 \text{ ft. per sec.}$$

The drop in head or pressure required to produce the speed, C_1, C_2 or C_3, can be computed from the well-known formula, $H = \frac{C^2}{2g}$.

If a flow of 200 gal. per min. (= 0.446 cu. ft. per sec.) be assumed:

$$C_1 = \frac{Q}{A_1} = \frac{0.446}{0.0553} = 8.05 \text{ ft. per sec.} \therefore H_1 = 1.010\text{-ft. drop}$$

$$C_2 = \frac{Q}{A_2} = \frac{0.446}{0.0625} = 7.13 \text{ ft. per sec.} \therefore H_2 = 0.765\text{-ft. drop}$$

$$C_3 = \frac{Q}{A_3} = \frac{0.446}{0.0694} = 6.43 \text{ ft. per sec.} \therefore H_3 = 0.645\text{-ft. drop}$$

Total drop in head $= H_1 + H_2 + H_3 = 2.410$ ft.

Next, assume a flow of 400 gal. per min., or 0.892 cu. ft. per sec.:

$$C_1 = \frac{Q}{A_1} = \frac{0.892}{0.0553} = 16.15 \text{ ft. per sec.} \therefore H_1 = 4.06\text{-ft. drop}$$

$$C_2 = \frac{Q}{A_2} = \frac{0.892}{0.0625} = 14.30 \text{ ft. per sec.} \therefore H_2 = 3.19\text{-ft. drop}$$

$$C_3 = \frac{Q}{A_3} = \frac{0.892}{0.0694} = 12.9 \text{ ft. per sec.} \therefore H_3 = 2.59\text{-ft. drop}$$

Total drop in head $= H_1 + H_2 + H_3 = 9.84$ ft.

Next, for a flow of 600 gal. per min., or 1.337 cu. ft. per sec.:

$$C_1 = \frac{Q}{A_1} = \frac{1.337}{0.0553} = 24.2 \text{ ft. per sec.} \therefore H_1 = 9.10\text{-ft. drop}$$

$$C_2 = \frac{Q}{A_2} = \frac{1.337}{0.0625} = 21.4 \text{ ft. per sec.} \therefore H_2 = 7.10\text{-ft. drop}$$

$$C_3 = \frac{Q}{A_3} = \frac{1.337}{0.0694} = 19.3 \text{ ft. per sec.} \therefore H_3 = 5.80\text{-ft. drop}$$

Total drop in head $= H_1 + H_2 + H_3 = 22.00$ ft.

Finally, for a flow of 800 gal. per min., or 1.780 ft. per sec:

$$C_1 = \frac{Q}{A_1} = \frac{1.780}{0.0553} = 32.2 \text{ ft. per sec.} \therefore H_1 = 16.10\text{-ft. drop}$$

$$C_2 = \frac{Q}{A_2} = \frac{1.780}{0.0625} = 28.5 \text{ ft. per sec.} \therefore H_2 = 12.60\text{-ft. drop}$$

$$C_3 = \frac{Q}{A_3} = \frac{1.780}{0.0694} = 25.7 \text{ ft. per sec.} \therefore H_3 = 10.30\text{-ft. drop}$$

Total drop in head $= H_1 + H_2 + H_3 = 39.00$ ft.

The head developed by this pump at "shut off", or the point of no delivery, is 137 ft. as found by a test.

For various rates of flow the head is obtained by deducting the total drop, as calculated for any assumed rate of flow, from the shut-off head of 137 ft. Hence,

The head at 200 gal. per min. = 137.0 — 2.41 = 134.6 ft.
" " " 400 gal. per min. = 137 — 9.84 = 127.2 ft.
" " " 600 gal. per min. = 137 — 22.00 = 115.0 ft.
" " " 800 gal. per min. = 137 — 39.00 = 98.0 ft.

This is shown graphically in Fig. 9 by the full line. The actual quantity-head curve, as obtained from the test (dash line), is shown for comparison. Evidently, the two are in substantial agreement. The slight differences may be due to the fact that the dimensions used in the calculations were obtained from the design drawings and not from actual pump measurements.

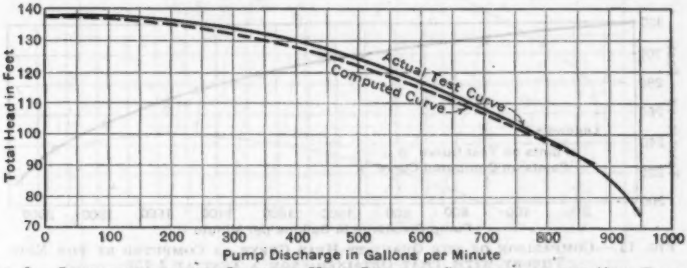

FIG. 9.—COMPARISON OF THE QUANTITY-HEAD CURVE AS COMPUTED BY THE NEW THEORY WITH THAT OBTAINED FROM A TEST AT 1 750 REVOLUTIONS PER MINUTE.

Similarly, Fig. 10 shows the analysis for a 3-in. pump for low or moderate heads and Fig. 11, that for a 6-in. high-head pump. The method is seen to yield satisfactory agreement for all three types.

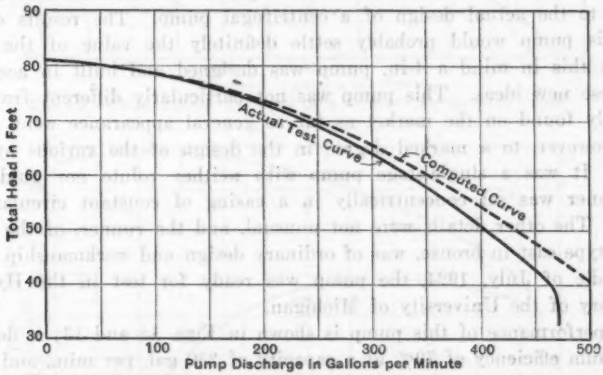

FIG. 10.—COMPARISON OF THE QUANTITY-HEAD CURVE AS COMPUTED BY THE NEW THEORY WITH THAT OBTAINED FROM A TEST AT 1 750 REVOLUTIONS PER MINUTE.

This should make clear the complete action of the centrifugal pump. It is then easy to explain the general effect of various changes in the design of a pump and to calculate the approximate numerical or quantitative effect of such changes on the pump characteristic. For obvious reasons this was not always possible with the previous theory.

APPLICATION OF NEW THEORY TO DESIGN

It would be a logical question whether this new theory is likely to result in any radical changes in the design or construction of centrifugal pumps. The fallacy on which the use of both the guide-vanes, or diffusers, and spiral casings, or volutes, is based, has already been mentioned. The new

theory indicates that all these accessories are not only useless but possibly even wrong. If this is correct it should be possible to obtain just as good results with a runner mounted concentrically in a plain circular casing of constant cross-section as with the most elaborately calculated spiral casings, volutes, diffusers, etc.

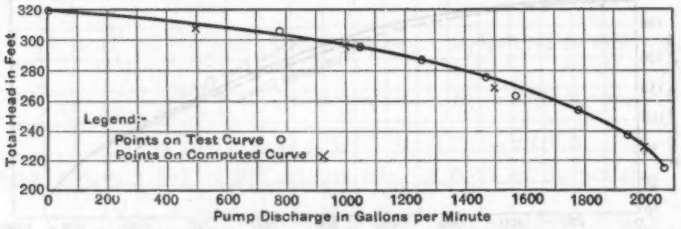

FIG. 11.—COMPARISON OF THE QUANTITY-HEAD CURVE AS COMPUTED BY THE NEW THEORY WITH THAT OBTAINED FROM A TEST AT 1 750 REVOLUTIONS PER MINUTE.

Results of First Design.—As this conclusion was a very radical departure from accepted current views it was felt that the final proof needed was to apply these principles (and others developed in connection with the new theory) to the actual design of a centrifugal pump. The results obtained with this pump would probably settle definitely the value of the theory.

With this in mind a 4-in. pump was designed and built in accordance with these new ideas. This pump was not particularly different from those ordinarily found on the market as far as general appearance went. It did differ, however, to a marked degree in the design of the various hydraulic details. It was a single-stage pump with neither volute nor guide-vanes. The runner was set concentrically in a casing of constant circular cross-section. The other details were not unusual, and the runner, of the double-suction type cast in bronze, was of ordinary design and workmanship. About the middle of July, 1924, the pump was ready for test in the Hydraulic Laboratory of the University of Michigan.

The performance of this pump is shown in Figs. 12 and 13; it developed a maximum efficiency of 79% at a capacity of 330 gal. per min., and a head of 67 ft. at 1 450 rev. per min. It is believed that this establishes a record for both American and European practice for a pump of such capacity.

The extreme flatness of the efficiency curve in Fig. 13 should be noted, also the broadness of the equal efficiency curves in Fig. 12, This indicates that it has been possible to develop extremely high efficiencies without any sacrifice of other desirable features.

Further Verification.—Those engaged in the design, manufacture, and sale of centrifugal pumps are likely to demand proof of an experimental nature rather than mathematical deductions no matter how skillfully and carefully they may be drawn. The writer, therefore, has made every effort to include actual test results in conjunction with his previous more or less mathematical conclusions.

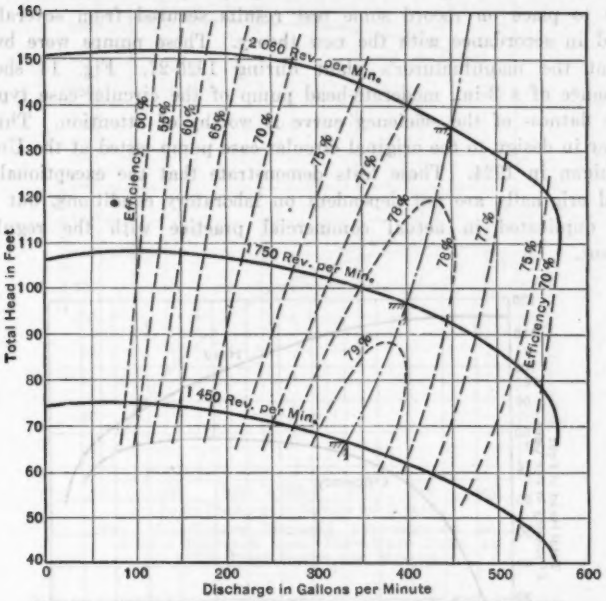

FIG. 12.—CHARACTERISTIC CURVE OF A 4-INCH CENTRIFUGAL PUMP.

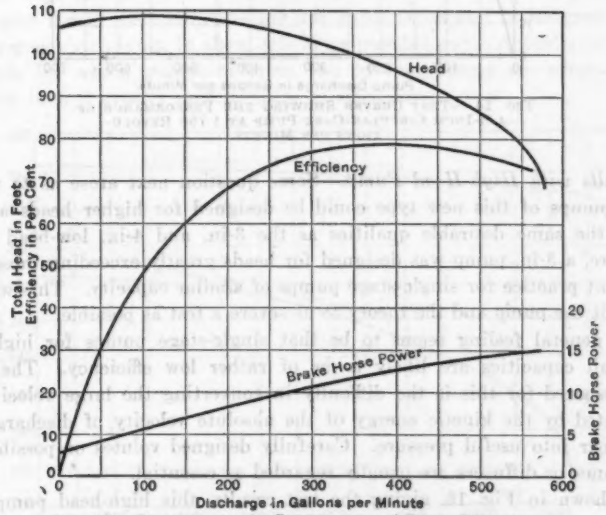

FIG. 13.—CHARACTERISTIC CURVES OF A 4-INCH CENTRIFUGAL PUMP AT 1 750 REVOLUTIONS PER MINUTE.

Through the courtesy of one of the large pump manufacturers, it is now possible to place on record some test results secured from several pumps designed in accordance with the new theory. These pumps were built and tested at the manufacturer's plant during 1925-27. Fig. 14 shows the performance of a 3-in., moderate-head pump of the circular-case type. The extreme flatness of the efficiency curve is worthy of attention. This pump is similar in design to the original circular-case pump tested at the University of Michigan in 1924. These tests demonstrate that the exceptional results obtained originally are not dependent on laboratory conditions, but may be readily duplicated in actual commercial practice with the regular test equipment.

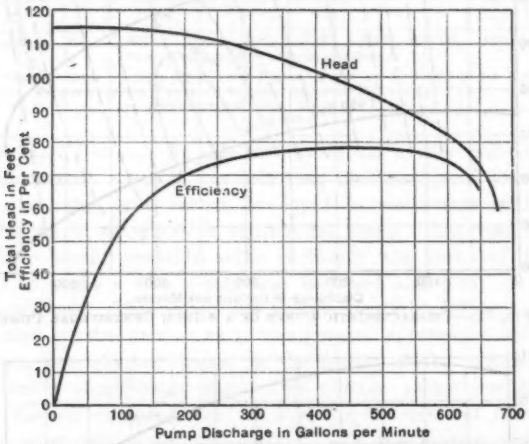

FIG. 14.—TEST CURVES SHOWING THE PERFORMANCE OF A 3-INCH CIRCULAR-CASE PUMP AT 1 750 REVOLUTIONS PER MINUTE.

Results with High-Head Pump.—Some question next arose as to whether or not pumps of this new type could be designed for higher heads and still exhibit the same desirable qualities as the 3-in. and 4-in. low-head pumps. Therefore, a 3-in. pump was designed for heads greatly exceeding those found in present practice for single-stage pumps of similar capacity. This was done to submit the pump and the theory to as severe a test as possible.

The general feeling seems to be that single-stage pumps for high heads and small capacities are likely to be of rather low efficiency. The reason often assigned for this is the difficulty in converting the large velocity head represented by the kinetic energy of the absolute velocity of discharge from the runner into useful pressure. Carefully designed volutes or possibly even guide-vanes or diffusers are usually regarded as essential.

As shown in Fig. 15, giving the test results, this high-head pump developed its maximum efficiency (72%) at a capacity of about 550 gal. per min. against a total head of 260 ft., at 1 750 rev. per min.

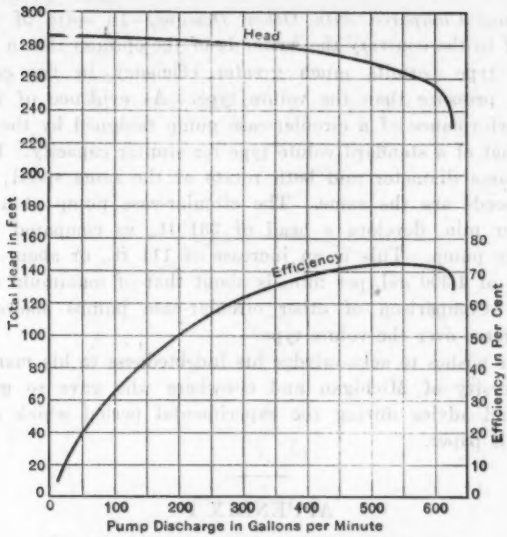

FIG. 15.—CURVES SHOWING PERFORMANCE OF A 3-INCH CIRCULAR CASE HIGH-HEAD PUMP AT 1 750 REVOLUTIONS PER MINUTE.

From this it would appear that the theory and design hold equally well for both high and low heads. It is interesting to note that the pump based on the new theory has neither volute nor guide-vanes and is designed, according to present standards, in about the worst possible way. Actually, it is doing the work for which pumps of from two to four stages are often required and even then it greatly exceeds them in efficiency.

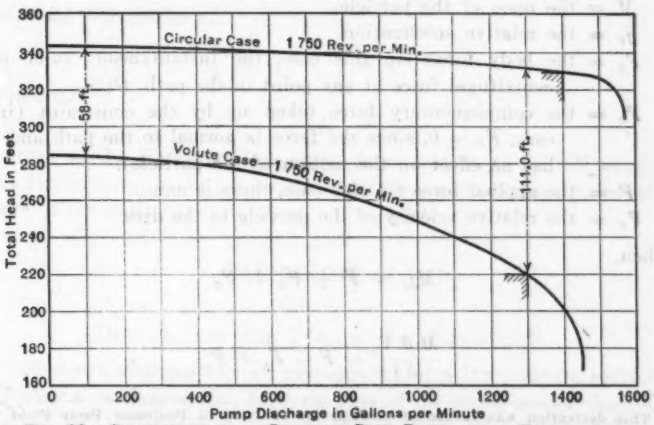

FIG. 16.—COMPARISON OF A CIRCULAR CASE PUMP AND A VOLUTE CASE PUMP OF THE SAME DIAMETER, SHOWING EXCESS HEAD DEVELOPED BY CIRCULAR CASE PUMP.

Performance Compared with Other Designs.—In spite of the probable general belief to the contrary the writer is of the opinion that a pump of the circular-case type permits much greater efficiency in the conversion of velocity into pressure than the volute type. As evidence of this, Fig. 16 shows the performance of a circular-case pump designed by the writer compared with that of a standard volute type for similar capacity. Both runners are of the same diameter and both rotate at the same speed; that is, the peripheral speeds are the same. The circular-case pump at a capacity of 1 300 gal. per min. develops a head of 331 ft., as compared with 220 ft. for the volute pump. This is an increase of 111 ft., or about 50 per cent. The capacity of 1 300 gal. per min. is about that of maximum efficiency for each pump. Comparison of other circular-case pumps showed somewhat the same increase over the volute type.

The writer wishes to acknowledge his indebtedness to his many colleagues at the University of Michigan and elsewhere who gave so generously of their time and advice during the experimental period which preceded the writing of this paper.

APPENDIX I*

Acceleration Caused by Rotation

Given a rotating disk of radius, r, turning at an angular velocity, ω. A particle is constrained to slide along a groove from the center, O, to a point, C, on the outer circumference. It is required to determine the relative velocity of the particle with respect to the disk, assuming that the particle starts from rest at the center, O.

From the general theory,† if,

M = the mass of the particle.

j_r = the relative acceleration.

F_b = the body force (in this case, the instantaneous value of the centrifugal force at any point in the path, OC).

F_c = the complementary force taken up by the constraint (in this case, $F_c = 0$, since the force is normal to the path and hence has no effect on the motion of the particle).

F = the applied force (in this case, there is none).

V_r = the relative velocity of the particle to the disk.

Then,

$$Mj_r = F + F_b + F_c$$

or,

$$\frac{M\,d\,V_r}{d\,t} = F + F_b + F_c$$

* This derivation was furnished through the courtesy of Professor Peter Field, of the College of Engineering, University of Michigan.

† "Introduction to Analytic Mechanics," by Ziwet and Field, p. 355.

Multiply by V_r; then,

$$M V_r \frac{d V_r}{d t} = (F + F_b + F_c) V_r$$

Multiply by $d t$; then

$$M V_r d V_r = (F + F_b + F_c) d r$$

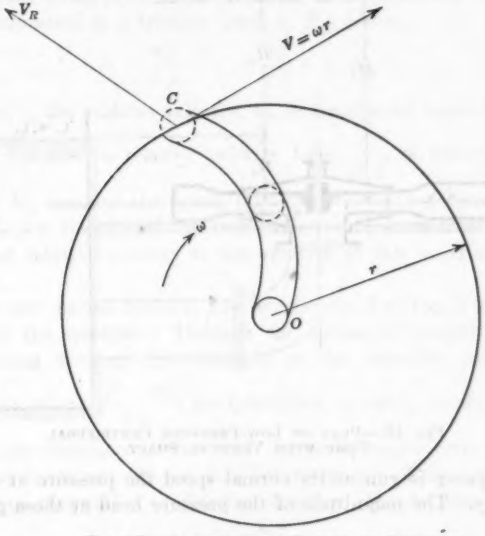

FIG. 17.—ACCELERATION CAUSED BY ROTATION.

But F and F_c are zero in this case; hence,

$$M V_r d V_r = \frac{M \omega^2 r^2 d r}{r}$$

This is the differential of,

$$\frac{1}{2} M V_r^2 = \frac{1}{2} M \omega^2 r^2$$

Therefore,

$$V_r^2 = \omega^2 r^2; \text{ or, } V_r = \omega r$$

In other words, if the particle starts from rest at O, it will accelerate to a relative velocity, $V_r = \omega r$, at the outer circumference, regardless of the curvature of the path.

APPENDIX II

DERIVATION OF THE FUNDAMENTAL EQUATIONS*

Fig. 18 shows schematically an arrangement of a low-pressure centrifugal pump having a vertical shaft. In every part of the pump proper there exists

* Reproduced substantially from "Centrifugal Pumps," by Lowenstein and Crissey.

a pressure greater than atmospheric, due to its depth below the level of supply. Imagine small pipes connected to the inside of the pump at points *s*, *e*, *a*, *l*, and *d*. As all these points lie in a horizontal plane, they have the same pressure head, h_a, when the pump is standing still.

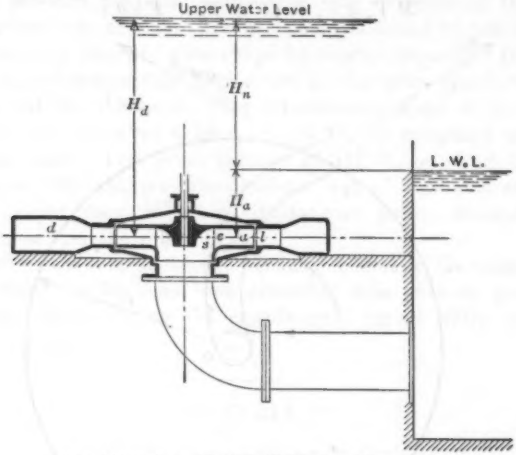

FIG. 18.—PLAN OF LOW-PRESSURE CENTRIFUGAL PUMP WITH VERTICAL SHAFT.

When the pump is run at its normal speed the pressure at each of these points will vary. The magnitude of the pressure head at these points is to be found.

The following derivation of the so-called "condition equation" is an old method used for determining the fundamental equation of water turbines. It gives a clear conception of the pressure and velocity distribution in the interior of a centrifugal pump. The pump shown in Fig. 18 is placed below the level of the supply water in order that all the pressure heads may be positive, that is, so that no suction exists. Of course the equations can be derived also for a pump placed above the level of the water.

When the pump is running there will be a pressure head, h_s, in the pipe at Point *s*. When the pump is at rest, it is less by an amount equal to a velocity head, $\frac{w_s^2}{2g}$, plus a friction head, $p_s H_n$. The friction head is dissipated in forcing the water through the entrance pipe up to Point *s*. The velocity in the entrance pipe, or suction tube, is designated by w_s, and the velocity head, $\frac{w_s^2}{2g}$, represents the loss of pressure head necessary to obtain the velocity, w_s, in the pipe.

Let H_n be the effective pressure or desired head of the pump. The condition equation may now be expressed by,

$$h_w = h_s + \frac{w_s^2}{2g} + p_s H_n \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

The next point, *e*, is taken directly at the entrance to the impeller. At this point a pressure head, h_e, and a velocity head, $\frac{w_e^2}{2g}$, exist, w_e being the absolute velocity of the water at this point. In the water flowing fr... Point *s* to Point *e* shock losses occur at the entrance to the channels of the impeller, which can be expressed as a friction head, $p_e H_n$, hence,

$$h_s + \frac{w_s^2}{2g} = h_e + \frac{w_e^2}{2g} + p_e H_n \quad \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

If, at Point *e*, the relative velocity, v_e, is considered instead of the absolute velocity, w_e, then a relative velocity head, $\frac{v_e^2}{2g}$, is obtained, while the pressure head, h_e, remains the same. It is understood, of course, that absolute velocity is the velocity of the water relative to some fixed or stationary point, and that relative velocity is the velocity of the water relative to the rotating parts.

The water now passes through the impeller to Point *a*, which is directly at the exit of the impeller. Through the action of centrifugal force the water, in flowing through the channels of the impeller, has its pressure increased by the value, $\frac{u_a^2 - u_e^2}{2g}$, the quantities, u_a and u_e, being the peripheral velocities of the impeller at exit and entrance, respectively. Due to the friction of the water against the impeller walls and of the individual water particles among themselves, a friction head, $p_a H_n$, is lost. At Point *a*, a pressure head, h_a, and a velocity head, $\frac{v_a^2}{2g}$, exist, v_a being the relative exit velocity. Therefore, Equation (3) may be written:

$$\frac{v_e^2}{2g} + \frac{u_a^2 - u_e^2}{2g} = h_a + \frac{v_a^2}{2g} + p_a H_n \quad \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

At Point *l*, which is directly at entrance to the guide-vanes, there exists a pressure head, h_l, and also a velocity head, $\frac{w_l^2}{2g}$. Due to shock losses at the entrance to the guide-vanes a friction head, $p_l H_n$, is lost in passing from Point *a* to Point *l*. At Point *a* the pressure head, h_a, and the velocity head, $\frac{w_a^2}{2g}$, exist, w_a being the absolute exit velocity. Hence,

$$h_a + \frac{w_a^2}{2g} = h_l + \frac{w_l^2}{2g} + p_l H_n \quad \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

In order to convert as much as possible of the velocity head, $\frac{w_l^2}{2g}$, into pressure, the velocity, w_l, should be gradually reduced in passing from Point *l* through the guide-vanes. Let w_d represent the velocity and $\frac{w_d^2}{2g}$ the velocity head at the exit from the casing, and let $p_d H_n$ be the friction head expended

in carrying the water through the guide-passages and casing. Then,

$$h_l + \frac{w_l^2}{2g} = h_d + \frac{w_d^2}{2g} + p_d H_n \quad \ldots\ldots(5)$$

The first form of the so-called fundamental equation is obtained by adding Equation (1) to Equation (5), which gives Equation (6). For convenience Equations (1) to (5) are here re-stated:

$$h_w = h_s + \frac{w_s}{2g} + p_s H_n$$

$$h_s + \frac{w_s^2}{2g} = h_e + \frac{w_e^2}{2g} + p_e H_n$$

$$h_e + \frac{v_e^2}{2g} + \frac{u_a^2 - u_e^2}{2g} = h_a + \frac{v_a^2}{2g} + p_a H_n$$

$$h_a + \frac{w_a^2}{2g} = h_l + \frac{w_l^2}{2g} + p_l H_n$$

$$h_l + \frac{w_l^2}{2g} = h_d + \frac{w_d^2}{2g} + p_d H_n$$

$$\frac{v_e^2 - w_e^2 - u_e^2 - v_a^2 + w_a^2 + u_a^2}{2g} = h_d - h_w$$

$$+ H_n (p_s + p_e + p_a + p_l + p_d) + \frac{w_d^2}{2g} \quad \ldots\ldots(6)$$

From Fig. 17, it follows that,

$$h_d - h_w = H_n \quad \ldots\ldots(7)$$

As already explained, H_n is the desired head at the exit from the casing. The friction head necessary to overcome the losses in the delivery pipe has not been considered, because these losses may vary between wide limits and are dependent on the length and cross-section of the pipe. The velocity head, $\frac{w_d^2}{2g}$, at discharge from the pump is a certain fraction of the desired head, H_n. This fraction can be represented by the coefficient, α, so that,

$$\frac{w_d^2}{2g} = \alpha H_n \quad \ldots\ldots(8)$$

The coefficient, α, gives the magnitude of the exit losses, and varies with the desired pressure head when the velocity, w_d, is constant.

In order to simplify Equation (6), let,

$$(p_s + p_e + p_a + p_l + p_d) = p \quad \ldots\ldots(9)$$

Substituting Equations (7), (8), and (9) in Equation (6), the general form of the fundamental equation is obtained,

$$v_e^2 - w_e^2 - u_e^2 - v_a^2 + w_a^2 + u_a^2 = 2g H_n (1 + p + \alpha) \quad \ldots\ldots(10)$$

Let,

$$(1 + p + \alpha) = \eta \quad \ldots\ldots(11)$$

In order to obtain the total head, H_b, which is used in the calculation of centrifugal pumps and represents the theoretical head which the pump can deliver, considering no losses whatever, the desired head, H_n, can be multiplied by the factor, η. Hence,

$$\eta H_n = H_b \quad \ldots\ldots (12)$$

From the geometric relations:

$$v_e^2 = u_e^2 + w_e^2 - 2 u_e w_e \cos \delta_e \quad \ldots\ldots (13)$$

and

$$v_a^2 = u_a^2 + w_a^2 - 2 u_a w_a \cos \delta_a \quad \ldots\ldots (14)$$

Substituting in Equation (10) the values of v_e^2, v_a^2, and $(1 + p + \alpha)$ from Equations (11), (12), and (13), the second form of the fundamental equation is derived,

$$u_a w_a \cos \delta_a - u_e w_e \cos \delta_e = \eta g H_n \quad \ldots\ldots (15)$$

DISCUSSION

J. W. MacMeeken,* Esq.—The theory expressed by the author is interesting in view of the fact that other recent research and experimental work has proved the reliability of accepted theories of the centrifugal pump. This novel explanation of the performance of these pumps is possibly applicable to machines designed to operate in a particular way, but it could not be applied to many centrifugal pumps of very recent design giving higher efficiencies than were obtained a few years ago and which show, under test and analysis, a greater generation of head for peripheral speed than can be explained by the author's theory. Accurate measurements of output and input energy and measurements by laboratory methods, of each of the mechanical losses, including disk friction, show that in a pump which is designed throughout for very high hydraulic efficiency, the head obtained can only be explained by the full effect of Equation (*B*), no element being omitted. Equation (*C*), on the other hand, is not strictly a practical equation because it assumes suction conditions that seldom exist. The author states that the fundamental laws of centrifugal pumps seem never to have been properly explained and that many misconceptions exist, even among those supposedly familiar with the hydraulics of centrifugal pumps. He further refers to fallacies and proclaims, referring to Equations (*B*) and (*C*), that "they do not, and cannot, furnish a rational basis for the analysis and design of centrifugal pumps." There is very strong evidence that he is wrong in discarding mathematical facts and replacing them by rational reasoning.

The increasing commercial value of pump efficiency, when obtained by designs that are economical for manufacture, resulted in a thorough study of the problem by the speaker and his associates, in America as well as with consultants in Europe. The theory was studied in a variety of ways and Equation (*B*) has been recognized as correct. To prove the theory experimentally, special pumps were designed and built, in order to deliver as nearly as possible the theoretical head, $\frac{V_2^2}{g}$, reduced only by the unavoidable slight rotational head of the pump suction. Some of these pumps gave a head of $\frac{0.85\ V_2^2}{g}$, or $\frac{1.70\ V_2^2}{2\,g}$. One pump, built in Europe, gave a total head of $\frac{0.96\ V_2^2}{g}$ at shut-off and practically the same at designed conditions. As 96% efficiency is the highest that can be expected, if friction and shock losses are reduced to a minimum, this pump proved that the total head, $\frac{V_2^2}{g}$, was being generated according to theory. However, these pumps were costly to manufacture and were not suitable for the American competitive field. They also showed some instability due to their susceptibility to air in the water.

Equation (*B*) having been proved experimentally by pumps of special design, a large number of different types and sizes were planned to include features more suitable for economical manufacture. This equation was used

* Engr., Byron-Jackson Pump Mfg. Co., Berkeley, Calif.

for head calculation and every hydraulic consideration, known to result in high efficiency was introduced into the design. The pumps were built with unfinished interior water-ways; and, when tested, they not only delivered the capacity and head for which they were designed, but gave the same shape of characteristic to within 1%, or 2%, as the designer had expected. The results in these cases pointed to Equation (*B*), when used with knowledge of the mechanical and hydraulic losses in the pump, as giving the accuracy obtained in designing electric motors. The effect of a change in suction design could also be computed by Equation (*B*). These pumps were of the volute design of an improved type and the volutes were of such a form that some remaining kinetic energy is discharged into the discharge cone of the pump where it is partly converted into pressure. In all cases, the head obtained could only be explained by the full effect of Equation (*B*), nothing being omitted.

In the pumps referred to by the author, which have a concentric case, it is possible that this exit velocity component is not discharged but retained unobstructed in the pump-casing and, therefore, no power is used in maintaining it. This would explain satisfactorily the difference between the author's theory and Equation (*B*) and between efficient volute pumps and efficient pumps of the author's design. This could be expressed in the following equation:

$$H = \frac{1}{g}\left(C_2\, V_2 \cos\, \alpha_2 - C_1\, V_1 \cos\, \alpha_1\right) - f\,\frac{V_3^2}{2\,g}$$

in which, V_3 is the velocity in the concentric case and f is a factor equal to, or less than, unity and possibly zero, depending on the design of the exit orifice, $\frac{V_3^2}{2\,g}$ being subtracted because it is not allowed to leave the pump, as in a volute type. This equation is used in the design of multi-stage pumps with concentric cases and permits the application of accepted and proved theory to both volute pumps if f is zero, and to pumps of the author's design, if f approaches unity.

The author's design will always require a greater impeller diameter than that required in the volute pump of good design. Therefore, pumps of large size involving thousands of horse-power and high head may reach 35% approximately more weight and cost than is necessary, and higher disk stresses in the impeller. It is noticeable that the most efficient volute centrifugal pumps of certain types generate a head greater than $\frac{V_2^2}{2\,g}$ throughout the entire range of capacity.

The author fails to be convincing in certain respects. His illustration of the hammer thrower is not applicable. In a centrifugal pump there are an infinite number of balls, all without restraining wires and all acting on one another. The final energy is the integral of the infinitesimals between limits of entrance and exit. The same error is repeated in the illustration entitled "New Conceptions of Pump Action". He mentions the case of a circular disk with radial grooves in which a smooth ball travels as the disk rotates. This is correct as regards the dynamics of a particle or a single mass. Were

this illustration applicable to a pump with radial vanes the head would be $\frac{V_2^2}{2g}$ at shut-off and $\frac{V_2^2}{g}$ when flow occurs. In the centrifugal pump there is a disk full of such balls, and the total head is the sum or integral of their combined energy. Integrating between the limits of r_1 and r_2 and expressing the velocities as functions of angular rotation and radius, Equation (B) is again the result, which shows the same head, $\frac{(V_2^2)}{g}$, at shut-off and all capacities for radial vanes. The illustrations in Fig. 2 apply very nearly to a lawn sprinkler, but not to a centrifugal pump. It has been proved experimentally that a volute or guide-vane, restraining the water from flying out of the impeller, does not result in appreciable losses. Pumps so constructed show very high hydraulic efficiencies and generate high heads, much higher than $\frac{V_2^2}{2g}$.

There is an apparent discrepancy in referring to Fig. 4 (b). The increment of power is equal to the capacity multiplied by the head. This means that the efficiency at small capacities is 100%, which is impossible if the hydraulic efficiency is considered. Certain losses are proportional to $\frac{V_2^2}{2g}(1 - k)$, in which, k is the ratio of the actual capacity considered to the designed capacity. These losses, therefore, will be great at very low capacities.

Referring to the objection to guide-vanes: These are not necessarily used to reduce the velocity, C_2. They have a useful function like that of a volute in controlling the output from the impeller. They prevent the water from flying out from the impeller and can do so with little reduction in efficiency; and they assist in obtaining high peripheral speeds with low impeller velocities, in cases where a volute presents structural difficulties.

Referring to the author's explanation of the performance of a volute pump (Fig. 8), an entirely different explanation could be given. Equation (B) may be transposed into the form:

$$H = \frac{V_2^2}{2g} + \frac{C_2^2}{2g} - \frac{W_2^2}{2g} - \frac{V_1^2}{2g} - \frac{C_1^2}{2g} + \frac{W_1^2}{2g}$$

In the event that,

$$\frac{C_2^2}{2g} - \frac{C_1^2}{2g} = \frac{W_2^2}{2g} - \frac{W_1^2}{2g}$$

then,

$$H = \frac{V_2^2 - V_1^2}{2g}$$

which would explain the performance. The method used by the author is incomplete in that it takes no account of the ratio of Dimension A to Dimension C. According to his method only the product of Dimensions A and C is effective. It is known that a change in the ratio of Dimension A to Dimension C will affect the characteristic curve very greatly.

The circular-case pump, referred to by the author has an efficiency of 79 per cent. The commercial efficiency of present-day pumps designed for this condition is 77%, not 60%, as stated by the author. Its efficiency could be raised to 79% by exact workmanship in the foundry and extra good mechanical condition. A good commercial pump of this type does not show falling off of the efficiency with increase of speed as shown in Fig. 12. When there is an obstruction in the volute, the efficiency has been found to fall with increased speed, as shown in Fig. 12.

The pump in Fig. 14 shows an efficiency of 78 per cent. A commercial pump, of the same specific speed type and about the same size, is rated at 80 per cent.

In the case of multi-stage pumps the circular case has been used by many manufacturers since about 1911 at least. Impellers of the same design have been found to give very much greater efficiencies in multi-stage volutes. This indicates again that the volute is superior.

Much misunderstanding has arisen regarding calculations for centrifugal pumps because old designs were inefficient compared with later machines in which 88.5% and even higher efficiencies have been obtained on very accurate tests.

Undefined losses led designers into empirical design constants that had no dynamic basis for their value. It is only when high efficiencies are obtained, that the losses can be analyzed with accuracy and the fundamental equation used in its theoretical form.

A centrifugal pump developing less head than that expressed by Equation (*B*) is a machine that is leaving uncompleted work and represents overexpenditure of material for work done. This is of great importance in very large pumps and might even warrant the restriction of impeller diameter, by contract specifications.

Large pumps, like large hydraulic turbines, are generally designed for as high a rotative speed as possible, with only a small margin of safety below the speed at which cavitation would occur. It has been proved that the design of the volute is important in avoiding cavitation. At very high speeds and heads a circular case with an orifice outlet is known to be noisy in large machines.

Equation (*B*) has a very wide field of application and is used by designers in hydraulic turbines, hydraulic meters, fans, and blowers. In each application designers have used their ingenuity to obtain the best results. The speaker has found it not only a useful and reliable means of designing centrifugal pumps, but also a means of analyzing results and obtaining indications of possible improvements.

THOMSON KINGSFORD,* ESQ. (by letter).—The author deserves great credit for the way he has handled his subject, and for the results he has obtained. The writer has had occasion to check several pumps against the principles given in the paper, and finds that the tests agree substantially with the results given in the author's experiments. Unquestionably the efficiency found

* Partner, Kingsford Foundry and Machine Works, Oswego, N. Y.

in pumps designed according to these principles as recorded in the paper is high, considering the pump size and other conditions of operation.

The author's Fig. 16 is particularly interesting as a comparison between two similar pumps, one of the old type with volute casing, and the other with the circular casing, as indicating the increased head obtained by the circular design. He does not state the differences in efficiency, but presumably this is in favor of the circular casing; at least it should be. Of course, the increased head is due to the specially designed impeller and larger casing. A comparison between the corresponding efficiencies would be of interest.

SANFORD A. MOSS,* ESQ. (by letter).—It is true, of course, that there are many misunderstandings in connection with the mathematics of centrifugal pumps. However, the fundamental equations, as usually given, are correct. If they are used by any one who really understands what they mean, they lead to correct results. The author mentions a new analysis, but he gives no detailed equations. It is quite probable that if these detailed equations were included, they could be shown to be exactly the same as those in current texts, properly interpreted, so that there would really be nothing new.

One item must be clearly borne in mind, that is, that a set of equations, or a set of computations, written for flow through a centrifugal pump, applies to a condition with a single load or quantity of flow. The vanes at the impeller inlet and the diffuser inlet (or volute angles if there are no diffuser vanes), must suit this one condition. This condition is a single point on the pump characteristic curve, presumably at the point of maximum efficiency. Other points on the curve—including conditions when the pump is shut off or running without flow, and when discharge is wide open—are those that appear when the various vane angles are incorrect. Hence, analysis for these conditions cannot be made on the same basis as that where maximum efficiency is expected.

Another item that must be borne in mind is that the set of equations for the occurrences in the pump apply primarily to the pump impeller extending from the impeller vane inlet to the impeller vane exit. At the impeller vane exit is a circular entrance to a region beyond the vanes, which may be called the diffuser or volute. At the entrance to this region and at the load or flow for which computations are made, there is definite pressure due to centrifugal force acting in the impeller, and a definite absolute velocity. Each of these effects represents energy put into the fluid by the impeller. The existence of a portion of fluid under the pressure found at the impeller exit means that a certain amount of energy was exerted to get the fluid into this region. The absolute velocity of the fluid similarly represents a given amount of kinetic energy. The fluid at the point in question certainly has the two additive amounts of energy in question. If the author means to point out that it is a fallacy to so consider the matter, his conclusion is incorrect.

The author gives frequent mention of a new design of pump which he has built and which shows signs of promising results. However, no details are

* Thomson Research Laboratory, General Electric Co., West Lynn, Mass.

given showing the nature of this design. The results obtained are so interesting that a desire is created for a description of details. Readers of a technical paper always like to have all the facts that are necessary to enable them to make use of the information given by the author.

P. L. REED,* M. AM. SOC. C. E. (by letter).—The author has probably noted that centrifugal pumps under test do not produce nearly as great a head as that computed by rational formulas based on the generally accepted theory, which is, as he states, that for very small rates of flow the water, as it leaves the periphery of the impeller, has a velocity nearly equal to that of the tips of the vanes and, hence, a velocity head of $\frac{U\,a^2}{2\,g}$; and that it has, in addition, a pressure head of the same amount, or a total head of $\frac{U\,a^2}{g}$. With considerable rates of flow the total theoretical head is modified by the shape of the vanes, but there is still a marked difference between the theoretical head and the actual head.

He meets this condition by boldly asserting that the fundamental theory, which is supported by Rankine, Church, and many other authorities, is all wrong and that for small discharges the water, as it leaves the impeller, has a velocity head about equal to $\frac{U\,a^2}{2\,g}$, or a pressure head of the same amount, but not both; and that the true theoretical maximum total head is, therefore, only one-half that computed according to the accepted theory.

The accepted theory is too well grounded in the laws of mechanics to be thus overthrown and the author's position will not be sustained. With radial vanes, the prevailing theory considers that the water just inside the tips of the impeller vanes has a velocity approximately equal to that of the periphery of this impeller, which can be diverted into a volute or guide-vanes and converted in large part into pressure. If conversion were perfect, the pressure thus converted from velocity would be $\frac{V^2}{2\,g}$, or $\frac{U\,a^2}{2\,g}$.

The author does not doubt that there is pressure inside the impeller. This pressure will not (disregarding friction) be lost during the subsequent diversion of the water into the volute or guide-vanes and the partial conversion of its velocity head into pressure head. There is undoubtedly both a velocity head and a pressure head at all points in the impeller. Both these heads increase as the distance from the shaft increases; caused to be sure, simultaneously and by the same medium, the rotation of the impeller.

A number of the author's original mathematical derivations and conclusions will be found to be unsound. One is the "Derivation by Principle of Angular Momentum", where the force, which is undoubtedly distributed over the length of the vanes of the impeller, is "conveniently regarded as concen-

* Capt., C. E. C., U. S. N., Bureau of Yards and Docks, Navy Dept., Washington, D. C.

trated" at their tips. This error exactly offsets or compensates for ignoring all centrifugal effects in this derivation, and the correct formula results.

The difference in the action between the round ball in the disk and the water in the impeller is that in the former case the centrifugal force is opposed only by the inertia of the ball, which receives a high radial velocity, while in the latter case the water is under restraint and is given a low radial velocity against resistance.

The author is misled by considering that the present pump theory is purely kinetic. The velocity head, represented by free radial velocity of the water produced by an impeller without a chamber, is not absent, but is represented by a pressure head in the encased impeller of a pump.

He presents his new theory of three orifices. As a rational theory it does not appeal. It implies that the head required to produce the velocity at the entrance of the impeller vanes is 100% lost in passing through the impeller; that the head required to produce the velocity at discharge from the impeller is 100% lost in passing around the volute; and that the velocity head at the throat is 100% lost in passing into the discharge pipe; or, at least, that the sum of these three hypothetical losses plus the loss at no discharge is the total loss of head in the pump. The only rational feature of this theory, which the writer can appreciate, is that the head losses due to discharge increase with the square of the quantity discharge. As an empiric formula it seems to have much merit when applied to the three pumps tested by the author. Whether it would be equally satisfactory if applied to pumps of different proportions would have to be developed by further experiments, which is the defect of all empiric rules.

Having pointed out what are believed to be fundamental defects in the author's theory, the fact remains that the actual head of a pump, operating with no discharge, is approximately $\frac{U\,a^2}{2\,g}$, and that this head is never much greater when there is a discharge (unless the pump has forward curved vanes), although the conventional application of the established theory would give a head nearly twice as great (for radial vanes). It will not do to say that the difference between the head, thus computed, and the actual head is represented by losses in friction, eddies, etc., as this would imply that the losses were nearly 50% of the total; whereas the actual measured efficiency of the pump in raising water often exceeds 70 per cent. With these facts at hand, attention is invited, not to the established theory of vortices, of which the centrifugal pump is a modified example, but to the conventional application of this theory to centrifugal pumps.

It has been noted that the actual head developed is considerably less than the rationally computed head and that all this difference cannot be explained as loss since it is not reflected in the efficiency of the pump. It must then be explained by some incorrect assumption in the application of the fundamental theory to the actual operation of the pump. The conventional application assumes that the water leaves the impeller in a direction, with respect to the impeller, parallel to the tips of the vanes. Now, if the water in the

outer part of the impeller lags behind, if it spills to some extent over the following impeller vane, the effect would be similar to bending back the impeller tips, thereby reducing the theoretical total head of the pump, and reducing, if not removing, the discrepancy between conventionally computed and actual heads. This seems plausible for other reasons. The water is being constantly pressed and accelerated tangentially by the vanes as it passes through the impeller; and near the periphery it may escape this pressure in part by lagging behind and passing through the periphery at a sharper angle than the backward curved tip of the impeller vane and at a lower absolute velocity than is conventionally assumed. This would be particularly the case with a small discharge, which would accord with test results. This effect would be increased by any cohesion or viscosity that the liquid may possess, since the tangential velocity of the liquid just outside the impeller is no doubt considerably less than it is inside.

MAX M. MUNK,* ESQ. (by letter).—The writer would like to register his disagreement with the author's conclusions, believing the old established blower theory to be correct.

In declaring the pressure to be "part and parcel of the velocity", Professor Sherzer flatly denies to the fluid pressure an existence of its own. This is in contradiction to the most fundamental conceptions. Each fluid particle is under the definite action of the adjacent particles, regardless of its motion together with them. The intensity of this action is called the pressure. How definite it is is demonstrated by the fact that the density of the fluid is influenced by the pressure. Velocity and pressure do exist independently of each other. Even the untrained man understands that perfectly well if he has ever been in a dense crowd. He moved with the crowd at a certain speed, and independent therefrom was pressed more or less by his neighbors.

The pressure created by the centrifugal force is not even a function of the exit velocity, U, only. The rotating fluid does not necessarily extend to the center, and the pressure created depends on the width of the rotating fluid ring. If the entrance radius is almost as large as the exit radius, the fluid hardly receives any increase of pressure, although it may be impelled to the same exit velocity, U, as a fluid entering at the center. The rotation of this narrow fluid ring, rather than the case of a rotating fluid disk, is illustrated by the whirling hammer.

As a matter of fact, good centrifugal pumps may furnish a pressure surpassing one-half the theoretical maximum pressure, that is, surpassing the pressure claimed as maximum by Professor Sherzer.†

ELMO G. HARRIS,‡ M. AM. SOC. C. E. (by letter).—It is evidence of a certain kind of courage on the part of the author to announce that all the heretofore recognized present-day authorities on centrifugal pumps are entirely wrong. That is a broad statement. The writer cannot concede that the author has established any one of the three claims made in the Synopsis.

* Research Dept., Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

† Compare, for instance, "Die Kreiselpumpen," by C. Pfleiderer, Berlin, 1924, p. 97.

‡ Prof. of Civ. Eng., Missouri School of Mines, Rolla, Mo.

They are so sweeping that to disprove all of them systematically would require a treatise on the subject. It would be inappropriate to fill these pages with matter that can be found in many recent publications. However, the following comments may be appropriate.

(*a*).—The quotation from John Perry and the author's statements will apply to many of the writings that are more than twenty-five years old, but not to the more recent ones.

(*b*).—The author is right in declaring that Bernoulli's theorem should not be applied in the case of water flowing through a centrifugal pump, for energy (head) is being continuously added to the water as it passes through the pump. Moreover, the pressure is not constant over any cross-section of a passage between propellers. It is relatively high next to the front side of a propeller and low on the back side. Doubtless, in some defective designs, a vacuum occurs at the back side of the runners. Also, in attempting to apply Bernoulli's theorem, some writers have used relative and absolute velocities indiscriminately to the utter confusion of the subject.

(*c*).—Under "Current Fallacies", the author's analogy of the "hammer" is incomplete. He should have considered a smooth rod with hammers strung on it from the center of rotation out to the last one.

(*d*).—The writer thinks that the author is entirely wrong in his statement that the head in the water at "shut-off" is $\frac{U_a^2}{2g}$ instead of $\frac{U_2^a}{g}$. This pressure head at shut-off has been the cause of much confusion, especially among the earlier students. It led one writer to state (in a book on centrifugal pumps) that the curve of the vanes was of no consequence. The confusion results in studying, and deriving conclusions from experiments on, pumps that are not in operation—not discharging, although revolving.

The author states that "there is a pressure created by centrifugal force which is equal to $\frac{U_a^2}{2g}$ and which is part and parcel of the velocity itself. The total head may be regarded as either, but not both". This statement does not make anything clear nor remove confusion. By the laws of mechanics the head, $\frac{U_a^2}{g}$, is there, although it cannot be utilized until the pump is discharging.

(*e*).—The "Derivation by Principle of Angular Momentum" is correct, although given by the author as incorrect. Equation (*C*) can be easily transformed into the writer's Equation (37),* discussed later. However, the writer prefers to use plain reaction of a jet to the change in angular momentum. The latter term does not look familiar to ordinary students of hydraulics.

(*f*).—Under "Reasons for Observed Discrepancies", no adequate reasons are given.

(*g*).—As bearing on most of the matter relative to "Real Action of Centrifugal Pump", in the references cited later, it is proved that with β_2 fixed, it is theoretically immaterial whether the water moves out under purely centrifugal action producing pressure; or centrifugal action producing accelera-

* "Compressed Air," 1917.

tion; and it is immaterial as to the point between center and periphery at which the water is picked up; and that the same effect will be obtained by short vanes or cups picking the water up impulsively; and that the writer's Equation (37) previously referred to, applies either with or without back pressure at the discharge. The discovery of this fact was a surprise and a revelation to the writer, and it much simplifies the whole subject. For these reasons the general term, centrifugal pump, is a misnomer. Engineers may be more ready to accept these statements if they will consider the action between a golf club and the ball. Also, consider the theory (nearly realized) in the Pelton water-wheel. By the laws of mechanics, if the rotation of the wheel is reversed and water is fed to the cups, it will be thrown off with a velocity twice that of the cups. Also, consider reversing the rotation of an axial flow turbine.

(*h*).—Under "Experimental Verifications" the author interprets results by his own erroneous theories. He seems not to have given due recognition to the fact that for small discharges (as compared with discharge at best efficiency) most of the work put into the pump is dissipated. Moreover, the observations under experiment cannot be properly interpreted without knowing the area of the discharge outlet, of the pump, and the angle, β_2. With this information and by the use of the writer's Equation (37) discussed subsequently, the experiments could be interpreted correctly—not otherwise.

(*i*).—Under "Effects of Casing": If, in the experiment, the pressure head, h_2, at the line of discharge (Point 2, Fig. 1) had been determined, the total head in the water at the discharge line would be $\frac{C_2^2}{2\,g} + h_2$, and if this were plotted on Fig. 6, the line would lie above the "Actual Head" line—the difference being the loss of head beyond the discharge line.

In the analogy of the paddle in a tank—whence comes the jet which, by inference, has a higher velocity than the paddles?

(*j*).—Under "Pump Considered as Three Orifices", the author is not correct in considering as orifices the three sections that he selects in Fig. 8. The sections, 2 and 3, are not orifices. He is also incorrect in computing the drop in pressure head at each so-called orifice as that which would occur if the water, at each place, started from a state of rest. His calculations show only slight differences of velocity at the three sections and what change occurs will be gradual. The three-orifice theory is groundless.

Under "Applications of New Theory": The outstanding item of interest in the paper lies in the fact that the author has designed a very efficient pump, but that is of little value unless he will give all its dimensions, angles, etc. With these data, the results of the experiment can be interpreted in the light of other theories.

The writer is unable to see that the three-orifice theory influenced the design in any way. The author states, in reference to the "Results of First Design", that "the runner, of the double-suction type cast in bronze, was of ordinary design and workmanship."

When, if at all, the dimensions and angles of these pumps are revealed, there will be shown a small angle between the backward tangent and V_a,

Fig. 1 ($180 - \beta_2$), and, when computed, V_a will be found nearly equal to U_a. This will make the absolute velocity, C_2, nearly radial and relatively small. (It is not possible to make it radial.) Thus, there will be no "drag" between the water in the circular receiving chamber and that escaping from the runners; and there will be but little kinetic energy to lose. If the author will put in a runner with as much forward pitch as it now has backward pitch (β_2 between 20° and 30°), the efficiency will drop below 50 per cent. This drop will be caused by the loss of most of the kinetic energy in the water, due to the drag against the relatively slow moving water in the outside circular receiving chamber. If the author will attach a pressure gauge at the discharge line (Point 2, Fig. 1), he will find most of the final head registered there as pressure.

This pressure will approximate $\frac{U_a^2}{2g}$ (although always less) when the vanes are turned backward as specified. However, when the rotational velocity of the water at Point 2 is computed ($= C_2 \cos \alpha_2$), it will be found to be relatively small, altogether too small to develop the pressure by centrifugal force, hence, the writer's statement that the term, centrifugal pump, is a misnomer when applied to the majority of such pumps as are now made. Fortunately, the writer's Equation (37), developed subsequently, covers every case with the qualification that it does not include dissipated energy.

In reference to guide-vanes: They should be used with caution, if used at all. They can function properly only with one combination of velocity of rotation, quantity of discharge, and angles such that the relative motion of the water will be tangent to the vanes at their tips. Since the combination of quantity and speed of rotation that will give best efficiency cannot be determined except by test after the pump is built, it may be advisable to change the angles of the guide-vanes slightly after testing the first pump built for a stock design.

Many years ago the subject of centrifugal pumps was young as compared to the present knowledge of the theory and to the present perfection of designs and excellence of performance. The writer sought, through the available literature, for something about centrifugal pumps, that he might impart the information to his class. He found the field blank so far as his search extended, except that in the accepted highest authority on civil engineering at that time—Trautwine's "Civil Engineer's Pocket-Book"—he found, in substance, the statement that the centrifugal pump was a low-efficiency machine in which the lift was practically limited to 27 ft.

Above this lift the efficiency was said to fall off rapidly. The writer, therefore, started to prepare a lecture for his class. The preparation of that lecture took up his otherwise spare hours for a year or two. The findings were published by the Society* in 1903, and, again, in somewhat better form in his textbook.† In both these publications can be found derivations of the writer's Equation (37):

$$H = \frac{U_a^2 + V_a U_a \cos \beta_1}{g}$$

* *Transactions*, Am. Soc. C. E., Vol. LI (1903), p. 166.

† "Compressed Air," 1917, Chapter VIII, "Fans".

Note that cos β_2 is minus when β_2 exceeds 90 degrees. In this, the symbols are those used by the author and shown on Fig. 1, except the symbol, H, which is discussed later. This formula is derived by three independent lines of approach. It is derived by Daugherty* and also by Slocum.† That it is based on correct assumptions as to the underlying mechanical principles seems beyond successful controversion. The writer prefers his Equation (37) to any other that he has found. The angle, β_2, is a constant for any one pump. It is under the control of the designer. The speed of rotation, U_a, is under the direct control of the operator. V_a can be computed directly when the quantity of discharge has been measured. Therefore, it is evident that the H of the writer's Equation (37) can be quite accurately computed in any well-controlled experiment. It is the control of the chief characteristics of the pump by the angle, β_2, that gives the formula value in designing. It is in the interpretation of H in the formula that the experimenter and the designer need to use caution and judgment.

Let Q be the weight of water moved per second. If no energy is dissipated between intake and discharge of the pump, the work required to drive the pump would be QH; but there are always losses due to several causes. These cannot be measured or computed separately, but the total can be determined and separated into inside and outside losses.

Let D equal the dynamometer record of rate of work put into the pump, in foot-pounds; let F equal the dissipated energy between the intake and the discharge, in foot-pounds; and H_1, the head lost between the intake and the discharge. Then,

$$F = D - QH$$

and,

$$H_1 = \frac{F}{Q}$$

Let H_2 equal the head in the water immediately after escaping from the propellers at the line of discharge, referred to still outside water; let h_2 equal the pressure head measured by a gauge at the line of discharge, plus the height of the gauge above still outside water (suction lift); and C_2, the absolute velocity at the line of discharge. (To be computed after determining V_a.) Then,

$$H_2 = \frac{C_2^2}{2g} + h_2$$

If H_3 is the pressure head in the discharge pipe measured by a gauge as near the pump as possible, but clear of the eddying effect of the discharge from the pump, plus the height of the gauge above still water; and H_4 is the head lost due to imperfections in the fixed parts of the pump, made to receive the discharge and conduct it into the plain pipe; then,

$$H_4 = H_2 - H_3$$

* "Hydraulics," 1925, p. 311, Formula (169); also, "Centrifugal Pumps," 1925, p. 62, Formula (36).

† "Elements of Hydraulics," 1917, p. 262.

So far as the writer knows, this means of locating the losses in a pump and finding their relative amounts has not been clearly shown before. It may give some light to designers who are trying to improve the efficiency of their pumps.

Other interesting, instructive, and valuable conclusions can be reached from the writer's Equation (37) as a starting point, but, since most of them appear in the papers cited, they will not be given here. However, the following historic notes will be interesting and will serve to show how the leading men in practice in this subject were floundering in ignorance twenty-five years ago.

About 1903 the writer tried to interest a pump manufacturing company (one of the largest) in some patents that he had taken out. After courteous attention and some days of consideration, the manager announced that, unknown to the public, the company had for several years conducted experiments to develop a centrifugal pump that it would be willing to advertise and sell. Having spent $300 000 in the effort, it was then about ready to put a pump on the market and it could not afford the delay and cost of starting on a new line.

About the same time and with the same object, the writer was discussing his Equation (37) with the chief engineer of another company that was making and selling centrifugal pumps. This man stated unqualifiedly that the highest head that could be attained by any centrifugal pump, regardless of the shape of the propellers, would be $\frac{V_a^2}{2g}$, and as conclusive proof he cited that his company had tested several pumps, and in every case the highest head was observed at "shut-off", and that head was, for every pump, $\frac{V_a^2}{2g}$. Any one who is able to interpret the writer's Equation (37) can find the fallacy of this argument and conclusions.

In 1894, there appeared a book entitled "Centrifugal Pumps". It was written by an American manufacturer and was probably accepted as authoritative. In this book appears, in substance, the statement that water must be held in the pump through at least one revolution in order to give it the necessary "send", and that the advantage in turning the vanes backward (β_2 greater than 90°) is that the water is given a final shove outward.

While the derivations are given in the references cited, the one that the writer prefers is given here for the convenience of the reader. It is direct, short, and clear. Referring to the author's Fig. 1, it may be assumed that the pump takes up the water from a state of rest; and, to get the basic mechanical principles involved, all dissipation of energy will be neglected. This dissipation consists of surface friction, friction of water on water (eddies), and, in some poor designs, spraying of water through a vacuum. It may be further assumed that the revolving wheel is immersed in water under pressure (this pressure may be either greater or less than that of the atmosphere).

The static pressure of the water on the outer surfaces of the wheel is everywhere perpendicular to the surface (this surface includes the peripheral area of discharge of width, b_2). Evidently, this perpendicular pressure neither aids nor retards rotation. When, and where, the water is picked up by the runners it exerts a dynamic pressure (reaction) resisting the imparting of velocity. Thus, the runner imparts energy to the water. This energy (pressure and motion) is retained by the water and more is added as it passes outward under the influence of the propellers. However complex this action is at the pick-up (Point 1, Fig. 1), and between there and the point of discharge (Point 2, Fig. 1), it is all a part of work done by the pump in preparation (one might say) for its final discharge, at Point 2, against the back pressure and with a velocity, C_2. Since static pressure in the outside water does not resist rotation, the resistance of the pump to rotation must be that due to reaction of the water escaping at the periphery.

If Q is the weight of water escaping in 1 sec., the reaction in the reverse direction of C_2 is $\frac{Q\ C_2}{g}$, and the component opposed to tangential motion is,

$$\frac{Q\ C_2}{g} \cos \alpha_2$$

but,

$$C_2 \cos \alpha_2 = U_a + V_a \cos \beta_2$$

(note that $\cos \beta_2$, as in Fig. 1 is minus).

The work done by the pump in 1 sec. is this force multiplied by the distance, U_a, through which it is overcome in 1 sec. Therefore,

$$\text{Work} = \frac{Q}{g} (U_a^2 + U_a V_a \cos \beta_2)$$

If H is the total head imparted to the fluid by the pump, then work done $= Q H$; therefore, in the writer's Equation (37),

$$H = \frac{U_a^2 + U_a V_a \cos \beta_2}{g}$$

In this formula, H is the head delivered by the pump at the periphery of the propellers (line of discharge). It is made up of suction lift, pressure head, and velocity head. It does not include head dissipated between intake to suction pipe and periphery of propellers. If the pump worked with perfect efficiency in all parts (both before and after passing the line of discharge), the work required of the motor would be $Q H$ and the lift would be H, as computed by the writer's Equation (37).

O. GRUENBERGER,* ESQ. (by letter).—The writer's criticism is intended solely for the purpose of helping to clear up any apparent discrepancies in the existing theory of centrifugal pumps.

In explanation of his new theory, the author describes how the sum of three velocity heads, corresponding to three points in the flow through the pump, can be used to calculate the actual head produced with various rates of discharge. It is difficult to understand why these three velocity heads, and only these three, should yield this result. Obviously, another point in the flow

* Engr., Worthington Pump & Machinery Corporation, East Orange, N. J.

could be added and the result would be different. Be that as it may, the author states that the sum of the three velocity heads is to be subtracted from the "shut-off" head as found by test. If that is the procedure, no help can be gained from this method.

The author does not state whether the "shut-off" head, found by test, is identical with a calculated shut-off head, although Figs. 9, 10, and 11, indicate that such is the case. This theory also fails to explain a "rising characteristic."

In the first part of the paper, Professor Sherzer states that the shut-off head can never be more than $\frac{U_a^2}{2g}$. As a matter of actual fact it is usually larger than that. Possibly the explanation for a small increase in head could be found in the fact that the water rotates with the impeller in a radial space of the casing, with a velocity slightly in excess of that of the impeller; but this would hardly account for pressures approaching the value of $\frac{U_a^2}{g}$.

ELMER G. HOOPER,* ASSOC. M. AM. SOC. C. E. (by letter).—Consideration of the several different theories of pump design advocated and successfully used by recognized authorities in this field of engineering would lead an observer to believe that there must be more in common among the theories than is inferred in this paper. Pumps have been designed, built, and operated according to each of the different theories, and the mere fact of continued faith in any particular idea is evidence enough of a reasonable degree of success in obtaining desired results. The only satisfactory explanation for similar results from apparently different methods is diversity in interpretation of design and test factors, and in the manner of co-ordinating them.

The author's statements, that a centrifugal pump may be considered as a series of three orifices through which all the water is to flow, that each orifice requires a difference, or drop, in head equal to the issuing velocity head beyond the arbitrarily assumed locations to produce the velocity; and, finally, that the sum of these drops is to be subtracted from the static head at no flow to give the resultant head per pound of water delivered, raise questions in the writer's mind as to logical interpretation of evidence.

There can be no doubt that the formulas representing the "new theory" gave convincing results when applied to the pumps designed and tested, and that they would undoubtedly do so with many others. However, the author's explanation that difference in pressure head equal to the delivered velocity head is needed in order to create such a velocity overlooks the fact that velocity through any opening, either orifice or nozzle, is the result of the combined velocity-of-approach head and pressure-difference head. Certainly there was an appreciable velocity of approach to the so-called orifices compared with the velocity of delivery from each one. The final interpretation by the author that these "drops" in head should be deducted from the normal static head at no flow to determine the delivered head puts a different light on the problem. A simple statement that "the loss in head

* Asst. Prof., Civ. Eng., New York Univ., New York, N. Y.

through the pump is equivalent to the sum of the velocity heads mentioned", would be more effective and would give less cause for controversy. It is a substantial contribution to the common store of knowledge, however, if this seeming fact can be more thoroughly analyzed and more amply verified. The writer does not find sufficient data in the author's paper to analyze and verify the "new theory", certainly not enough to support the contention that all present theories are wrong.

Whether or not a centrifugal pump will produce a head equal to $\frac{U^2}{g}$ or $\frac{U^2}{2g}$ per lb. of water delivered, may never be settled to the satisfaction of every partisan, but either value may be obtained under proper conditions. In a pump with a circular casing and at no discharge there is likely to be a circumferential velocity producing a velocity head closely approaching $\frac{U^2}{2g}$ and a pressure head of $\frac{U^2}{2g}$. A piezometer at the circumference would register a head equivalent to the latter value; a Pitot tube inserted through the rim against the stream would register the sum of the two values, $\frac{U^2}{g}$. How much of this last value is available for delivery depends on the losses necessarily following transformation of this high circumferential velocity into the velocity in the system. For radial tip vanes, carefully designed and built, and with pump outlet designed to convert volute velocity gradually into discharge pipe velocity, a lift greater than $\frac{U^2}{2g}$ can reasonably be expected.

In any case the energy imparted to the water to lift it and to overcome all friction incident to the delivery is from work done by the impeller in its rotation. The energy equation would have to be for the whole system, including pump losses, pipe losses to and from the pump, sudden changes in absolute velocity wherever it occurred, bend and gate losses, the useful lift, and the work done by the pump. There may be some question as to the most accurate form in which the work done by the impeller may be expressed but, in the final analysis, the only difference is in form.

A constant speed pump can be really designed only for one fixed condition and output. When all passages are open and water is flowing smoothest, more energy per pound will be delivered for the work put in than under any other condition. To reduce the flow it is always necessary to close down on a gate in order to add friction or resistance to flow that the pump itself fails to offer. Every pound of water delivered then has to lose the additional friction head purposely introduced by the gate. The apparent efficiency of a pump at maximum is influenced very much by the design of the system, of which it is a part, and the efficiency curve by the relative importance of gate friction to the whole. The author cites an effective lift of 134.6 ft. at 200 gal. per min. and an effective lift of only 98 ft. for 800 gal. per min. For full range of operation in one setting, delivery head must be fixed at 98 ft., and for all

flows less than the maximum the gate must serve to provide, directly or indirectly, friction loss or waste energy equivalent to the difference between the 98 ft. and the effective lift corresponding to that discharge. For example, in order to reduce the flow from 800 gal. per min. to 200 gal. per min., the gate must be closed so that every pound of water passing will lose 36.6 ft. lb. of energy.

F. THEODORE MAVIS,* ASSOC. M. AM. SOC. C. E. (by letter).—The author states repeatedly that the "present" theory of the action of centrifugal pumps as presented in standard textbooks is incorrect, but he does not explain his reasons very clearly. He states that Equations (*B*) and (*C*) "form the basis of all present theories", whereas the equations follow as a consequence of the hypothetical properties of an ideal fluid and its orderly behavior as it flows through an imaginary pump. The assumptions and corollaries from which these equations follow, regardless of the mathematical tools which are used in deriving them, may be summarized somewhat as follows:

I.—The Fluid:
- (1) Homogeneous.
- (2) Incompressible.
- (3) Non-viscous.

II.—The Flow:
- (1) Vortex free (that is, there is no flow in closed paths within the pump).
- (2) No energy losses.
- (3) Relative velocity at every point on a circle concentric with the axis of rotation is the same.
- (4) Steady; the rate of discharge through the pump does not change from instant to instant.
- (5) Continuous; all pump passages are filled at all times with the fluid.

III.—The Pump:
- (1) Frictionless.
- (2) The surfaces of all fluid passages coincide with stream lines.
- (3) There are an infinite number of impeller blades.

IV.—The External Forces:
- (1) Gravitational.
- (2) Mechanical.
- (3) Non-frictional.

Water is a homogeneous fluid which can be considered incompressible, but its viscosity cannot be neglected. Inseparably linked with the viscosity are resistances opposing every motion of this otherwise ideal fluid and, in the case of higher velocities, turbulence, eddies, and the inevitable consequence, loss of useful energy. The water passages of the actual pump are not perfectly smooth and frictionless and there are not an infinite number of infinitely thin impeller blades, each exerting no pressure on the water in the impeller. Since neither the water nor the actual pump meet the requirements laid down by the elementary theory, it is quite unreasonable to expect agreement between tests of pumps and calculations made according to this theory.

* Asst. Prof., Mechanics and Hydraulics, Univ. of Iowa, Iowa City, Iowa.

The equations of the elementary theory are very useful, however, in making first approximations. They lead to the familiar straight line characteristic passing through $H = \frac{C^2}{g}$ for $Q = 0$, which may be considered as the first approximation of the actual characteristic curve.

Professor Pfleiderer* shows that a curve, very similar to the experimental characteristic, can be estimated for the purpose of design. Subsequent corrections are necessary to allow for the following factors:

1.—The effect of a finite number of impeller blades in the actual pump.
2.—Shock losses, or losses due to sudden changes in velocity.
3.—Friction losses.
4.—Leakage and recirculation losses.

The first may be made experimentally and the others, which involve losses of useful energy, can be made only by consideration of experimental data. Correction 1 may also be made analytically (assuming an ideal fluid) and as a consequence a newer theory of pumps and turbines has been developed which differs from the elementary theory before mentioned in the following details:

1.—Circulation around each propeller blade.
2.—Between two impeller blades the velocity at no two points on a given circle concentric with the pump axis is the same.
3.—There are a finite number of impeller blades and their position is known.

The mathematical analyses of the flow through pumps according to the newer theory, which considers a finite number of impeller blades, are interesting as problems in applied mathematics, but at present they are so difficult and so restricted in their application to ideal cases that they will not be likely to appeal to the designer. From a purely mathematical standpoint, Professor Spannhake† studied the flow through a pump with from one to eight radial blades and compared the absolute discharge velocity, C, for the pump having a finite number of blades with the corresponding absolute velocity, C_∞, for the pump with an infinite number of blades as assumed in the elementary theory. He also compared the corresponding moments, M and M_∞,‡ applied at the shaft of the pump and presented curves showing the ratios, $\frac{C}{C_\infty}$ and $\frac{M}{M_\infty}$, as functions of the number of impeller blades and the ratio of the radii, $\frac{r_1}{r_2}$. Table 1 shows the results of these studies.

Kucharski§ shows that the relative flow of an ideal fluid in a rotating canal may be resolved into two components: (*a*) A flow through the canal

* See Pfleiderer, "Die Kreiselpumpen," p. 71 and 123 *ff*, J. Springer, 1924.

without circulation (hence vortex free and in agreement with the assumptions of the elementary theory); and (*b*) a circulation or rotation within the canal at a constant angular velocity which, relative to the canal, is equal, but opposed in sense, to the absolute angular velocity of the canal about the axis of rotation. The circulation can be determined from measured deformations of an elastic membrane stretched (under constant stress) across a plane section of the canal perpendicular to the axis of rotation and inflated under constant (air) pressure. The deformations should be small so that the stresses in the membrane are not materially changed as a result of the deformation. Contours on the deformed membrane correspond to the stream lines; the inflating pressure corresponds to the angular velocity of the vortex relative to the canal; and the slope of a tangent to the surface of the membrane corresponds to the velocity of flow in a direction at right angles to that tangent.

‡ $\frac{M}{M_\infty}$ = ratio of corresponding moments.

This elastic membrane or soap-film analogy is well known and very helpful in its application to problems of torsion and it is equally applicable to problems of hydrodynamics. This is true from a mathematical standpoint because the differential equation that describes the deformation of the thin elastic membrane is of the same form as the one which describes the vortex motion of an ideal fluid. The differential equation in rectangular co-ordinates, x and y, that expresses the deformation, f, of a thin elastic membrane from a plane position, is:

$$\frac{\delta^2 f}{\delta x^2} + \frac{\delta^2 f}{\delta y^2} = \frac{P}{T} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

This is the same as the differential equation for vortex motion in an ideal fluid:

$$2\omega = \frac{\delta v}{\delta x} - \frac{\delta u}{\delta y} = -\left(\frac{\delta^2 \psi}{\delta x^2} + \frac{\delta^2 \psi}{\delta y^2}\right) \quad \ldots\ldots\ldots\ldots (17)$$

in which,

ω = the angular velocity about an axis perpendicular to the plane of x-y;

u = the velocity in the direction of x;

v = the velocity in the direction of y; and,

ψ = the so-called stream function.

If the stream lines are drawn for constant differences in the values of the stream function, ψ (or by analogy equal contour intervals on the inflated membrane), the same quantity of fluid flows between each pair of stream lines. The velocity, which is tangential to the stream lines, is therefore inversely proportional to the distance between these lines.

The flow through the canal, or component, a,* of the relative flow, may be determined in a few ideal cases by the methods of classical hydrodynamics, that is, by conformal representation, using functions of complex variables.† These methods are certainly to be classed with the most difficult ones in the field of applied mathematics and are quite outside the field of design. However, the determination of the flow of an ideal fluid through any given canal can be made by an experimental process suggested by Hele-Shaw which is more generally usable and vastly simpler than purely mathematical processes. This investigator has shown that, if a fluid dye is introduced through capillary tubes into water flowing between two glass plates placed close together, stream lines are traced by the threads of dyed fluid which, for any boundary conditions, agree with those stream lines calculated by the methods of mathematical hydrodynamics.‡ If a stream-line diagram is available for a given set of boundary conditions, or for a given shape of impeller blade, it can be "twisted" into another stream-line diagram with a different set of boundary conditions, by graphical methods of conformal representation discussed by Prasil.§

Oertli's studies‖ conducted in the hydraulic laboratory at the Technische Hochschule, in Zurich, Switzerland, show pictorially how the flow of water through a pump with a finite number of impeller blades differs from the flow of an ideal fluid through a pump with an infinite number of blades, as assumed in the elementary theory. He experimented with a special radial flow pump which had plate-glass windows in the upper impeller disk so that photographs could be made of the flow of the water between the blades. The impeller disks were 400 mm. in diameter and 40 mm. apart. The impeller blades were curved backward on a radius of 196 mm. and were placed so that the forward tangents to the blade and the outer impeller circle intersected at an angle of 30 degrees. A motion picture camera was mounted on the vertical axis of the pump and the relative flow of the water through the pump was recorded

by photographs. Aluminum filings served to indicate the movement of the water in some of the tests and a concentrated solution of potassium permanganate introduced into the water through syringe needles indicated the stream lines in others.

In the first series of tests the entrance and discharge circles were closed with plates and one of the cells thus formed between the blades was filled with water while the adjacent cell was filled with oil. The photographs of these fluids, taken as the impeller rotates, show no appreciable eddy in the oil cell, but they do show an eddy in the water with an angular velocity, relative to the rotating disk, nearly equal to the angular velocity of the impeller. If the impeller is rotating clockwise the relative eddy motion is counterclockwise, and conversely. Before the eddy is disturbed by the effect of the viscosity of the water it bears a very close resemblance to the eddy determined by the elastic membrane method.

In the second series of tests, in which the pump was operated against a closed discharge valve, eddies were again formed which behaved much like those mentioned. The viscosity of the water soon disturbed the results as before, and violent eddies, nearly circular in shape, formed between the blades at the inlet and the discharge circles of the impeller blades. Evidently, these eddies transform a large amount of the energy input into heat, and Oertli calls attention to the fact that the pump becomes warm when it is operated against a closed discharge valve.

In the third series of tests the pump was operated at three different speeds, but discharged the same quantity of water at each speed: (1) At "normal speed" which was that speed at which the water entered the impeller relatively tangential to the blades at entrance; (2) at one-half the normal speed; and (3) at twice the normal speed. The stream lines were indicated in each test by means of concentrated potassium permanganate solution introduced through syringe needles. Oertli concludes from these tests: (1) That the relative flow through the impeller is not steady, but the pulsations which occur do not seem to have any definite period. They are caused primarily by friction and consequent eddies, etc.; (2) that for two conditions of normal flow, that is, for two equal ratios of $\frac{Q}{n}$, the directions of the middle stream lines are the same. The flow at the discharge end of the impeller is less quiet for a smaller discharge than for a larger discharge since larger eddies are formed at small flows; (3) that the absolute direction of flow at the entrance to the impeller is radial regardless of the value of $\frac{Q}{n}$; and (4) that the relative velocity at the discharge end of the blades is deflected from tangential to the blades (as indicated by the elementary theory) clockwise if the impeller rotates in a counterclockwise direction, and conversely. The angle of deflection increases as $\frac{Q}{n}$ decreases.

The results of Professor Spannhake's work are in agreement with Oertli's Conclusion (4). This is evident if one constructs the conventional discharge velocity diagrams for different quantities of flow through a given pump and

reduces the absolute velocity vector in the ratio, $\frac{C}{C_\infty}$ (see Table 1), for the given quantity of water flowing through the pump.

The problems of hydrodynamics are of such a complex nature that even a study of an ideal fluid entails mathematical difficulties which have not been surmounted. The problems are infinitely more complicated if the viscosity of the fluid is taken into consideration in the primary analysis, and it is not to be expected that any theoretical equation, similar to the author's Equations (B) and (C), can be developed for the flow of water through a pump. The elementary theory as a first approximation of the solution of a given problem is by far the most logical and satisfactory one that has been proposed. The newer theory, which considers the effect of a finite number of impeller blades, indicates corrections to the velocity diagrams of the elementary theory which bring them more nearly into agreement with those determined from actual performance tests. Subsequent corrections for friction, sudden changes in velocity, and recirculation can be made only on the basis of experimental work. The characteristic curves that follow from the elementary theory and the corrections that are logically necessary if a real fluid is considered, are not unlike those determined from tests of centrifugal pumps.*

MARIO MEDICI,† ESQ. (by letter).—The author's statement as to the fallacies of modern theories of centrifugal pumps is well founded only as applied to theories that are typical of British and American texts, or of the old German method (Neumann, for instance). On the Continent, such methods, all of which are based on the Eulerian theory, are being displaced by new ideas developed from the deductions of modern hydrodynamics. This is especially true of calculations for the design of centrifugal pumps, turbo-blowers, and compressors.

Professor A. Stodola‡ and the writer§ both give (see Fig. 19) the theoretical value of H as $\frac{v_2^2}{2g}$, or $\frac{u_2^2}{2g}$, when the discharge is zero. This seems reasonable when considered in the light of the more exact characteristic equation developed by the writer for the theoretical potentiality of centrifugal impellers. However, if the discharge valve is opened a little, that is, if the discharge is almost zero, there must obviously be a certain difference between the actual and theoretical head of the impeller and the pump. This difference is the only thing that can explain the actual quantity-head curves, such as A (Fig. 19). How does the author make his theory harmonize with characteristic curves of this kind?

The writer does not concur in the opinion of Professor Sherzer as to the effect of the vane angle, β_2, on the shape of the pump characteristic. For an impeller without casing, the author accepts, as being substantially correct, the results usually given in textbooks. The writer has shown§ that at supple-

§ "Contributo alla teoria delle turbomacchine centrifughe," by Mario Medici, *L'Industria*, September, 1926.

mentary angles of β_2 ($\beta_2 = 60°$ and $\beta_2 = 120°$, for example), the same trial characteristics occur and that the best values of β_2, for centrifugal impellers, are those between 24 and 30 degrees. This is in perfect harmony with current practice. Tests have verified the conclusion that both the vane angles, β_1 and β_2, and the number of impeller vanes, z, control the shape of the quantity-head curve.

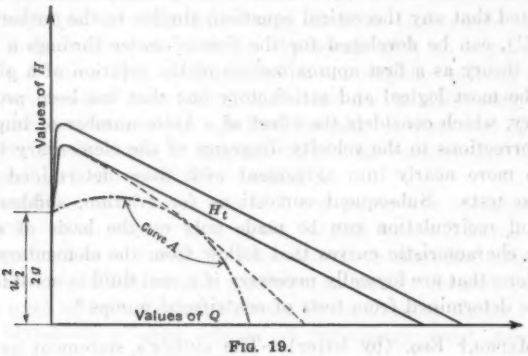

FIG. 19.

On the other hand, Professor Sherzer is to be congratulated on his conclusions as to the effect of casings and on his valuable suggestion to mount the impeller in a plain circular casing with constant cross-section. Working independently, and analyzing critically the real effect of the casing on the performance of centrifugal pumps, the writer reached the same conclusion but only with regard to series pumps (1927). The results have been published in the Italian technical press* after a delay due to a desire to obtain some proof of an experimental nature. The writer has not yet completed this experimental verification and, therefore, he is especially glad to learn of Professor Sherzer's test results as they apply to circular-case centrifugal pumps. Some of these results, as, for instance, the extreme flatness of the efficiency curves, are in perfect harmony with the writer's theoretical deductions.

However, Fig. 16 is not clear. It seems to contradict the theory given by the author. According to his theory, the head at zero discharge must be, $H_2 = \frac{v_2^2}{2g}$, or $\frac{v_3^2}{2g}$, if the effect of the side-walls is ignored. Referring to Fig. 16, if the impellers are both of the same diameter and rotate at the same speed, how can the value of the head at zero discharge in a circular casing be so different from that in a volute casing? What does Professor Sherzer mean to illustrate with the values, 284 ft. and 342 ft., as the total head at zero discharge, using volute and circular casing, respectively?

The writer hopes that these comments will not be considered as destructive criticism, but as an effort to become better acquainted with the results of this

* *L'Industria*, December, 1927.

very interesting investigation. In further support of these views, the writer submits an abridgment of his paper, "The Theoretical Potentiality of Centrifugal Impellers",* translated from the Italian and paraphrased as follows.

Designers of centrifugal pumps, fans, turbo-blowers, and compressors are recognizing, more and more, the need of abandoning the ancient Eulerian theory in favor of a more complete one. Calculations made by the old theory not only give results that are always greater than the actual values, but also (especially within forward and radial vanes) results that are far from being explained by the customary shape and size of the actual characteristic curves and the values of the impeller efficiency.

The Eulerian theory takes no account of the number of impeller vanes, z, in determining theoretical potentiality. It is based on conditions that obtain at the middle of the fluid stream passing through the impeller and diffuser vanes. In this theory the fluid trajectories and the vanes are considered congruent. With such an assumption it is easy to compute the theoretical change of energy in the fluid through the runner. This computed value will never be the same as that found under actual working conditions because the number of vanes, z, is finite, and the Eulerian theory tacitly assumes that z is infinite. In practice, it is only very close to the impeller vane that the fluid really travels in a direction that can be controlled by the inclination of the vanes. In the space between two adjacent vanes, variations both as to velocity and direction of flow appear in the stream (Fig. 20). Both these influences are responsible for reducing the actual head to less than the theoretical result as determined by considering the number of vanes infinite.

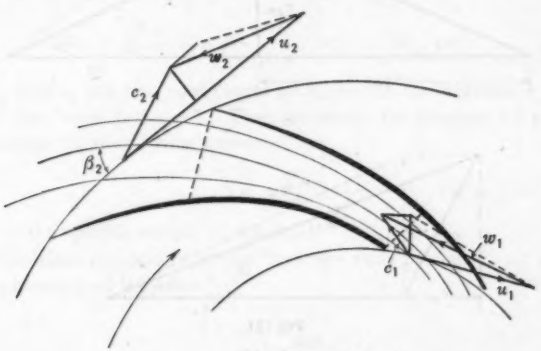

FIG. 20.

It is the variation in velocity (see Fig. 20) between vanes that forms a basis for the conception of "vane pressure"; that is, difference in pressure must undoubtedly take place between two centrifugal impeller vanes in order that power be transmitted. The effect of variations in the direction of flow is to make necessary an exaggeration of the vane angles as would be determined by the Eulerian theory.

* "Contributo alla teoria delle turbomacchine centrifughe," by Mario Medici, *L'Industria*, September, 1926.

A precise determination of the effect produced by each of the principal vane parameters (z, the number of vanes; β_{1c}, the vane angle at the inlet; and β_{2c}, the vane angle at the outlet), on the theoretical characteristics of the impeller is possible only by studying the fluid stream along the impeller; that is, by applying the methods of modern hydrodynamics, which in some respects has been as slow in making progress as aerodynamics. Under the present state of applied hydrodynamics, it seems to be much more rational to elaborate the ancient theory again, making proper allowances for β_{1c}, β_{2c}, and z, on the theoretical potentiality of centrifugal runners.

Usually, the theoretical potentiality of centrifugal impellers is expressed as:

$$H_t = \frac{u_2\, c_{2u}\, u_1\, c_{1u}}{g} \qquad (18)$$

in which,

H_t = theoretical head at the impeller;
g = acceleration due to gravity;
u_2 = peripheral speed of the impeller at the outlet;
u_1 = peripheral speed of the impeller at the inlet;
c_{2u} = the peripheral component of the absolute outlet velocity of the fluid, reduced because of "vane pressure"; and
c_{1u} = the peripheral component of the absolute inlet velocity of the fluid, reduced because of "vane pressure".

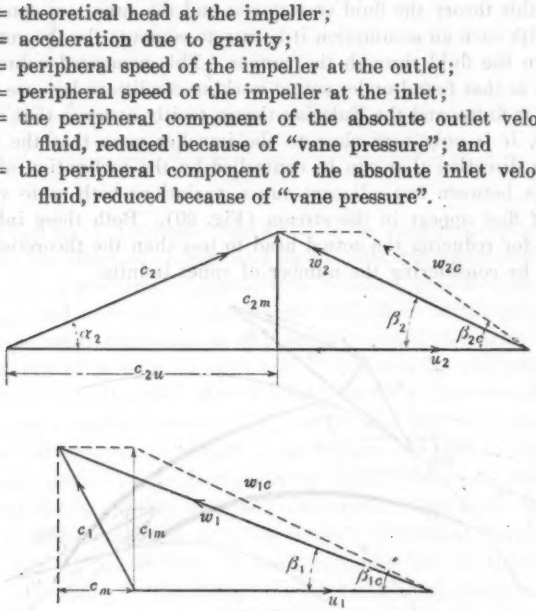

FIG. 21.

From the speed triangles (Fig. 21):

$$c_{2u} = u_2 - \sqrt{W_2^2 - c_{2m}^2} = u_2 - \sqrt{W_2^2 - \frac{Q^2}{\pi^2 D_2^2 b_2^2}} \qquad (19)$$

$$c_{1u} = u_1 - \sqrt{W_1^2 - c_{1m}^2} = u_1 - \sqrt{W_1^2 - \frac{Q^2}{\pi^2 D_1^2 b_1^2}} \qquad (20)$$

so that,

$$H_t = \frac{u_2^2 - u_1^2}{g} - \frac{u_2}{g}\sqrt{W_2^2 - \frac{Q^2}{\pi^2 D_2^2 b_2^2}} + \frac{u_1}{g}\sqrt{W_1^2 - \frac{Q}{\pi^2 D_1^2 b_1^2}} \qquad (21)$$

in which,

Q = the delivery or capacity of the impeller;
D_2 = the outlet diameter of the impeller;
b_2 = the outlet width of the impeller;
D_1 = the inlet diameter of the impeller; and
b_1 = the inlet width of the impeller.

On every cylindrical element between D_2 and D_1:

$$d\,p = \frac{1}{2\,g}\,(W_f^2 - W_b^2) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22)$$

in which, $d\,p$ equals the difference in pressure between the two sides of a vane, and W_f and W_b are the relative fluid velocities on the front and on the back of the vane on the aforementioned element of the impeller.

According to the hypothesis of Kucharski* the relative fluid velocities on the front and on the back of the vane are quite different, but along the arcs, $A\ C$ and $E\ F$ (Fig. 22), they may be considered as uniform and equal, respectively, to W_1 and W_2. At the point, D, on the back of the vane the relative fluid velocity caused by "vane pressure" will be W_{1b} which is greater than W_1. Similarly, at Point G_f for the same reason, the relative fluid velocity will be W_{2f} which is less than W_2. At Point D_f, on the front side of the vane, the relative fluid velocity will be W_{1c} which is less than W_1, and at Point G_b, the relative fluid velocity will be W_{2b} which is greater than W_{2c} (Fig. 22). From Equation (22), then:

$$d\,p_G = \tau_2\,d\,p = \frac{1}{2\,g}\,(W_{2b}^2 - W_{2f}^2) = \frac{1}{2\,g}\,(W_2^2 - W_{2f}^2) \ldots\ldots (23a)$$

$$d\,p_D = \tau_1\,d\,p = \frac{1}{2\,g}\,(W_{1c}^2 - W_{1c}^2) \ldots\ldots\ldots\ldots\ldots (23b)$$

in which, τ_1 and τ_2 are two coefficients to allow for the difference in the distribution of the "vane pressure". They generally lie between 1.2 and 0.8. If p_m is the average value of "vane pressure":

$$d\,p = \frac{p_m}{\zeta} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

in which, ζ is the specific weight of the fluid.

The peripherical component of the "average vane pressure", $p_m \sin \beta$, gives on a surface element of the vane:

$$d\,s = d\,b\,\frac{d\,r}{\sin\,\beta} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (25)$$

the turning moment:

$$d\,m = p_m \sin\,\beta\,r\,d\,s - p_m\,r\,d\,r\,d\,b \ldots\ldots\ldots\ldots\ldots (26)$$

Assuming that p_m is uniformly distributed over the central portion of the vane, $D_f\,G_f$ (Fig. 22):

$$m = p_m \int_{r_D}^{r_G} \int_0^{b_m} r\,d\,r\,d\,b = p_m\,b_m \int_{r_D}^{r_G} r\,d\,r \ldots\ldots\ldots\ldots (27)$$

* Kucharski, "Strömungen in rotierenden Kanälen," *Zeitschrift für das Gesamte Turbinenwesen*, 1917, s. 201.

Since:

$$\int_{r_D}^{r_G} r\,d\,r = \varepsilon \int_{r_1}^{r_2} r\,d\,r = \varepsilon \left(\frac{D_2^2 - D_1^2}{8}\right) \ldots\ldots\ldots\ldots (28)$$

in which, ϵ is a coefficient, defining the shape of the vane, then:

$$m = \varepsilon\, p_m b_m \frac{(D_2^2 - D_1^2)}{8} \ldots\ldots\ldots\ldots\ldots\ldots (29)$$

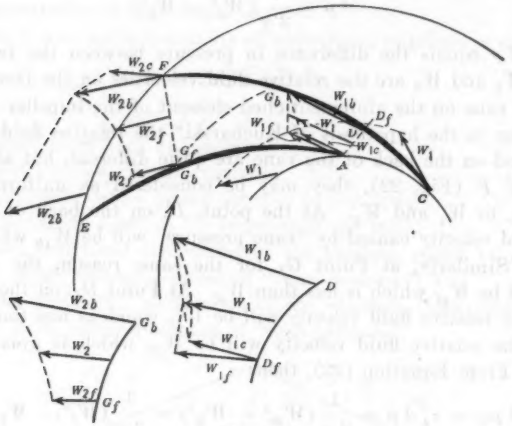

FIG. 22.

The turning moment for every vane is:

$$M = K \frac{N}{G\,z\,n} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (30)$$

in which,

K = a constant;

$\frac{N}{G}$ = the power, in horse power, required by each impeller;

G = the number of the impellers; and

n = the revolutions per minute.

therefore,

$$m = f\,M = K\,f\,\frac{N}{G\,z\,n} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (31)$$

in which, f denotes the relation between the turning moment, M_1, which corresponds to the part, G-D, of the vane, and the total turning moment, M, for every vane.

It follows that:

$$p_m = K \frac{f}{\varepsilon} \frac{N}{G\,z\,n\,b_m\,(D_2^2 - D_1^2)} = K\,\sigma \frac{N}{G\,z\,n\,b_m\,(D_2^2 - D_1^2)} \ldots (32)$$

The coefficient, σ, may vary between 0.25 and 0.6. Since:

$$N = \frac{\zeta\, Q\, H_m}{550\, \eta_t\, \eta_v\, \eta_m} = \frac{\zeta\, Q\, H_t}{550\, \eta_v\, \eta_m} \quad \ldots\ldots (33a)$$

$$\psi = K \frac{\sigma}{\eta_v\, \eta_m\, z\, n\, b_m\, (D_2^2 - D_1^2)} \quad \ldots\ldots (33b)$$

then,

$$d\, p = \psi\, Q\, H_t \quad \ldots\ldots (34)$$

Solving Equation (34) simultaneously with Equations (23*a*) and (23*b*), respectively:

$$W_2^2 - W_{2b}^2 = 2\, g\, r_2\, \psi\, Q\, H_t \quad \ldots\ldots (35a)$$

$$W_{1b}^2 - W_{1c}^2 = 2\, g\, r_1\, \psi\, Q\, H_t \quad \ldots\ldots (35b)$$

However, from Fig. 22,

$$W_2^2 - W_{2b}^2 = (W_2 + W_{2b})\,(W_2 - W_{2b}) = 2\, W_{2c}\, 2\,(W_2 - W_{2c}) \quad \ldots (36a)$$

$$W_{1b}^2 - W_{1c}^2 = (W_{1b} + W_{1c})\,(W_{1b} - W_{1c}) = 2\, W_1\, 2\,(W_1 - W_{1c}) \quad \ldots (36b)$$

so that:

$$W_{2c}\,(W_2 - W_{2c}) = \frac{g\, r_2\, \psi}{2}\, Q\, H_t \quad \ldots\ldots (37a)$$

$$W_1\,(W_1 - W_{1c}) = \frac{g\, r_1\, \psi}{2}\, Q\, H_t \quad \ldots\ldots (37b)$$

From Fig. 21:

$$W_{2c} = \frac{C_{2m}}{\sin \beta_{2c}} = \frac{Q}{\pi\, D_2\, b_2 \sin \beta_{2c}} \quad \ldots\ldots (38a)$$

$$W_{1c} = \frac{C_{1m}}{\sin \beta_{1c}} = \frac{Q}{\pi\, D_1\, b_1 \sin \beta_{1c}} \quad \ldots\ldots (38b)$$

Combining Equation (38*a*) with Equation (37*a*) and Equation (38*b*) with Equation (37*b*):

$$W_2 = \frac{g\, r_2\, \psi\, \pi\, D_2\, b_2 \sin \beta_{2c}}{2}\, H_t + \frac{Q}{\pi\, D_2\, b_2 \sin \beta_{2c}} \quad \ldots\ldots (39a)$$

$$W_1 = \frac{Q}{\pi\, D_1\, b_1 \sin \beta_{1c}} - \frac{G\, r_1\, \psi\, \pi\, D_1\, b_1 \sin \beta_{1c}}{2}\, H_t \quad \ldots\ldots (39b)$$

Let:

$$K_u = \frac{g\, r_2\, \psi\, \pi\, D_2\, b_2 \sin \beta_{2c}}{2} \quad \ldots\ldots (40a)$$

$$K_1 = \frac{g\, r_1\, \psi\, \pi\, D_1\, b_1 \sin \beta_{1c}}{2} \quad \ldots\ldots (40b)$$

then Equations (39) become:

$$W_2 = K_u\, H_t + \frac{Q}{\pi\, D_2\, b_2 \sin \beta_{2c}} \quad \ldots\ldots (41a)$$

$$W_1 = \frac{Q}{\pi\, D_1\, b_1 \sin \beta_{1c}} - K_1\, H_t \quad \ldots\ldots (41b)$$

Substituting in Equation (18), the values W_2 and W_1 as given by Equations (41):

$$H_t = \frac{u_2^2 - u_1^2}{g} - \frac{u_2}{g}\sqrt{\left(K_u H_t + \frac{Q}{\pi D_2 b_2 \sin \beta_{2c}}\right)^2 - \frac{Q^2}{\pi^2 D_2^2 b_2^2}} + \frac{u_1}{g}\sqrt{\left(\frac{Q}{\pi D_1 b_1 \sin \beta_{1c}} - K_1 H_t\right)^2 - \frac{Q^2}{\pi^2 D_1^2 b_1^2}} \quad \ldots\ldots\ldots (42)$$

Equation (42) is a fourth-power equation of H_t and Q.

When $Q = 0$:

$$H_{0t} = \frac{\frac{u_2^2 - u_1^2}{g}}{1 + K_u \frac{u_2}{g} + K_1 \frac{u_1}{g}} \quad \ldots\ldots\ldots (43)$$

but when the discharge is zero, the fundamental equation is, $\frac{u_2^2}{2g}$. Apparently, therefore, there are two values of the head when $Q = 0$; but, in reality, the value, $\frac{u_2^2}{2g}$, corresponds to the condition when $Q + Q_v = 0$, in which, Q_v denotes the portion of delivery lost in the clearances and the value, H_{0t}, given by Equation (43), applies to the useful delivery, Q. Consequently, there must be a certain skip in the theoretical head of the impeller as shown in Figs. 19 and 23.

With $H_t = 0$,

$$K_a = \frac{n}{60\, g\, b_2}\sqrt{\left(\frac{1}{\sin^2 \beta_{2c}} - 1\right)} - \frac{n}{60\, g\, b}\sqrt{\left(\frac{1}{\sin^2 \beta_{1c}} - 1\right)} \quad \ldots\ldots (44)$$

and Equation (42) becomes:

$$K_a Q - \frac{(u_2^2 - u_1^2)}{g} = 0 \quad \ldots\ldots\ldots (45)$$

and,

$$Q_0 = \frac{u_2^2 - u_1^2}{K_a g} \quad \ldots\ldots\ldots (46)$$

The graphical representation of Equation (42) is a fourth-order curve in H_t and Q. As Fig. 23 shows, this curve cuts the H_t-axis at a point, P_0, which corresponds in value to H_{0t} and it cuts the Q-axis at a point, P_1, which corresponds to the delivery value, Q_0, given by Equation (46).

This theory explains the value, $\frac{u_2^2}{2g}$, which is so often measured in actual characteristics near the point of zero discharge, and which, until now, was an unexplained feature in the old theory.

In Fig. 23 the part of the curve, P_0-P_2, that is most important is approximately a straight line. Making the assumption that it is a straight line is justified for the sake of greater simplicity and gives results that are in

accord with all the latest hydrodynamic theories. The result is the straight line equation:

$$H_t = \frac{W \Gamma z}{2 \pi g} = \frac{n \Gamma z}{g} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (47)$$

in which, Γ denotes vane rotation.

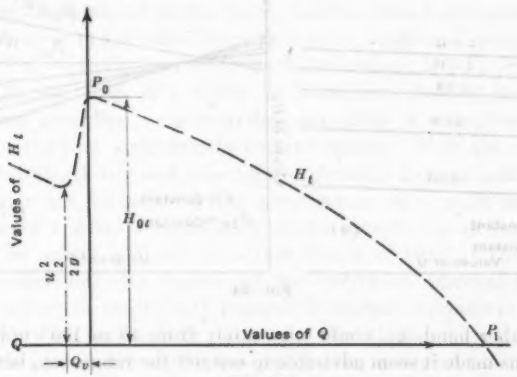

FIG. 23.

It is evident, therefore, that the number of vanes to be provided in turbo-pumps, blowers, and impellers is limited by practical conditions at two opposite extremes. Considering friction losses in the impeller ducts as the most important factor in the design, it would be desirable to use the least possible number of impeller vanes; but if the cavitation losses were considered most important, it would be necessary to avoid choosing z below a certain value, which may be easily determined by studying the performance of each specific impeller. For radial impellers, these conditions may be expressed, in metric units, as follows:*

$$z \text{ (minimum)} = 10 \frac{Q H_m}{n \eta_t b_m (D_2^2 - D_1^2)} \quad \ldots\ldots\ldots\ldots\ldots (48)$$

$$z \text{ (maximum)} = 30 D_2 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (49)$$

For an impeller with given values of D_2, D_1, b_2, b_1, β_{2c}, and β_{1c}, the theoretical characteristics, H_t and Q, can be found by assuming different values of z. Plotting these values results in a set of curves similar to Fig. 24(a) which refers to a centrifugal pump impeller. By inspection it is apparent in this case that there is little advantage gained by increasing z to more than eight or decreasing it to less than six. Increasing the number of vanes does not cause a proportionate increase in theoretical head and, conversely, decreasing z causes an ever-increasing and disproportionate reduction in head.

The proper choice of the inlet angle, β_{1c}, is also confined, normally, to a narrow range (12 to 25°), because its value is dependent, each time, on the

* "Pompe Centrifughe," by M. Medici, Capitoli III e IX, Hoepli, Milano, Italy, 1927.

best assumption of the value, C_{1m}, the radial component of the absolute speed of the water passing through the inlet. For example, Fig. 24(*b*) shows the way in which (H_t-Q)-values of a centrifugal pump impeller vary for different values of β_{1c} when z and β_{2c} are kept constant at seven vanes and 24°, respectively.

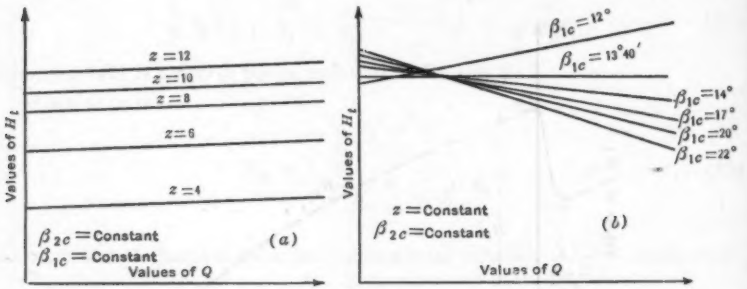

FIG. 24.

On the other hand, β_{2c} could vary safely from 10 to 170° unless practical considerations made it seem advisable to restrict the range, say, between 20 and 150 degrees. Vanes that are inclined too far backward (β_{2c} less than 20°) introduce undue friction losses and those that are inclined too far forward (β_{2c} greater than 150°) promote fluid disturbances and regurgitations within the impeller.

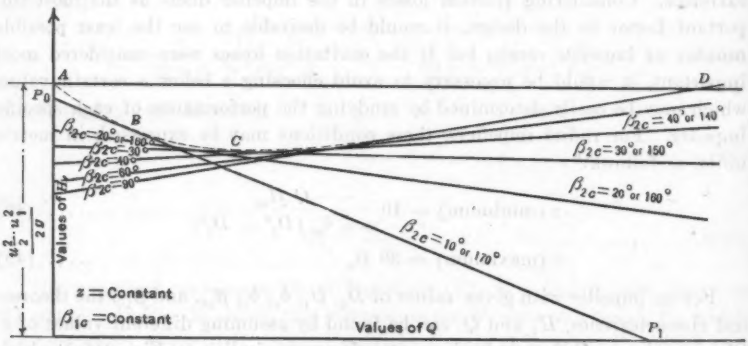

FIG. 25.

Fig. 25 is a set of (H_t-Q)-curves plotted by assuming different values for β_{2c}. Values of D_2, D_1, b_2, b_1, z, and β_{2c}, are fixed and remain constant in each case. It is apparent that, with Q equal to zero (or nearly zero), the head, H_{0t}, decreases as β_{2c} is increased from 10 to 90°; but as β_{2c} continues to increase from 90 to 170°, H_{0t} increases again at the same rate. In other words, H_{0t} has the same value for β_{2c} = 30° and 150°, for β_{2c} = 10° and 170°, etc. Furthermore, with β_{2c} fixed somewhere between 24 and 32° (depending

on the different types of impeller), the (H_t-Q)-characteristic is parallel to the Q-axis, or the head is constant, theoretically, for varying values of Q. For values outside this range, the head varies as indicated in Fig. 25. According to present theory it seems that the most effective values of β_{2c}, for radial pump impellers, lies somewhere between 24° and 30° and this is in perfect harmony with practical research findings.

The direct development of this theory leads to the establishment of a "non-effective" zone for radial impellers with a finite number of vanes. This zone is shown in Fig. 25 as the area above the dotted line, *A B C D*. Vanes inclined backward (β_{2c} less than 90°), which are considered the best for the development of head according to present-day standards of manufacture, are also shown to be the best according to present theory. With the modern, more complete analysis, theory and practice are perfectly harmonized.

The writer has investigated the performance of a multi-stage pump in order to obtain a definite verification of the present theory and, if possible, to control the values assigned to σ (see Equation (32)). These tests were made in connection with studies of the cavitation phenomenon and suction performance in centrifugal pumps.* Different depressions at the pump suction nozzle were regulated by means of a throttle flap located in the suction pipe. The head and delivery of the pump were measured after each change. The tests were repeated for three values of n: 1 450, 1 600, and 1 750.

Other values were: $D_1 = 0.36$ ft.; $D_2 = 0.82$ ft.; $b_2 = 0.023$ ft.; $b_1 = 0.0492$ ft.; $\beta_{2c} = 30°$; $\beta_{1c} = 17°$; $z = 6$; $G = 3$; P_a (atmospheric pressure) = 29.8 in.; water temperature = 64.5° Fahr.; specific weight of water = 62.25 lb. per cu. ft.; and $P_t = 0.83$ in. (water column). The suction pipe was straight and was 5 ft. in length. Packings were very carefully lined in order to introduce a minimum amount of air. The artificially produced suction heads were 23.8, 26.2, and 27.8 ft. The results of the research are shown in Fig. 26. The largest suction heads always cause the most pronounced cavitation, with a corresponding decrease in the quantity of water delivered. Values of σ were computed by use of the formula:†

$$\sigma = \frac{\zeta\, G\, z\, n\, \eta_t (D_2^2 - D_1^2)\, b_m \left[\frac{\zeta_w}{\zeta}\right\} (P_a - P_t) - \frac{C_{1a}^2 - C_1^2}{2g}\left\} - H_a\right]}{K\, Q\, H_m\, \zeta_w} \quad ..(50)$$

in which, ζ_w is the specific weight of water at — 15.56° Fahr. The results of these tests are given in Table 2.

Under the conditions of Test No. 8, which is the normal performance of the pump, $\sigma = 0.25$. Then, from Equation (40*a*),

$$K_u = 0.0856$$

From Equation (40*b*),

$$K_i = 0.0474$$

$$1 + k_u + k_i = 1.2265$$

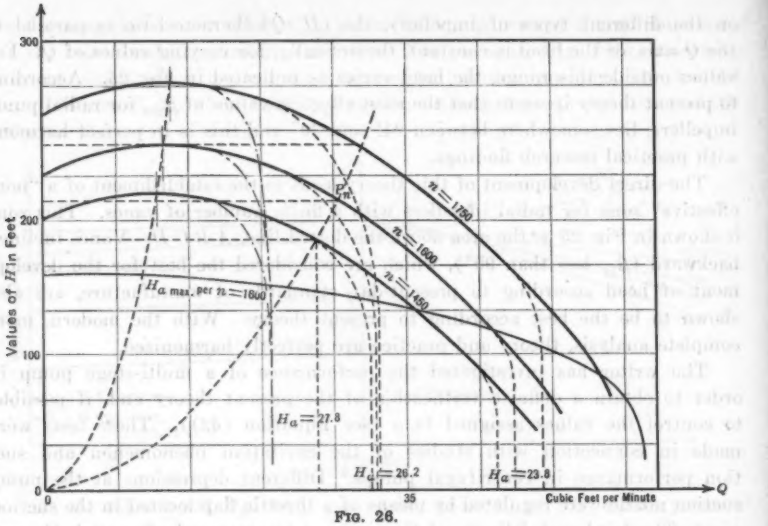

FIG. 26.

TABLE 2.—RESULTS OF TESTS ON A CENTRIFUGAL PUMP.

Test No.	H_a.	n.	Q_e, in cubic feet per minute.	σ.
1	27.8	1 450	21.8	0.364
2	27.8	1 600	21.8	0.346
3	27.8	1 750	21.8	0.318
4	26.2	1 450	31.4	0.305
5	26.2	1 600	32.0	0.3
6	26.2	1 750	32.6	0.25
7	23.8	1 450	44.5	0.27
8	23.8	1 600	46.0	0.25
9	23.8	1 750	49.0	0.24

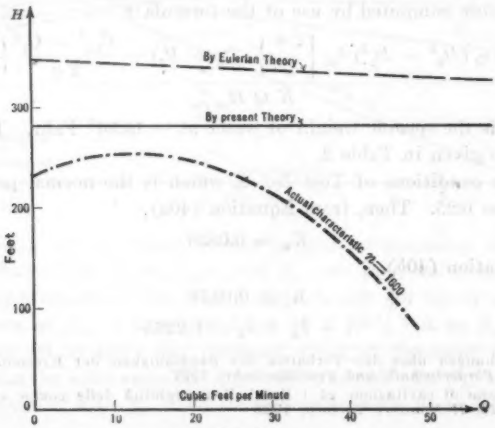

FIG. 27.

$$G\,\frac{u_2^2 - u_1^2}{2\,g} = 348 \text{ ft.}$$

$$G\,H_\alpha = \frac{348}{1.2265} = 284 \text{ ft.}$$

From Equation (44),

$$K_u = 5.75 \text{ ft.}$$

From Equation (46),

$$Q_0 = \frac{348}{5.75} = 60.5 \text{ cu. ft. per sec., or 3 630 cu. ft per min.}$$

Fig. 27 shows a comparison of theoretical characteristics (H_t-Q), obtained by the use of the new theory and the Eulerian theory and also shows the actual characteristic curve of a pump investigated when n = 1 600 rev. per min.

A. H. BLAISDELL,* ESQ. (by letter).—After a careful study of this paper, the writer cannot bring himself to the point of agreeing with the author on the basic assumption which lies at the foundation of the latter's argument. Professor Sherzer states that,

"* * * water being set in rotation in a cylindrical vessel by the action of a paddle or impeller, there is pressure created by centrifugal force which is equal to $\frac{U_a^2}{2\,g}$ and which is part and parcel of the velocity itself. The total head may be regarded as either, but not both".

The fallacy of this idea should not be difficult to comprehend.

In Fig. 28 is shown in cross-section a cylindrical casing, *a*, containing a paddle, *b*, which is attached to a vertical shaft that projects through the upper side of the casing. Assume the shaft and its paddle to be rotating with a uniform angular velocity. If the casing contains a liquid the latter will be forced into rotation and, as Professor Sherzer states, a static pressure is developed due to the centrifugal action; but, contrary to the author's viewpoint, this pressure or potential energy head can be considered, together with the velocity head, as the total energy head imparted to the liquid, if hydraulic losses are neglected.

At the outer edge of the casing are located two piezometer tubes, *c* and *d*. Tube *c* is a static tube with its lower end opening directly into the casing, and Tube *d* has its lower end projecting down into the whirling liquid, the end being turned through 90° with the opening facing directly into the flow. That is, *d* is a Pitot tube. Evidently, with the upper ends of the tubes open to the atmosphere, liquid will rise upward in both, but not to the same heights, as the author's theory indicates. In Tube *c* the liquid will rise to a height, h_a, just sufficient to balance the pressure due to the rotation of the liquid. At Tube *d*, it will be found that the liquid has mounted to a height of H ft., which is equal to twice the height of the liquid in Tube *c*. This is not strange since this tube measures the sum of the static and velocity heads. In order to

* Asst. Prof., Mech. Eng., Carnegie Inst. of Technology, Pittsburgh, Pa.

convince oneself that h_a and H can be properly considered as energy heads, it is only necessary to cut off the tops of the tubes at heights a little less than h_a and H. Liquid will start flowing out from the tops of both tubes and the discharge will continue as long as liquid is supplied to the casing. In other words, the casing and its rotating paddle is a rude sort of pump which is doing the work of lifting liquid through the heights of h_a and H.

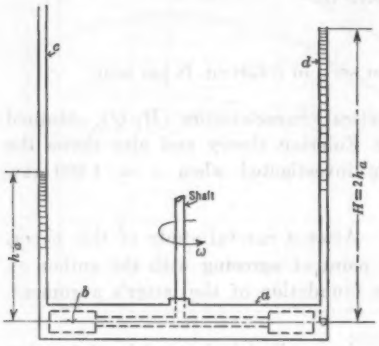

FIG. 28.

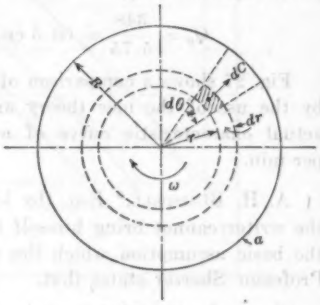

FIG. 29.

The fact that the pressure developed by the centrifugal action can also be considered as an energy head, may be demonstrated analytically as follows. Let a of Fig. 29 represent the casing of the pump in which liquid is rotating with the uniform angular velocity, ω. Consider an elementary ring of the liquid at a distance, r, from the center of rotation. In order that the shape of the ring may be maintained it is necessary that the centrifugal force developed by the rotation of the ring be counterbalanced by the pressure of the liquid against the outer surface of the ring.

The centrifugal force generated by the rotation of the section, $r\ d\theta\ dr$ (and of unit thickness), will be,

$$dC = r\ \omega^2\ dm = \frac{\gamma}{g}\ r\ d\theta\ dr\ r\ \omega^2$$

in which, γ is the density of the liquid, in pounds per cubic foot. The total pressure acting on the outer wall of this differential section can be expressed as $(r + dr)\ dp\ d\theta$, which is, $r\ d\theta\ dp$, if the product, $dp\ dr\ d\theta$, is neglected. Equating the expressions for centrifugal force and restraining pressure gives,

$$p = \frac{\gamma}{g\ \omega^2} \int_0^R r\ dr = \frac{\gamma}{g} \frac{\omega^2\ R^2}{2} = \gamma \frac{U_a^2}{2\ g}$$

in which, U_a is the linear velocity at the radius, R. Dividing the pressure by the density now provides,

$$\frac{p}{\gamma} = h_a = \frac{U_a^2}{2\ g}$$

as the pressure head (or energy) which must be added to the velocity head to obtain the total energy head at a distance, R, from the center of rotation.

With respect to the application of Bernouilli's theorem to the flow of liquids, the writer again finds it necessary to disagree with the author. Strictly speaking, this theorem, which is only a restricted form of the law of conservation of energy, applies only to flows where the motion is steady or stream like and the form of channel or nature of the motivating mechanism which maintains the flow does not come into consideration. In the case of actual liquids, the steady state can only be approximated since the effects of viscosity and boundary friction cause an eddying and turbulent motion where the kinetic energy of translational motion is only a part of that present. For these reasons it is quite necessary to apply the theorem with considerable care to engineering problems where one is dealing with real fluids.

To be sure, the theory of centrifugal pumps as discussed by Professor R. L. Daugherty* has many limitations but these have been recognized and the only excuse for the continued use of this theory has been its simplicity and familiarity as compared to the more intricate analyses obtained by use of higher mathematics. Relatively recent investigations in aerodynamics have led to a new interpretation of the classical hydrodynamics,† making it possible to analyze the fluid action in turbo-machinery with very good approximation to the actual flow phenomena. By revealing what takes place in a blower or pump, these same researches have made it possible to apply the classical theory of centrifugal pumps with satisfactory results.

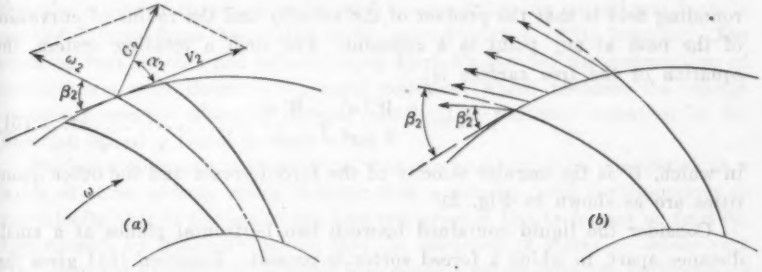

FIG. 30.

The writer believes that Equation (*B*) is quite satisfactory as it stands. Without doubt the motion of the impeller extends back into the liquid in the suction pipe giving a swirl or corkscrew motion to the approaching mass. The practical effect, in so far as Equation (*B*) is concerned, is to increase the magnitude of the term, $C_1 V_1 \cos \alpha_1$, since under this condition angular momentum is supplied to the liquid before it reaches the impeller. Aside from this direct influence of the impeller, there is (contrary to Professor Sherzer's viewpoint) energy in the liquid which enters the rotor due in most cases (if supply head is negative) to the action of atmospheric pressure. Of course, an equal amount of energy must be furnished to the liquid by the impeller.

* In "Centrifugal Pumps."

† "Hydrodynamics," by Horace Lamb, 4th Edition, 1916.

Very careful analytical and experimental work has shown conclusively that the liquid discharges from an impeller with a relative angle, β_2' (Fig. 30 (*b*)), which is less than the one indicated by the customary vector layout (Fig. 30 (*a*)). Moreover, the relative velocity of discharge at a given section of the impeller channel is not constant. For example, at the exit section, the liquid at the rear of the blades discharges with a greater relative velocity than that on the front side. Consequently, the pressure of the flowing liquid is higher in front and less on the rear, etc. However, these facts, when understood, make it possible to continue to use the classical theory.*

MORROUGH P. O'BRIEN,† JUN. AM. SOC. C. E. (by letter).—Professor Sherzer's comparison of the centrifugal pump to an athlete throwing a hammer is very apt, but not in the manner suggested. The tangential velocity determines the kinetic energy which will propel the hammer and is for this reason the only energy content of interest to the athlete; but there is also present in the rotating system an additional energy due to the stretching of the wire. In a centrifugal pump, the tension in the wire is replaced by the centripetal force exerted by the pump casing.

Probably the simplest manner of considering the shut-off condition in a centrifugal pump is to regard it as a forced vortex surrounded by a liquid moving irrotationally.‡ The condition of irrotational motion in the surrounding field is that the product of the velocity and the radius of curvature of the path at any point is a constant. For such a rotating system, the equation of the free surface is:

$$Z = -\frac{W^2 a^4}{2 g r^2} + \frac{W a^2}{g} \qquad (51)$$

in which, W is the angular velocity of the forced vortex and the other quantities are as shown in Fig. 31.

Consider the liquid contained between two horizontal planes at a small distance apart, in which a forced vortex is present. Equation (51) gives the pressure difference between the center of rotation and a point at a distance, r. It is seen that for $r = \infty$, the pressure is $\frac{W^2 a^2}{g}$ or $\frac{V^2}{g}$, and that at $r = a$, it is $\frac{W^2 a^2}{2 g}$ or $\frac{V^2}{2 g}$.

For any value of r, the vertical distance from the z-line to the value of z at $r = \infty$, represents the velocity head still present in the liquid. As the casing of a pump is somewhat larger than the impeller, but is never of infinite

dimensions, the pressure head at shut-off may be greater than $\frac{V^2}{2g}$, but can never be $\frac{V^2}{g}$.

When liquid is being discharged through the forced vortex and surrounding irrotational field, the determination of the pressure distribution is greatly complicated by the fact that the angular velocity of any fluid particle is not

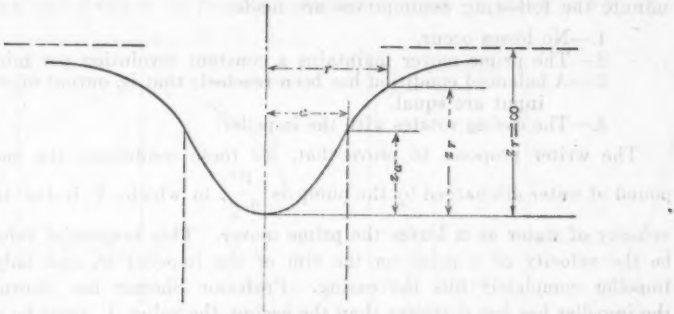

FIG. 31.

the same as that of the impeller, except for radial blades, and by the fact that the radius of curvature to be used in computing the centrifugal force is not the distance from the particle to the axis of rotation of the impeller. The equation may be obtained by combining Corioli's law for the composition of accelerations with Bernoulli's general equation, which includes the change in energy content along a stream tube.* The resultant equation is the Eulerian equation found in most texts.

Professor Sherzer's data showing that the pump may be considered as a series of three orifices, really indicate that a velocity head corresponding to the velocity that is normal to the first two areas is lost in impact or friction. Experiments by Stanton† showed that the efficiency of vortex chambers very often does not exceed 10%, a result that roughly agrees with the indication of losses shown by these experiments. As to the third orifice, at the entrance to the discharge line, the velocity head present at this point must also be present at the point at which the pressure is measured. Since there are no dimensions of the experimental pumps given, it is impossible to consider the data in the light of accepted theories. From the general description, the new design seems to correspond to some of the earliest types of centrifugal pumps. Other references to this subject may be found in theories proposed by Mr. A. H. Gibson.‡

R. T. LIDDICOAT,§ ESQ. (by letter).—The writer has studied the problem and his conclusions are squarely in line with Professor Sherzer's arguments.

§ Asst. Prof., Dept. of Eng. Mechanics, Univ. of Michigan, Ann Arbor, Mich.

It seems that some of those interested in centrifugal pumps do not realize what findings Professor Sherzer has presented. If he is correct in his work, he gets an amount of energy h ft-lb. per lb. of water pumped at a given revolution per minute, whereas by the present theory he should get $2h$; but this is not all. He assumes that he pumps water without losses as do the proponents of the present theory. Both theories cannot be right. To determine the maximum energy a given pump can give to the water at a given revolution per minute the following assumptions are made:

1.—No losses occur.
2.—The prime mover maintains a constant revolution per minute.
3.—A balanced condition has been reached; that is, output of water and input are equal.
4.—The casing rotates with the impeller.

The writer proposes to prove that, for these conditions, the energy per pound of water discharged by the pump is $\frac{V^2}{2g}$, in which, V is the tangential velocity of water as it leaves the prime mover. This tangential velocity will be the velocity of a point on the rim of the impeller if, and only if, the impeller completely fills the casing. Professor Sherzer has shown that if the impeller has less diameter than the casing, the value, V, must be corrected to give the real tangential velocity of the water. To avoid any confusion regarding conditions after the particles are thrown off by the prime mover, the writer proposes to build a casing around the impeller, so as to know definitely what water is and is not rotating. To be more specific, the energy given to the water by the prime mover is the important factor to be considered. What is done with the energy after it is developed is of no interest at present. The writer is only trying to prove that the most the prime mover can possibly give the water is $\frac{V^2}{2g}$ and not $\frac{V^2}{g}$.

In building the centrifugal pump, the purpose is to construct an apparatus with which to whirl water as efficiently as possible. Considering, first, the shut-off conditions when no water is pumped, suppose the water whirled is contained in a cylindrical box of a radius, r. Suppose that in this box there are radial vanes, quite close together. For convenience, put the box on a vertical axis as shown in Fig. 32(a).

Fill the box at atmospheric pressure and then seal it completely. Now the prime mover brings the water to a stated speed and then keeps it moving uniformly. The pressure developed according to well-known laws will be atmospheric at the center and will attain a maximum at the outside. Taking the center as an origin and plotting pressure against radial distance, a parabolic curve is obtained as shown in Fig. 32(b).

A careful study of conditions in the closed box will throw considerable light on the centrifugal pump. Consider the particle, w, of Fig. 32(a) after the cylinder has attained its constant speed. In Fig. 32(c), the particle, w, is shown as a free body with the radial forces acting on it.

The radial forces acting will be: P, caused by the water pressure back of the particle, w; C, caused by inertia due to centrifugal force, of the col-

umn of water between w and the axis of rotation; and dC, caused by the inertia due to the centripetal acceleration of the particle, w.

P will always be greater than C by an amount just sufficient to keep the particle, w, traveling in a circular path. This is the important factor in the writer's argument. Particle w must be forced to travel in a circle; it will not do so otherwise. However, it travels in a circle only as long as the difference between P and C is dC (Fig. 32(c)). This will hold absolutely true as long as P and C follow the parabolic pressure distribution shown in Fig. 32(b).

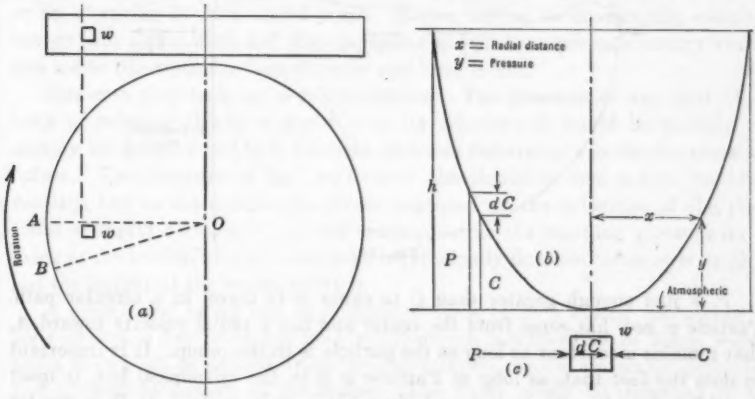

FIG. 32.

Now, suppose that, by some means, it were possible to give w a slight radial velocity, V_r, toward the center of the cylindrical tank. Particle w, now having all radial forces balanced, then moves toward the center of rotation, O. Having more tangential velocity than it needs for the new position, it is slowed up tangentially by pressing on Vane AO (Fig. 32(a)). At the same time the particle taking the position formerly occupied by w must be speeded up tangentially. Therefore, it presses against Vane BO so that the prime mover is not affected. The radial forces are still perfectly balanced on the particle, w, although P, C, and dC have all changed in value; w continues on its way to the center at this constant velocity. To get a clear idea of this behavior, consider the actual water surface to take the form of the paraboloid of revolution (Fig. 32(b)) and then, putting in the guide-vanes, consider the motion of the particle, w, in the form of a wood block having the density of water and acting under similar initial radial velocity conditions at the water surface.

Conclusions to Be Drawn from Shut-Off Condition.—Neglecting losses and assuming perfect guide-vanes, a particle of water is free to move radially. Given a radial velocity, V_r, that velocity will be maintained as long as the parabolic pressure distribution, originally assumed, exists.

Now, suppose water is admitted at the center of the pump with whatever radial velocity, V_r, is needed to supply the demand. Then a series of holes is opened all around the periphery of the cylindrical tank. The prime mover

maintains the constant speed necessary to make input equal to output. As long as the pump remains full and slip is neglected (which will be the best condition attainable), the pressure distribution within the cylindrical box will have the parabolic distribution. In any position, the forces acting upon the particle, w (P, C, and dC), are balanced just as they were in the box at shut-off.

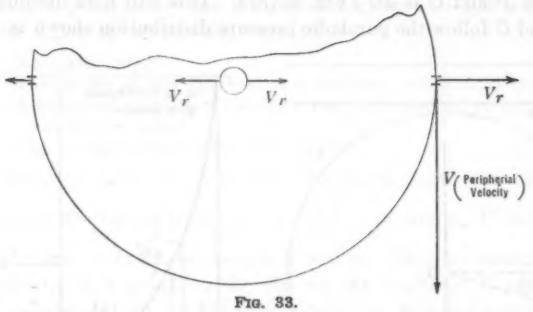

FIG. 33.

P is just enough greater than C to cause w to travel in a circular path. Particle w now has come from the center and has a radial velocity toward A, that remains a constant as long as the particle is in the pump. It is important to note the fact that, as long as Particle w is in the cylindrical box, it must travel in a circle. Since it travels in a circle only as long as P is greater than C, it follows that P is necessary to keep the particle in the box and after it leaves, of course, P, C, and dC all vanish together. Therefore, the writer believes that, after a careful unbiased study, it will be agreed the particle, w, entered with a radial velocity, V_r, and left with identically the same radial velocity.

Based on this discussion, the energy considerations are quite simple. The velocity of the jet issuing from the cylindrical box (Fig. 32(a)) will be as shown in Fig. 33.

The total energy contained in the water is obviously $\frac{V_r^2}{2g} + \frac{V^2}{2g}$, but $\frac{V_r^2}{2g}$ was given to the water before it entered and must be deducted from the output to give that furnished by the prime mover.

Some will say that the pressure head at the point of discharge has been neglected. This pressure was needed to keep the particles in the box in their circular paths.

Another point of view on energy is that particles entering with radial velocity, V_r, and no tangential velocity, are given a tangential velocity, V, by the prime mover, or the input is $\frac{V^2}{2g}$.

The purpose of allowing the casing to rotate is simply to place definite limits on the subject-matter. The energy given to the water by the prime mover is the important factor.

LLOYD H. DONNELL,* ESQ. (by letter).—The author brings up the interesting question as to whether, in a rotating body of liquid, there is both kinetic energy due to its motion and potential energy due to its pressure, or whether these are merely two successive steps in the transformation of the same energy from one form to another.

At first, the latter view does not seem unreasonable. It is natural to feel that the pressure is due solely to the motion and that this pressure would instantly disappear if the velocity were destroyed by any means, by friction or by changing it into useful work. Hence, trying to change the velocity energy into useful work and then expecting to still have pressure energy available seems like trying to "eat the cake and have it too."

However, this rests on a misconception. The pressure of any part of a body of rotating liquid is not due to its velocity; it would be possible to destroy its velocity and still have the pressure remaining exactly the same as before. The pressure of any particle of the liquid is due, not to its own velocity, but to the centrifugal forces produced by the velocities of the particles of liquid between it and the center, just as the crushing pressure on a brick at the bottom of a pile of bricks is principally due, not to its own weight, but the weight of the bricks above it.

A centrifugal pump can be considered roughly as a casing containing a body of liquid kept rotating by a motor-driven paddle-wheel or rotor, water being drawn off as desired from the outer layers, which are under pressure, and allowed to flow in at the center. The water might be imagined to be divided along the radius into thin layers. The outermost layer flows out through the discharge pipe and the next layer moves up to take its place, etc.

The point to be noted is that the tangential velocity of each successive outermost layer could be completely destroyed just before it was discharged, without affecting its pressure (as this pressure is due to the centrifugal force on the inner layers and only negligibly to the centrifugal force on the outermost layer itself, if the layers are assumed to be thin enough). The velocity could be destroyed by friction with the casing wall (as must actually be the case, to a large extent, at very low discharge rates), converting its energy into heat; or, theoretically, it could be changed into useful work with a set of miniature water-wheels. Thus, water would be discharging under the full pressure head and at the same time the kinetic energy of all the water discharged (no matter how thin each successive layer was assumed) would be converted into heat or some other separate form of energy.

Hence, there is, in the casing, both pressure energy (of which full use is made) and kinetic energy, which must have been paid for at the drive shaft, but which there is evidently some difficulty in utilizing. Some of it can be used as velocity in the discharge pipe, especially at high discharge rates when this velocity is comparable to the tangential velocity in the casing (hence it is possible to get high energy efficiencies at full discharge). However, especially at low discharge, much of the velocity energy must be changed into pressure energy, or else it will probably be wasted in eddy currents.

* Instructor, Dept. of Eng. Mechanics, Univ. of Michigan, Ann Arbor, Mich.

It is possible to change velocity energy into pressure energy efficiently, by providing an expanding closed path in which the velocity gradually decreases as the pressure increases, as in a Venturi meter. It is difficult to understand how a spiral casing provides any such thing, because the expanding passage formed is entirely open all along one side and the pressure kept more or less constant all along this side. However, a closed expanding passage can be provided, either outside the casing with the small end forming the discharge opening of the casing, or in the form of a number of small passages arranged around the rotor inside the casing. To be effective, however, the velocity inside such a passage at the small end (which depends on its area and the discharge rate) must be the same as that of the water just outside the passage (which depends largely on the speed of rotation of the pump). With a fixed pump speed this can be the case only at one particular rate of discharge. Such a passage will be ineffective or even harmful at other rates of discharge—unless its size can be varied by some mechanical means.

S. TIMOSHENKO,* ESQ. (by letter).—This paper contains in several places a severe criticism of the usual theory for centrifugal pumps. The accepted theory is based on the assumption of an "ideal fluid" and on the neglect of various kinds of losses of energy; hence it is quite natural to expect considerable discrepancy, between the theoretical and experimental results. Although this discrepancy is very large the writer does not agree with Professor Sherzer that the causes are fundamental errors in the present theory, such as an erroneous addition of the "pressure head" to the "velocity head" or a neglect of the pressure in the casing which prevents the free radial acceleration.

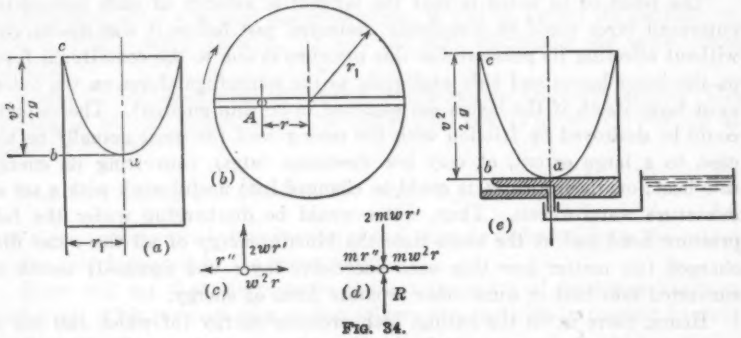

FIG. 34.

The technical part of the paper contains very interesting experimental results and applications of these results in design. However, the writer wishes to discuss only that part in which the usual theory is criticized. By use of two simple examples, it may be shown that the "velocity head" and the "pressure head" are not "part and parcel of each other," but are separate and distinct quantities, both of which can be utilized under certain conditions. In

* Dept. of Eng. Mechanics, Univ. of Michigan, Ann Arbor, Mich.

the usual theory, the pressure in the casing does not affect the amount of work done on the water in the radial grooves of the runner. Consider, first, a fluid rotating in a circular cylindrical container with a constant angular velocity, w (Fig. 34 (a)). It is well known that the surface of the rotating fluid will be a paraboloid of revolution. At the center, a, the velocity of the fluid and the pressure are both zero. At the point, c, the pressure is also zero, but the velocity is $v = wz_1$ and kinetic energy of 1 lb. of the fluid at this point will be $\frac{v^2}{2g}$. At the point, b, the kinetic energy and the so-called "pressure energy" are both equal to $\frac{v^2}{2g}$.

Consider, as a second elementary problem, the motion of a ball in a smooth groove of a rotating disk. For simplicity, assume that the groove is radial (Fig. 34(b)), that there is no friction, and that the ball can move freely along the groove. In order to investigate the motion of the ball, apply the principle of d'Alembert. On this basis equations for bodies in motion can be obtained in the same manner as equations for bodies in equilibrium, it being necessary only to add the inertia forces to the external forces. The inertia forces will be obtained by multiplying the components of acceleration with -1 and with the mass of the moving ball. In the present case, the complete acceleration of the ball will consist of three parts: (a) The acceleration of the ball in its relative motion along the radial groove, which will be represented by the second derivative, r'', of the radial distance, r, of the ball with respect to time; (b) the acceleration of A the instantaneous point of contact between the ball and the disk; in the case of uniform rotation, this is given by the magnitude of the centrifugal acceleration, w^2r; and (c) Corioli's acceleration, $2wr'$, which is perpendicular to the relative velocity, r' in the direction of motion. These three components of acceleration and the corresponding inertia forces are shown in Fig. 34(c) and (d). In addition to inertia forces, the external forces acting on the ball should be considered. Neglecting the weight of the ball, only one force remains—the reaction, R, of the groove, which produces the work on the ball. The differential equations of motion, (Fig. 34(d)), will be:

$$mr'' - mw^2r = 0 \quad \ldots\ldots(52)$$

$$R = 2mwr' \quad \ldots\ldots(53)$$

Equation (52) determines the motion of the ball along the groove. It may be written in the form:

$$r = r_0 \cosh w\,t + \frac{r_0'}{w} \sin w\,t \quad \ldots\ldots(54)$$

in which, r_0 denotes the initial displacement, and r_0' the initial relative velocity of the ball. Consider only the particular case, $r_0' = r_0 w$; that is, the ball at the initial instant has its radial and circumferential velocities equal. Under such an assumption:

$$r = r_0 \,(\cosh wt + \sinh wt) \quad \ldots\ldots(55)$$

$$r' = r_0 w \,(\cosh wt + \sinh wt) = rw \quad \ldots\ldots(56)$$

The radial component of the velocity remains equal to the tangential component during the motion of the ball in the groove, and the ball will leave the disk with the total velocity equal to,

$$\left(\sqrt{(r')^2 + w^2 r^2}\right)_{r=r_1} = \sqrt{2}\, w r_1 = \sqrt{2}\, v$$

in which, v denotes the circumferential velocity of the disk. The kinetic energy of the ball is equal to,

$$E = m v^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (57)$$

Neglecting the initial value of this energy, and assuming that the ball has been introduced at the center of the disk, the kinetic energy, Equation (57), must be equal to the work done by the reaction, R, which is the only force acting on the ball. In calculating this work, Equation (53) will be used. The reaction, R, is always perpendicular to the radius, and its moment with respect to the center of the disk will be $2\, m\, w\, r'\, r$. The work done by this moment per element of time, $d\, t$, will be $2\, m\, w^2\, r\, d\, r$, and the complete work produced on the ball during its motion from $r = 0$, to $r = r_1$, will be:

$$W = \int_0^{r_1} 2\, m\, w^2\, r\, d\, r = m\, v^2 \ldots\ldots\ldots\ldots\ldots\ldots (58)$$

which agrees with Equation (57). Imagine now that the ball is no longer free to move along the groove, and that a radial force, F, directed always toward the center of the disk, opposes the free motion of the ball in the groove. It is easy to see that in such a case Equation (54) remains unchanged and Equation (52) must be replaced by:

$$m\, r'' - m\, w^2\, r + F = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (59)$$

The relative velocity of the ball will depend now on the magnitude of the force, F. When this force is very small and can be neglected, Equation (52) is sufficient. When the value of F approaches $m\, w^2\, r$ (the centrifugal force), the relative velocity, r', approaches zero, the total velocity of the ball leaving the groove approaches v, and the kinetic energy of the ball will be $\frac{m\, v^2}{2}$; that is, only one-half the kinetic energy obtained for the case of the free relative motion of the ball in Equation (57). Then, considering the work done on the ball during this very slow motion along the groove, it is easy to see, from Equation (53), that the reaction, R, of the groove diminishes in the same proportion as the relative velocity, r', but the time of action of this force increases in the same proportion and, finally (Equation (58)), the work done on the ball does not depend on the relative velocity, r', and is always equal to $m\, v^2$. In this case, however, only one-half this work is transformed into the kinetic energy of the ball and the other half is spent on work against the pressure, F.

In order to apply this discussion to the study of pumps, unite the two problems represented in Fig. 34(a) and (b), into that shown in Fig. 34(c). The circular cylinder rotates about its vertical axis with a constant angular velocity, w, such that the parabolic surface of the liquid is tangent to the bottom of the container at the center, a. The bottom of the container consists of a circular disk with a smooth radial channel, $a\, b$, and provision is made for bringing the liquid to the center, a, of the disk with zero pressure and

zero velocity. When the opening, b, is closed the same conditions occur as in the case shown in Fig. 34(a), and if friction is neglected, rotation with constant angular velocity will proceed without the introduction of any work from the outside. Imagine, now, that there is an opening at b such that the liquid is moving slowly along the channel, $a\,b$, and that the depth of the container is a little less than $\frac{v^2}{2g}$. Then, for each pound of fluid brought (at zero pressure and zero velocity) to the point, a, 1 lb. of liquid will be delivered at the point, c, where the velocity is equal to v and the pressure is equal to zero. From the discussion of Fig. 34(b), it is clear that the work done on each pound of liquid during its motion along the channel, $a\,b$, is equal to $\frac{1}{g}v^2$. This work will be spent partly in increasing the kinetic energy of the fluid and partly in overcoming the pressure.

Considering now the extreme case of a very slow motion in the channel it is found, as before, that one-half the work will be transformed into kinetic energy, $\frac{v^2}{2g}$, and the other half into the so-called "pressure energy." In this manner there occurs at the point, b, a "velocity head" equal to $\frac{v^2}{2g}$ and a "pressure head" equal to $\frac{v^2}{2g}$. Both these parts have a definite physical meaning, namely, for each pound of liquid introduced at the point, a, there will be obtained a pound of liquid at c, at which point it has the kinetic energy, $\frac{v^2}{2g}$ and the potential energy, $\frac{v^2}{2g}$. The sum of these two forms of energy is equal to the work, $\frac{v^2}{g}$, done during motion of the liquid along the channel, $a\,b$, which work is exactly the same as in the case of the free radial acceleration, which occurs in pumps without casings and discharging in the air.

By a special arrangement, the kinetic energy of liquid at the point, c (Fig. 34(c)), can be utilized and if there are no friction losses or other sources of dissipation of energy, the liquid will be raised to the level of $\frac{v^2}{g}$ given by the usual theory.

Thus, it is evident that there are no fundamental errors in the usual theory. It will give correct results provided the assumptions on which it is derived are fulfilled. In actual pumps, if such a level as $\frac{v^2}{g}$ is not attained, it must be attributed to various kinds of losses in energy which are not taken into consideration by this theory, and to other deviations from the assumptions made. It is assumed, for instance, that in its relative motion the fluid has a velocity uniformly distributed over the cross-section of the groove and that

this velocity has a radial direction. More detailed investigations* show that the distribution of the velocity over the cross-section is not uniform. Velocity is smaller at the side of the groove at which pressure on the liquid is produced and larger on the opposite side. The same investigations show also that in a radial groove the relative velocity of the fluid near the periphery is no longer in a radial direction, and that it has a component in a circumferential direction. These deviations from the assumptions made in the usual theory must affect the final result, and may yield some explanation of discrepancies between theoretical and experimental values.

A. B. Cox,† Esq. (by letter).—Any one who has given any study to the history of science and engineering cannot but be impressed with the way in which new theories and practices have been—and are—constantly overthrowing old theories and practices, only to be themselves overthrown by still other theories and practices later. A thousand years or so from now, practically all the present theories and practices will certainly have been superseded or radically changed; but why wait a thousand years?. Why not encourage—rather than discourage—such men as Professor Sherzer, who are trying, now, to discover the errors in old theories and to devise others, better and more workable?

In Fig. 35 is shown a series of head-capacity curves of a steam-condenser circulating water pump with low head and high capacity, and in Fig. 36 a series for an oil-cooler circulating water pump with high head and low capacity. A notable feature of the curves of Fig. 35 is the V, or notch, near the middle of each curve. This droop in the curve was not noticed during the test until the last curve was being taken—at 720 rev. per min.—whereupon the points at this speed were carefully checked and found to be correct. It was then discovered that similar notched curves could be drawn through the points of all the other curve points taken at the lower speeds. The droop in the head-capacity curve appears to be characteristic of centrifugal pumps and fans.‡ Probably the chief reason that this peculiarity has not been noticed before is that most pumps and fans have only a slight droop in the head-capacity curve which is scarcely noticeable, and the points of the curve are usually taken on test only at the shut-off point and near the rating point, the section in which the V is most likely to occur nearly always being omitted.

The diameters of the pump runner of Fig. 35 were 19 in. outside and 14⅞ in. inside, and that of Fig. 36, 11⅝ in. and 5½ in., respectively. The values of the head at shut-off, as calculated by the formula, $\frac{V^2}{g}$, for the two pumps, are 110.6 ft. and 245 ft. at speeds of 720 and 1 750 rev. per min., respectively, instead of 33.5 ft. and 117.5 ft. as actually obtained on test. The values calculated by the formula, $\frac{V^2}{2g}$, are 55.3 ft. and 122.5 ft., respectively.

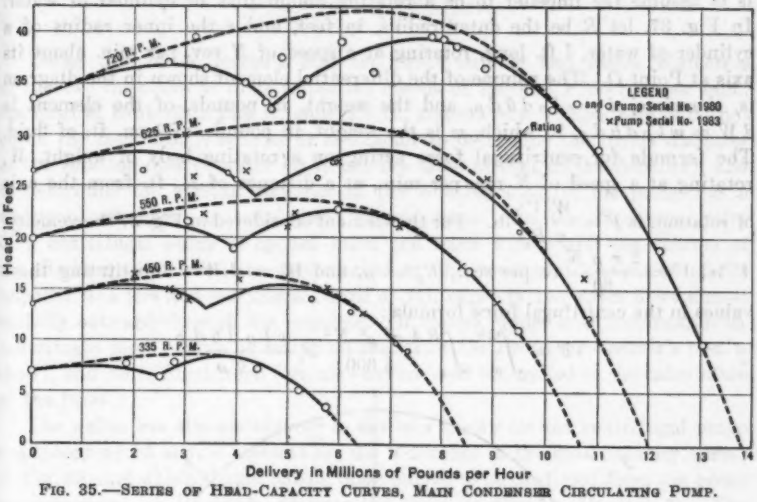

FIG. 35.—SERIES OF HEAD-CAPACITY CURVES, MAIN CONDENSER CIRCULATING PUMP.

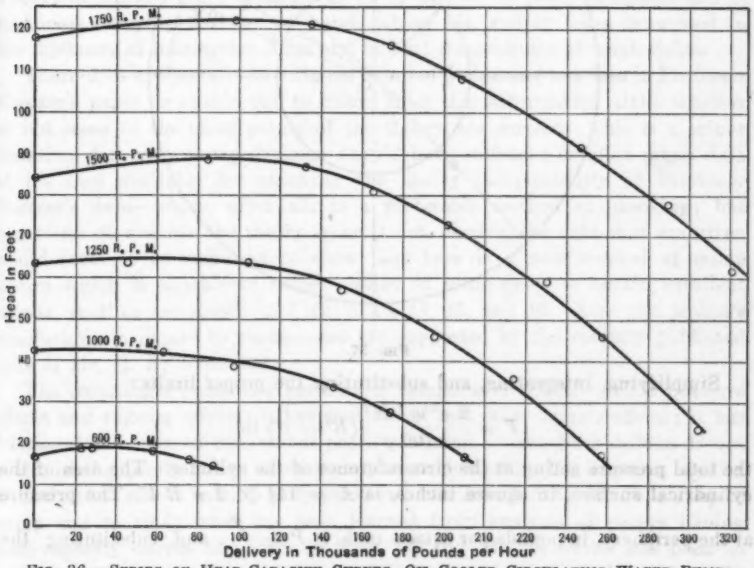

FIG. 36.—SERIES OF HEAD-CAPACITY CURVES, OIL-COOLER CIRCULATING WATER PUMP SERIAL NO. 1984.

Another way of considering the action of a centrifugal pump at shut-off is to assume the impeller to be a rotating hollow disk or cylinder of water. In Fig. 37, let R be the outer radius, in feet, and r the inner radius of a cylinder of water, l ft. long, rotating at a speed of N rev. per min. about its axis at Point O. The volume of the differential element shown in the diagram is, therefore, $dv = l\,\rho\,d\theta\,d\rho$, and the weight, in pounds, of the element is $dW = w\,l\,\rho\,d\theta\,d\rho$, in which, w is the weight, in pounds, of 1 cu. ft. of fluid. The formula for centrifugal force acting on a rotating body of weight, W, rotating at a speed of N rev. per min., at a distance of R_c ft. from the axis of rotation, is $F = \dfrac{W\,V^2}{g\,R_c}$ lb. For the element considered in Fig. 37 the velocity, V, is, $V = \dfrac{2\,\pi\,\rho\,N}{60}$ ft. per sec., $R_c = \rho$, and $W = d\,W$. Substituting these values in the centrifugal force formula:

$$F = \int_0^{2\pi} \int_r^R \frac{4\,\pi^2\,\rho^2\,N^2}{3\,600} \times \frac{w\,l\,\rho\,d\,\theta\,d\,\rho}{g\,\rho}$$

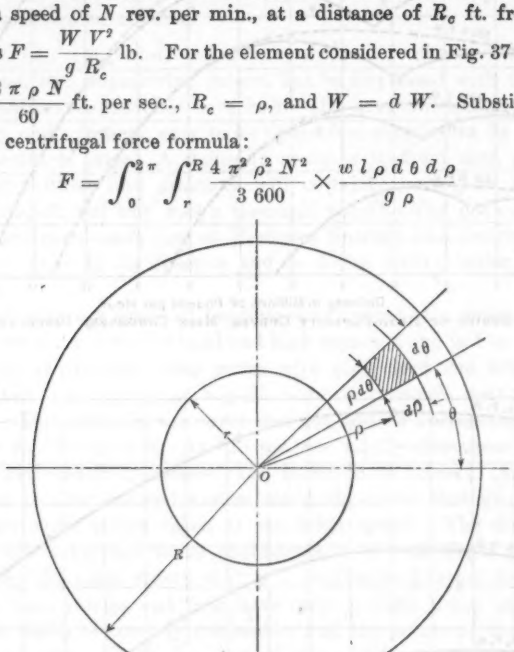

FIG. 37.

Simplifying, integrating, and substituting the proper limits:

$$F = \frac{2\,\pi^3\,w\,l\,N^2}{2\,700\,g}\,(R^3 - r^3)\text{ lb.}$$

the total pressure acting at the circumference of the cylinder. The area of the cylindrical surface, in square inches, is $A = 144 \times 2\,\pi\,R\,l$. The pressure at the periphery, in pounds per square inch, is $P = \dfrac{F}{A}$, and substituting the values of F and A,

$$P = \frac{\pi^2\,w\,N^2}{144 \times 2\,700\,g} \times \left[\frac{R^3 - r^3}{R}\right]$$

and the head, in feet, is,

$$H = \frac{\pi^2 N^2}{2\,700\,g} \times \left[\frac{R^3 - r^3}{R}\right]$$

Using this latter formula and the exact outside and inside diameters of the two impellers at their respective speeds of 720 and 1 750 rev. per min., the head at shut-off is 29.4 ft. and 72.8 ft., respectively. These results do not check the tests either, because it is difficult to determine the inside diameter of the rotating disk of water (it is not the same as that of the impeller), and to determine the outside diameter of the rotating disk, if the pump has a whirlpool chamber—as both these pumps have. As the discharge valve of a centrifugal pump is opened more and more widely and the volume of the discharge increases, the water takes up the rotational movement of the impeller to a less and less degree, until at full capacity the water flows almost radially outward through the impeller. Of course, under such circumstances, centrifugal force cannot be acting on the water (as Professor Sherzer's results show), and centrifugal force formulas cannot well be applied to the calculation of the head.

The writer has also endeavored to devise a theory for the centrifugal pump —a theory which should account for the V-notches in the head-capacity curves of Fig. 35, and which should enable these curves to be predicted from the pump measurements, as Professor Sherzer has done in Figs. 9, 10, and 11. The writer's endeavor has not yet been successful, but it has resulted in "A New Theory of Fluid Flow",* which may be of interest to pump designers and to engineers studying the flow of water, oil, or air, and to those interested in the thickness of lubricating films and in heat transmission through fluids.

There does not seem to be sufficient detail of design and test data in Professor Sherzer's paper to enable one to check from this information alone whether or not some of the chief points of the theory are correct. This is a minor omission, for every pump designer should have sufficient detailed pump data of his own available for checking the theory independently of Professor Sherzer's data—which, after all, is a preferable method of checking; but regardless of whether the theory is, or is not, correct, the data that are given would seem to be sufficient to show that here is a new method of pump design which is capable of being applied in some cases to obtain excellent results, such as are shown in Figs. 9, 10, 11, 15, and 16. Also, the author's conclusions in regard to guide-vanes are supported by the recently published tests of Mr. H. F. Schmidt.†

The centrifugal pump is a machine of complicated action. It has pressure effects and velocity effects; it has centrifugal and other inertia effects; it has frictional and eddy effects; and if poorly designed, it may have sudden droops in the head-capacity curve, or vacuum pockets formed in the impeller, similar to cavitation effects in ship propellers, etc. In an effort to design a simpler pump and to apply what has been learned from analysis of pumps having head-capacity curves as shown in Figs. 35 and 36, the writer has been so

* *Journal*, Franklin Inst., December, 1924, and December, 1926.

† "Some Screw Propeller Experiments with Particular Reference to Pumps and Blowers," *Journal*, Am. Soc. of Naval Engrs., February, 1928.

fortunate as to have developed a radically new but simple type of axial flow pump. The first tests indicate that the weaknesses typical of the usual design of this type of pump have been avoided and the good points of the centrifugal pump—particularly for high-head work—have been retained and improved upon.

ALLEN F. SHERZER,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer wishes to record his appreciation of the very intelligent discussion accorded his paper. An analysis of the response reveals two interesting facts. First, as might be expected, any attempt to question the logic and accuracy of the present pump theory was keenly resented by many readers and was often regarded as the height of presumption. On the other hand it was gratifying to note that many readers, while skeptical at first, began to apply the new theory to pumps of their own design with quite satisfactory results. It is believed that as time goes on others may feel inclined to adopt this method of analysis in principle at least. It should be regarded in the same light as other hydraulic investigations in that factors and coefficients from practice are essential, and these are modified by proportions and other features of the design. Knowledge of the flow over weirs, through orifices, and in channels rests on the same sort of foundation. There are many variables and they are difficult to separate.

The second feature of interest brought out by the discussion is that those who contributed to it are often quite unable to agree among themselves as to what is the correct theory for the centrifugal pump. Some maintain what they term "the old established theory" to be correct, others say its errors have been recognized long ago, and that it has been replaced by new theories. Some say the head at shut-off is $\frac{V_2^2}{g}$, others that it is equal to, or less than, $\frac{V_2^2}{2g}$. In general, it may be said that most of the facts claimed as correct by one contributor are denied by another, and the chief point in common is their disagreement with the writer. It is gratifying that nothing more serious than this was raised against the new theory.

In order to avoid useless repetition several of the points to which most frequent objection was taken will be singled out for special attention and discussed first. Following this, an attempt will be made to reply adequately to each discussion contributed.

The four points subject to most general criticism were: First, the question of adding the pressure and velocity heads in order to obtain the total head in the theory of the centrifugal pump; second, the question as to the correctness of Equations (*B*) and (*C*) as applied to the centrifugal pump; third, the logic of the three-orifice theory; and fourth, the application of the three-orifice theory to pumps having rising characteristics. These will be discussed in the order given.

The question of adding the pressure and velocity heads to obtain the total head supplied to the water in a centrifugal pump seems to have been the cause

* Associate Prof., Mech. Eng., Univ. of Michigan; Cons. Hydro-Mech. Engr., Ann Arbor, Mich.

of most of the objection to the new theory. The writer stated emphatically that it is incorrect to regard these two as separate and distinct amounts of energy in studying the action of a centrifugal pump. The pressure developed by such a pump is due, as the name implies, to centrifugal force; and that force is not, and never was, energy. It seems incredible that so many are apparently unable to distinguish correctly between force and work.

Another fact that seems to have escaped general attention is that the existence of pressure in an incompressible fluid like water does not at all imply the presence of energy. Consider, for example, a strong steel box entirely filled with water under a pressure of 100 lb. per sq. in. Neglecting the elasticity of the box and the compressibility of the water, this pressure, which has a definite existence, and can easily be measured, has no significance whatever as energy. Nothing useful can be done with it. If a small valve in the box is opened no water would flow, and the pressure would have disappeared.

Under some conditions pressure may be regarded as energy, but not always. Messrs. Blaisdell and Timoshenko both devote some space to this question, but conclude that in the pump theory it is correct to add the velocity head to the pressure head produced by it to get the total head given to the water. They submit diagrams purporting to show how this may be done. The main difficulty with their arguments is that the machines they describe are not centrifugal pumps as generally known. Their conclusions are perfectly correct for the machine they are considering, but not for the modern centrifugal pump.

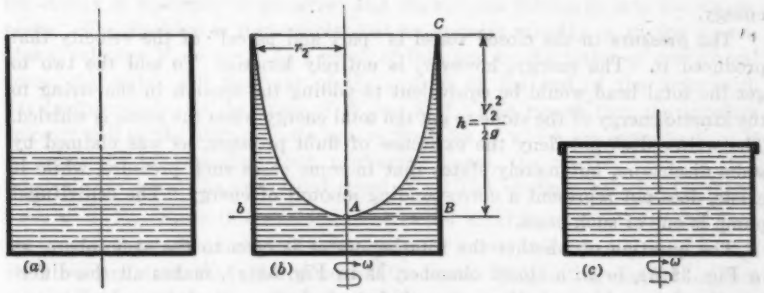

FIG. 38.

An illustration will make this clear. Assume a cylindrical tank free to rotate about its central axis and partly filled with water, as in Fig. 38 (*a*). If this vessel is set in rotation with an angular velocity, ω, the surface of the water, as is well known, will take on the shape of a paraboloid of revolution (see Fig. 38 (*b*)). At the center, (*A*), both the velocity and pressure are zero. Considering a pound of water at Point *C*, and with reference to a horizontal datum plane through Point *A*, it is clear that since *C* is revolving with a peripheral velocity, $V = \omega R$, a pound of water there possesses a kinetic energy, $\frac{V^2}{2g}$. It is also evident that this same pound of water is located $h = \frac{V^2}{2g}$ ft. above

the datum plane through Point A and hence possesses $h = \frac{V_2^2}{2g}$ ft-lb. of potential energy. The total energy is, therefore, the sum of the two, or $\frac{V_2^2}{g}$. The writer is in entire agreement with this result, but would venture to point out that this is not the way centrifugal pumps are built.

In Fig. 38 (c) the cylindrical tank has been cut off at the water-line and a tight-fitting cover has been placed so that the tank is entirely filled with water. Now, if this closed tank is set in rotation with an angular velocity, ω, as in Fig. 38 (b), conditions are found to be entirely changed. In the case of the closed vessel less work is done on the water than when the surface is open. The reason is simple since in starting from rest, work is done in accelerating the water just as a fly-wheel is brought up to speed; and, in addition, the water (Fig. 38 (b)) has been given potential energy. In the closed vessel (Fig. 38 (c)) the only work done is in bringing the mass of water up to speed since no change of level takes place. The pressure at the circumference of the closed vessel is $\frac{V_2^2}{2g}$, or exactly the same as at Point B of the open vessel; but in the former case the pressure has no significance as energy and no work is done to maintain it. In the latter case the pressure is a measure of the potential energy, $h = \frac{V_2^2}{2g}$, and work was done to give the water this energy.

The pressure in the closed vessel is "part and parcel" of the velocity that produced it. The energy, however, is entirely kinetic. To add the two to get the total head would be equivalent to adding the tension in the string to the kinetic energy of the stone to get the total energy when the stone is whirled. The writer does not deny the existence of fluid pressure, as was claimed by some discussors, but merely states that in some cases such pressure, while it exists, does not represent a corresponding amount of energy. The centrifugal pump is one of such cases.

The question of whether the rotating water is open to the atmosphere, as in Fig. 38(b), or in a closed chamber, as in Fig. 38(c), makes all the difference in the world as to the amount of work done on each pound of water. It will be easily seen that conditions in the centrifugal pump correspond to Fig. 38(c) and not to Fig. 38(b). A particle of water at the outer circumference (Fig. 38(c)) has both pressure and velocity heads, but its energy is only kinetic. To state in the general pump theory that conditions are as illustrated in Fig. 38(b) would be about the same as saying that in considering a particle of water below the surface of a lake the pressure due to its depth is added to the depth which produced the pressure to get the total head.

The second point to which considerable objection was made was the writer's statement that his Equations (B) and (C) were not applicable to the centrifugal pump. Several discussors have insisted that Equation (B) was the only one that could satisfactorily explain the performance of a centrifugal pump; others preferred Equation (C), or some simple modification of it. Some

remarked that the equations must be used by one who understands what they mean—the idea being that every one was not so qualified. Judging solely from these statements, the writer doubts whether any of those discussors have a clear conception of the actual meaning and physical significance of Equations (*B*) and (*C*). Equation (*B*), while correct in principle, at least for a turbine, can be eliminated at once from consideration as applied to a centrifugal pump. The reason for this is given on page 6 of the paper and may be found elsewhere in texts and works of reference. Equation (*C*), therefore, remains to be discussed.

Referring to Fig. 1 it is seen that,

$$C_2 \cos \alpha_2 = V_2 - W_2 \cos (180° - \beta_2) = V_2 + W_2 \cos \beta_2$$

Substituting this value of $C_2 \cos \alpha_2$ in Equation (*C*):

$$H = \frac{V_2^2}{g} - \frac{V_2 W_2}{g} \cos (180° - \beta_2) = \frac{V_2^2}{g} + \frac{V_2 W_2}{g} \cos \beta_2 \ldots\ldots (60)$$

This will be recognized as Equation (37) so often referred to in the discussion by Professor Harris. The writer prefers to take an indirect method of showing the real physical meaning of Equations (*C*) and (60).

Consider a machine which might be termed a mechanically driven lawn sprinkler, as shown in Fig. 39. This consists of two radial arms attached to a central pipe by which they may be revolved about the center of the pipe as an axis. The ends of the arms are plugged and an orifice is made in each, as shown. The pipe and arms are filled with water and provision is made for keeping up the supply at atmospheric pressure; and the streams discharge into the atmosphere. The machine is then revolved at an angular velocity, ω, giving a peripheral velocity, $V_2 = \omega r_2$. As a result of this, and by the action of centrifugal force, the water will flow out of the orifices at the end of the arms with a velocity relative to the arms of $W_2 = V_2$.* This means that the absolute velocity will be the diagonal of a square the sides of which are equal to V_2. It is important to remember that, neglecting losses, the relative velocity, W_2, must always equal the peripheral speed, V_2. The absolute velocity is, therefore, $\sqrt{2}\ V_2$. Since this machine receives the water at zero velocity and zero pressure at the center and gives to it ultimately a final velocity, ($C_2 = \sqrt{2}\ V_2$), it is evident that the work done on the water (neglecting losses) is that required to produce the absolute velocity, C_2, and its energy is entirely kinetic and equal to $\frac{C_2^2}{2g}$, or $\frac{(\sqrt{2}\ V_2)^2}{2g} = \frac{V_2^2}{g}$ for each pound of water.

Now, assume a more general case in which the arms are not radial, but are curved forward as in Fig. 39(*b*). The only change in this case is that, while $W_2 = V_2$ as before, it now leaves at a different angle relative to V_2. The absolute velocity, C_2, is the vector sum of (V_2) and ($W_2 = V_2$). The work done is $\frac{C_2^2}{2g}$ as before, for each pound of water. By trigonometry,

$$C_2^2 = V_2^2 + W_2^2 - 2\ V_2\ W_2 \cos (180° - \beta_2)$$

or,

$$C_2^2 = V_2^2 + W_2^2 + 2\ V_2\ W_2 \cos \beta_2$$

* For proof, see p. 24.

The total head given to each pound of water is $\frac{C_2^2}{2g}$; hence,

$$H = \frac{C_2^2}{2g} = \frac{V_2^2 + W_2^2 + 2\,V_2\,W_2 \cos\beta_2}{2g}$$

By the conditions of the problem, W_2 must always be equal to V_2. Hence,

$$H = \frac{C_2^2}{2g} = \frac{2\,V_2^2 + 2\,V_2\,W_2\cos\beta_2}{2g} = \frac{V_2^2 + V_2\,W_2\cos\beta_2}{g}$$

This will be recognized as the transformed Equation (C), or Equation (37), as given by Professor Harris.

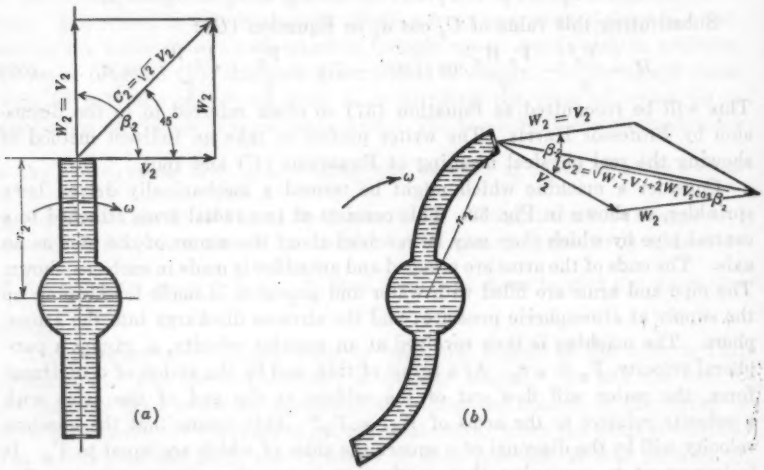

FIG. 39.

It should now be clear as to just what kind of machine these equations apply. It is certainly not a modern centrifugal pump; it resembles more a lawn sprinkler mechanically driven. Equations (C) and (60) apply only to such machines as have all their energy in the kinetic form at the point of discharge from the wheel. The theory of its operation is based on the assumption that the water is discharged against only atmospheric pressure. As neither of these conditions are even remotely realized in the centrifugal pump, it is not unreasonable to suspect that this difference in the assumptions might be the cause of the generally observed discrepancy between the ordinary theory and the actual performance of a pump.

At this point another error has come into the generally accepted pump theory and equations. It is well known that the quantity is a function of the head for a centrifugal pump at constant speed. Most texts attempt to prove this by reference to Equation (60), as follows: By the law of continuity of flow, $W_2 = \frac{Q}{A_2}$, in which, A_2 is the total area of the impeller perpendicular

to W_2. By substituting this value in Equation (60) the result is:

$$H = \frac{V_2^2}{g} + \frac{V_2 \cos \beta_2 \, Q}{g \, A_2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (61)$$

This is the usual straight-line equation so often seen in texts and generally mentioned as the ideal quantity head curve. The error here lies in the fact that, while $W_2 = \frac{Q}{A_2}$, W_2 is fixed by the conditions of the problem as always equal to V_2, and since A_2 is fixed by the design of the pump, it cannot be a variable and the whole equation is meaningless. In fact, it can be easily seen that with such a machine running at constant speed the flow would be a definite and fixed amount, and nothing but a change of speed could alter it. It is now evident that all these familiar straight-line curves are based on the same fallacy. It is small wonder that no better agreement has been obtained. Equations (*C*) and (60) are merely different expressions for the kinetic energy of the water discharged from the arms of such a machine as is shown in Fig. 39(*a*) and (*b*), but this simple relationship does not appear to be generally known. The present pump theory seems to be almost perfectly applicable to what might be called a kinetic pump the object of which is to give only kinetic energy to water. To make this clear it will be noted from Equation (60) that if $\beta_2 = 90°$, $H = \frac{V_2^2}{g}$; if $\beta_2 = 0°$, $H = \frac{2\,V_2^2}{g}$; and if $\beta_2 = 180°$, $H = 0$. All these results have been recently verified by tests on such a kinetic pump which demonstrates beyond any doubt the real meaning of those equations.*

The three-orifice theory has been the subject of much of the adverse criticism of the paper, largely, the writer believes, due to misunderstanding. Every centrifugal pump designer appreciates very well that the greater part of his calculations center about these three points and that almost the entire performance of a pump is determined by its proportions at these places.

The usual theory as well as those modified ones suggested in the discussion are invariably weak in that no attempt has been made to take any account of the action of the case in determining the pump characteristic. Any designer knows that a change in what the writer terms Orifice No. 3 (Fig. 8), will completely alter the performance of an impeller. This fact has been given little if any attention in the various opinions presented in the discussion. The effect of a change in the area of Orifice No. 3 is shown graphically by a comparison between Curves *A* and *B* in Fig. 40. This was obtained from an actual test of an impeller in two casings in which the area of Orifice No. 3 was varied. The writer fails to see how Equations (*B*) or (*C*), or Professor Harris' Equation (37), would explain this fact. It is well known to most designers that a change in Orifice No. 3 has two distinct effects: First, a change in the shut-off head; and, second, a change in the slope of the pump characteristic. To study the effect of the area on the slope of the curve the two have been adjusted so as to have the same shut-off head as in Curves *A* and *C*. It is easily seen that the smaller orifice, No. 3, gives the steeper curve, which is just as might be expected and in perfect agreement with the writer's theory. In other words,

* For test results covering this point see p. 98 *et seq.*

if it is small, a greater fall in pressure is necessary to obtain a given quantity of water through Orifice No. 3 than if it is large. The other effect in determining the shut-off head must be gained largely from experience and, while it might be liable to cause trouble for a beginner, any experienced pump designer would have sufficient data at hand to estimate this quite accurately. Beyond this point the theory given in the paper will apply.

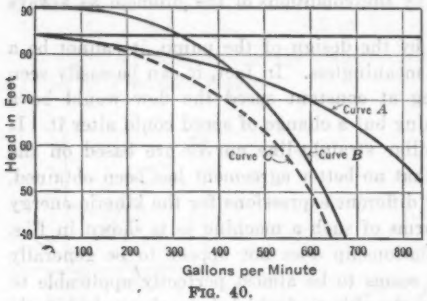

FIG. 40.

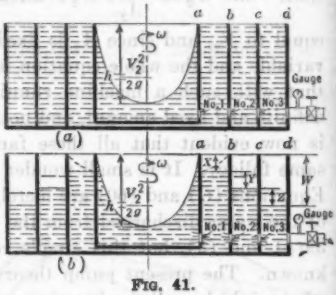

FIG. 41.

To make this clear, assume a machine, as shown in Fig. 41(*a*), which is the familiar rotating water paraboloid, Fig. 38(*b*), except that a hole has been made in the side (*a*) of the tank at the level of the vertex of the parabola (Orifice No. 1). Next, assume a stationary cylinder, (*b*), in Fig. 41(*a*), containing water, to be placed concentrically with the rotating cylinder, (*a*). If the water levels in Cylinders (*a*) and (*b*) are the same, no water will flow from Cylinder (*a*) to Cylinder (*b*) since the pressures on either side of Orifice No. 1 are equal and of an amount, $h = \frac{V_2^2}{2g}$. Next, assume a second stationary cylinder, (*c*), (Fig. 41(*a*)), to be placed as shown and a hole made in the side of the tank, (*b*), to form Orifice No. 2. If the water level in Cylinder (*c*) is that of Cylinders (*a*) and (*b*), no water will flow through Orifice No. 2. If a third stationary cylinder, (*d*), in Fig. 41(*a*), is provided and filled to the same level as Cylinders (*a*), (*b*), and (*c*), no water will flow from Orifice No. 3. Now, if a pipe with a valve is provided, as shown in Cylinder (*d*), and the pipe either leads to the atmosphere or some point where the pressure is less than $\frac{V_2^2}{2g}$, water will flow from Tank (*d*). This means that the level will fall in Tank (*d*) and water will flow in from Tank (*c*) through Orifice No. 3. This, in turn, will cause a drop in level in Tank (*c*) and water will flow through Orifice No. 2. Again, this will cause a drop in the level in Tank (*b*) and water will flow in from Tank (*a*) through Orifice No. 1. Of course, it is assumed that the water in Tanks (*b*), (*c*), and (*d*) is stationary and only Tank (*a*) revolves; also, that water is added to Tank (*a*) to make up for that discharged from Tank (*d*).

Fig. 41(*b*) shows the water levels in the tanks when flow is taking place. The drop to cause flow from Orifice No. 1 is shown at *X*, through Orifice No.

2 at Y and through Orifice No. 3 at Z. The total drop in pressure to cause flow through the pump is W, which is the sum of X, Y, and Z. As in the case of a centrifugal pump, the quantity of water allowed to flow is controlled by the discharge valve from Tank (d). When this valve is closed the tanks fill up to the level, $h = \frac{V_2^2}{2g}$, and this is the shut-off condition or point of no delivery. Then, if the discharge valve is opened a little some water will flow and the levels in Tanks (b), (c), and (d) will adjust themselves accordingly. The amount of the drop in level between the tanks is controlled largely by the area of the three orifices. The level in Tank (a) is, of course, always constant since it revolves at constant speed. If it were desired to express the relation between the flow of water through this pump and the reading of a pressure gauge located in the discharge line from Tank (d), that is, to draw the Q-H-curve of the pump—as it is usually called—the procedure would be as follows: When no water is discharged, the pressure gauge would read $h = \frac{V_2^2}{2g}$, and this may be represented by a horizontal line in Fig. 42. Next, draw the curves for the orifices as shown. Then add these together and obtain the combined curve. Next, subtract this curve graphically from the horizontal line, $H = \frac{V_2^2}{2g}$, and obtain the Q-H-curve for the pump. It should now be evident that this, in principle at least, is exactly what is taking place in a centrifugal pump although the details of design and construction may be different.

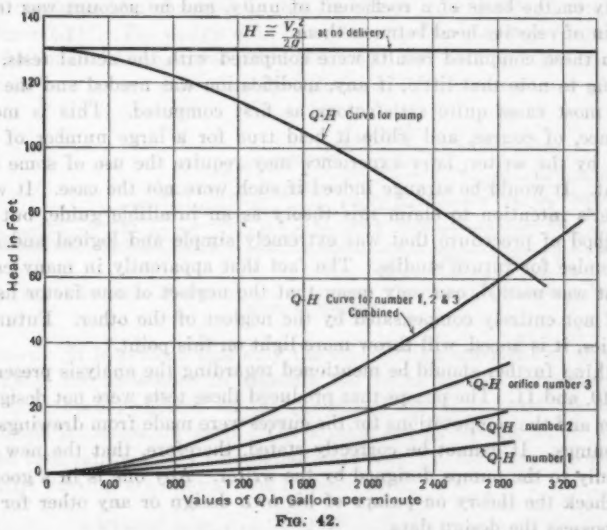

FIG. 42.

A closer approach to actual similarity would be to consider that the water in Tank (b) might be set in revolution by the dragging friction with Tank

(*a*), as well as by the jet-like action of the absolute velocity of the water flowing from Orifice No. 1. This would cause the surface in Tank (*b*) to be as shown in dotted lines in Fig. 41(*b*), and would have the effect of increasing the height of the shut-off head, thereby raising all points of the curve. This is often noticed in actual pumps. In fact, as several discussors pointed out, most of the better pumps exhibit this to a greater or less degree, and shut-off heads exceeding $\frac{V^2}{2g}$ are often obtained. This shows the elementary action of a centrifugal pump and that the shape of the final curve is determined to a large extent by the dimensions of the three orifices. No higher mathematics is needed and the result agrees well with practice, after a few simple coefficients are obtained.

One matter of criticism for which the writer must accept responsibility was his failure to explain fully the apparent neglect of velocity of approach in determining the drop through the three orifices. This was by no means ignored, but the full reasoning was not given. Having accepted the three-orifice theory as a matter of principle it was realized that the flow through any orifice is governed, among other things, by a coefficient of discharge. The difficulties in determining this coefficient for each of these orifices separately were obviously too great to hold out much hope for success. It was decided, therefore, to determine a blanket factor or coefficient by which to multiply the combined discharge of the three to bring the computed results into agreement with actual tests. Accordingly, the drop was computed for each orifice separately on the basis of a coefficient of unity, and no account was taken of the regain of velocity head between them.

When these computed results were compared with the actual tests, it was interesting to note that little, if any, modification was needed and the results were in most cases quite satisfactory as first computed. This is merely a coincidence, of course, and while it held true for a large number of pumps analyzed by the writer, later experience may require the use of some sort of coefficient. It would be strange indeed if such were not the case. It was not the writer's intention to claim this theory as an infallible guide, but rather as a method of procedure that was extremely simple and logical and showed great promise for future studies. The fact that apparently in many cases no coefficient was needed, can only mean that the neglect of one factor has been nearly if not entirely compensated by the neglect of the other. Future tests and studies, it is hoped, will throw more light on this point.

One thing further should be mentioned regarding the analysis presented in Figs. 9, 10, and 11. The pumps that produced these tests were not designed by the writer and the computations for the curves were made from drawings of the several pumps. It cannot be correctly stated, therefore, that the new theory applies only to the pumps designed by the writer. Any one is in a good position to check the theory on pumps of his own design or any other for which he may possess the design data.

It was claimed by several discussors that the new theory failed to account for pumps having a rising characteristic. This is not the case; but the claim

is possibly valid since such an analysis was not worked out in detail, being merely alluded to in the paper. Under the heading, "Effects of Casing", the writer mentions that the jet-like action of the water discharged from the impeller assists the general rotation of the water in the pump-case and thereby in some cases increases the head developed by the pump.

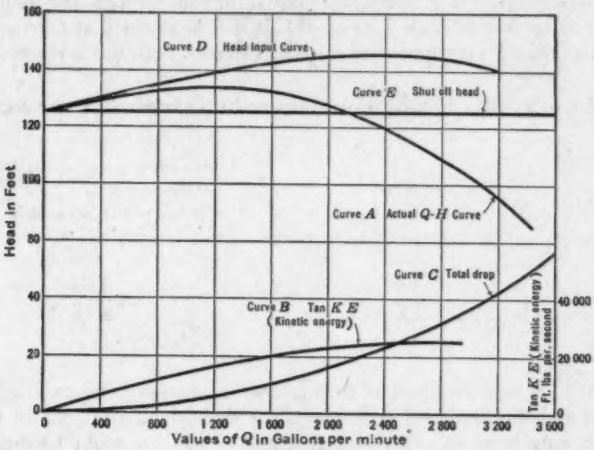

FIG. 43.

The characteristic obtained by test is shown in Fig. 43 marked "Actual Q-H-Curve (A)". The design data being known, the discharge diagrams were drawn for rates of discharge of 800, 1 600, 2 400, and 3 200 gal. per min. These are shown in Fig. 44. The absolute velocities, C_2, for these rates of flow are

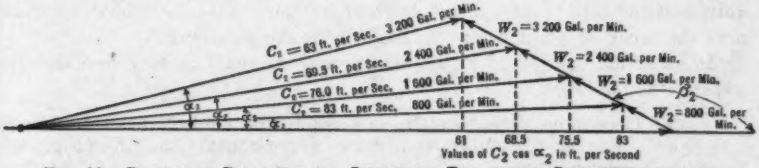

FIG. 44.—DISCHARGE DIAGRAMS FOR COMPUTING TANGENTIAL COMPONENT OF THE KINETIC ENERGY.

also shown. It is evident that only the tangential component of this velocity is available for assistance in rotating the water in the pump-case. These values have been projected on the peripheral speed, V_2, and the tangential components indicated for each. The kinetic energy of this water discharged into the case can be easily calculated since both the mass per second and the tangential velocity are known—the formula being,

$$\text{Kinetic energy} = \frac{1}{2} M V^2 = \frac{\gamma Q}{2g} (C_2 \cos \alpha_2)^2$$

The computations are arranged for clearness in Table 3.

Curve *B* (Fig. 43), represents the tangential kinetic energy as a function of the rate of flow through the pump. The total drop through the three orifices is shown combined in Curve *C*. If Curve *C* is added graphically to the Test Curve *A*, for purposes of analysis, Curve *D* is obtained. This represents the total head input to the water passing through the pump as a function of the rate of discharge. If a horizontal line is drawn through the shut-off head determined by test as Line *E* (Fig. 43), it will be noted that Curve *D* is in a relation to Line *E* very much the same as Curve *B* is to the horizontal axis.

TABLE 3.—KINETIC ENERGY COMPUTED FROM TANGENTIAL COMPONENT OF C_2.

Gallons per minute.	C_2, in feet per second.	Kinetic energy computed from tangential component of $C_2 = \frac{\gamma Q (C_2 \cos a)^2}{2g}$, in foot-pounds per second.
0	90.5	0
800	83.0	11 930
1 600	75.5	17 750
2 400	68.5	24 400
3 200	61.0	25 700

All that is now required is to establish a relation between the values of Curve *B* and the increased head above the shut-off point shown in Curve *D*. This can only be done experimentally, and it will no doubt be different for various designs and proportions. The writer has found from the analysis of a large number of such pumps that, for the ordinary pump and over most of the range of the characteristic, for every 1 000 ft-lb. per sec. of tangential kinetic energy, the head is increased about 0.8 ft. This varies somewhat and it is best that each designer determine such a value for himself, based on his usual designs and proportions. In the absence of such data 0.8 ft. will prove quite satisfactory. This will not hold, of course, for the section of the curve near the break-off point where the capacity is the maximum.

In an actual analysis of a pump the procedure would be very similar. The steps are as follows:

(1) Determine as accurately as possible the shut-off head (either by test or formula) and draw a horizontal line, *E* (Fig. 43), through it.
(2) Compute and plot Curve *B*.
(3) Apply the suggested coefficient of 0.80 per 1 000 ft-lb. per sec. to the values of Curve *B* and plot it above Line *E* as feet of head. This gives Curve *D*, or the total head curve.
(4) Calculate and plot Curve *C* showing the total drop through the three orifices given in the paper (page 18).
(5) Subtract Curve *C* from Curve *D* graphically and obtain Curve *A*, the approximate characteristic curve.

This is a very simple and direct method which the writer has used successfully for some time. Its accuracy rests entirely on the correct selection of the factor converting tangential kinetic energy into head. After a few such analyses are made, any one is in a position to determine that factor for himself.

It is not by any means constant over a single characteristic and, of course, varies in different designs. Pumps of unusual proportions will require special coefficients. One great advantage of this method is that it enables a designer to predict in advance whether a pump will have a rising, flat, or steep characteristic. It is easy to see that if the values of Curve C are greater than those of Curve D above Line E, then a falling characteristic will be obtained.

Referring to the point of no delivery, pumps which ordinarily have a flat or falling characteristic may appear to having a rising one on some tests because of the presence of air in the water or a slight leakage of air through the stuffing-box or suction line. This is due to the depression of the head at that point. Of course, the foregoing analysis will not fit such tests. Care should be taken to make sure that a reliable characteristic is obtained when accurate comparisons are desired. An error in the head of no delivery will be reflected in all the other values to the same degree. In many cases the tangential kinetic energy is so small that little if any effect is noticed, and it is sufficiently accurate to deduct Curve C directly from Line E. This was the case for the pumps analyzed in the paper and is perhaps the situation most frequently encountered.

Mr. MacMeeken attaches great importance to Equation (B) stating that it is the only one that can properly explain the action of a centrifugal pump. He further points out that no element must be omitted; but neglects to explain how the term, $C_1 V_1 \cos \alpha_1$, is obtained and this is the question that has given almost universal difficulty. Most other authorities disagree with him in preferring Equation (B) to Equation (C). Other discussors have denied the correctness of either. The writer has made inquiries regarding the special pumps mentioned which gave heads approximating $\frac{V_2^2}{g}$. From such information as was obtained it would appear that these were not centrifugal pumps at all, but were of the rotary type.

Mr. MacMeeken mentions the accepted and proved theory, which raises the point as to who accepts it and how it was proved. The statement that the writer's design will always require a larger impeller than a volute pump of good design is in direct contradiction to the data presented. Reference to Fig. 16 will clearly show the greater head developed by the circular case-pump compared with a good volute pump. Both impellers are of the same diameter and run at the same rotative speed. It is well known that volute pumps may develop greater heads than $\frac{V_2^2}{2\,g}$ and the same is true of circular case-pumps to an even greater degree.

Mr. MacMeeken's objection to Fig. 4(b) indicates a lack of understanding of the reasoning. The total power required to drive the pump may be divided into two parts, one to give energy to the water and the other to overcome the various losses in the pump (mechanical and otherwise). The total losses were determined by test as approximately 3.75 h.p., which left 1.25 h.p. as the energy given to the water. The sum of the two was 5.00 h.p., which was found by test to be required to drive the pump at a discharge of 50 gal. per min.

The 1.25 h.p. was found to be just what was required to lift 50 gal. per min. to the head of 100 ft. and this was checked by an actual test. This indicates a hydraulic efficiency of about 100% for small rates of flow. As a matter of fact it could not be otherwise. Assume, for example, that Mr. MacMeeken was correct and that the efficiency was less than 100% (say, 60 per cent.). Then, there would arise the interesting situation of putting into the water 0.60×1.25 h.p. $= 0.75$ h.p., and actually getting out 1.25 h.p. in useful work. This would be better than perpetual motion. When little or no water flows there are no great losses of energy and the hydraulic efficiency is nearly 100 per cent. Mr. MacMeeken states that, on the contrary, the losses will be very great. A few simple tests should show his error. The writer agrees with the transformation of Equation (B), but does not believe that,

$$\frac{C_2^2 - C_1^2}{2g} = \frac{W_2^2 - W_1^2}{2g}$$

Even if that relation is correct the situation is no better than before. The ratio of the dimension, A to C, as mentioned, affects the shut-off head which has been already considered.

Mr. MacMeeken claims that the so-called commercial efficiency of pumps mentioned in the paper is 77 per cent. The efficiency of 60% as given was determined by taking the average of ten quotations submitted by leading pump manufacturers, including the company with which Mr. MacMeeken was associated. This was the best information obtainable at the time the paper was written. However, no quotation as high as 77% was received.

It is true, that the circular case is not new as emphasized in the paper. Mr. MacMeeken's statement that the volute is superior to the circular case is contrary to easily proved facts. In the case of the multi-stage designs there were other reasons for the difference.

It is gratifying to learn that Mr. Kingsford applied the new theory to his own pumps with such success. It should be stated that the relative efficiencies of the two pumps compared in Fig. 16 were about the same. This is due to the fact that the head for the circular case-pump was more than 100 ft. greater than for the volute pump. When the circular case-pump impeller was reduced so as to give the same head as the volute pump, there were about five points of efficiency in favor of the circular-case design.

Mr. Moss raises the question as to who is qualified to pass on the meaning of the fundamental pump equations. From the discussion it is evident that he is one of the few who still believe in them. Most of the others believe that to be of any use at all they require considerable modification. Mr. Moss feels that not enough detailed equations are given in the paper. The fact is that none is needed except those that were given. The writer considers this simplicity rather an advantage than otherwise. Whatever else may be said about the theory it is certainly new and not at all similar to any found in current texts. The paper was not intended to go into matters of design, except in a very general way. Only the question of theory was involved. For this reason, no detailed design data were considered necessary.

Captain Reed states the generally known fact that the ordinary accepted theories for the centrifugal pump do not even come close to agreeing with observed test results. His explanation is typical of that now given great prominence abroad, to the effect that it is due to the difference between the actual angle of discharge and that obtained from the ordinary diagrams. While the writer does not doubt that there may be some slight difference, it is almost impossible to imagine any such difference as would bring about agreement. The writer suggests that Captain Reed try such a calculation once and see what the difference would have to be. This is only one of a number of straws that have been snatched at in an effort to save the present theory.

Mr. Munk registers his belief in what he terms the "old established blower theory." Contrary to his statement the writer has not denied the existence of fluid pressure, and is perfectly aware that velocity and pressure may and usually do exist independently in a fluid. What the writer did say was that the pressure in the pump-case is not a separate and distinct amount of energy from the velocity which produced it and that pressure is not energy any more than force is work, when applied to an incompressible fluid like water. The writer never claimed the maximum pressure to be $\frac{V_2^2}{2g}$ for centrifugal pumps; all those described in the paper develop heads exceeding that amount. The reason for the amount, $\frac{V_2^2}{2g}$, is that in most of the current texts such a value is given for the head developed at shut-off. In many cases it agrees fairly well with practice, but there are, of course, exceptions.

In replying to Professor Harris it will be convenient to take each paragraph separately. The answer to Item (*a*) is a matter of opinion. Some of the recent writings are after all not so different from those of twenty-five years ago. To be more specific Equation (37) which Professor Harris claims for his own has been in existence even longer.

In Item (*b*) the writer feels that Professor Harris has greatly magnified the difficulties encountered in the ordinary application of Bernoulli's theorem.

Item (*c*) is "hair-splitting" and affects the amount, but not the principle.

Item (*d*) again involves the old question: "Is the head at shut-off $\frac{V_2^2}{g}$, or $\frac{V_2^2}{2g}$?" Professor Harris claims $\frac{V_2^2}{g}$, which opinion is shared by some discussors and denied by others. The writer maintains that no such head, regarded as energy, was ever present nor can it in any manner be utilized.

Item (*g*) is badly confused and the writer cannot see its bearing on the question. Such a discovery would surprise the writer fully as much as it did Professor Harris.

In Item (*h*) the fact as he states it is true, but his conclusions are far from correct as explained under Item (*j*). Neither Equation (37) nor the other data for which he asks, would be of any great help.

As to Item (*i*) the writer did not state that the jet had to have a greater velocity than the paddles although it would have, of course, in the case of radial or forward curved vanes.

In Item (*j*) Professor Harris assumes the rôle of a prophet and speculates on the probable values of the design angles, etc. While not wishing to go into the complete design data the writer can say that not a single guess was correct. Furthermore, the writer has done as Professor Harris suggested, and has tested the pump with forward curved vanes. The efficiency was not below 50%, as Professor Harris claims, but a value well above that. His Equation (37), as given, is the equivalent of Equation (*C*) and does not apply to a centrifugal pump at all. This equation is old and has been commonly used by many writers. Professor Harris gives a method of separating and analyzing the losses in a pump and suggests that it may enlighten designers who are trying to improve the efficiency of their pumps. It is not difficult to understand why designers have not made more use of his method. Professor Harris states that $F = D - Q\,H$ and then that $H_1 = \frac{F}{Q}$, in which, D is the dynamometer input to the pump, F is the energy dissipated in the pump, Q is the discharge, and H is the head developed by the pump. H_1 is said to be the head lost between intake and discharge. This is impossible since in his reasoning he has assumed that all the losses in the pump are of a hydraulic nature. He seems to have completely forgotten that mechanical losses such as bearing friction, stuffing-box friction, and disk friction of the impeller form the bulk of all the losses.

Mr. Gruenberger wonders why only the sum of the three given velocity heads should be used, and further suggests that if another were added the result would be different. The writer knows only three points of control in the pump and hence the three velocity heads. As to the shut-off heads in Figs. 9, 10, and 11, these were obtained by test.

Many of the points in the discussion of Professor Hooper are exceedingly well taken. The head he mentions, registered by a piezometer, measures merely a force and does not represent energy separate and distinct from the velocity which produced it. One is the measure of the other. Centrifugal force is not energy in itself, but it may serve to measure and indicate the presence of kinetic energy.

The discussion by Professor Mavis is of interest as it gives data obtained in various hydraulic laboratories in Europe. The data in Table 1 impress one as being rather too academic. In quite a number of years' experience as a pump designer the writer has never found any such difference in performance, due to a variation in the number of vanes, as these data would imply. He also disagrees with the fundamental assumptions on which the computations were made. A theory based on an infinite number of vanes is not rational and is not at all necessary in order to explain the present theory. It is used on the incorrect assumption that complete guidance of the water could not be obtained with any finite number.

Professor Medici supports the writer's claims as to the fallacies of the theories found in most of the modern texts. Professor A. Stodola is also said to agree with Professor Medici that the head at shut-off is $\frac{V_2^2}{2g}$ and not $\frac{V_2^2}{g}$. This, again, adds to the conflict of opinions expressed in the discussion. The writer does not feel that Fig. 19 in any way explains a rising characteristic accounted for by his new theory. His views on the effect of the vane angle, β_2, on the pump characteristic apply only to an impeller discharging into air and without a case. Under such conditions the question is merely one of simple trigonometry, and any one can verify it for himself. In such cases the results of the angles, β_2, equal to 60° and 120°, would not be at all the same, as claimed by Professor Medici. Construction of the vector diagrams will show this. The criticism of Fig. 16 is based on a misunderstanding. The writer did not claim that the head at shut-off was always $\frac{V_2^2}{2g}$. In fact, he showed that under certain conditions heads much higher than $\frac{V_2^2}{2g}$ were easily obtained. Fig. 16 was for the purpose of showing that the circular-case pumps were capable of greater heads for the same value of V_2 than the ordinary volute pump. The writer does not believe that the various assumptions of vane pressure, recirculation, etc., given by Professor Medici, are sufficient to explain the observed differences. They all involve a loss of energy while accurate tests will readily show that no such loss has taken place.

Professor Blaisdell goes on record as believing the head developed to be $\frac{V_2^2}{g}$ rather than $\frac{V_2^2}{2g}$ and gives an illustration to prove his point. The illustration and his reasoning are both correct, but it is easily perceived that the machine he describes is not a centrifugal pump. The variation in the angle, β_2, emphasized by Professor Blaisdell has been mentioned by others, but a few simple computations will show it to be entirely inadequate to explain errors as large as almost 100 per cent.

Professor O'Brien's discussion is of interest, but does not apply directly to a centrifugal pump. His criticism that the writer neglected to consider the stretching of the wire is not well taken so far as pumps are concerned, because the water is assumed usually to be incompressible.

The discussion of Mr. Donnell contains some unusual statements which the writer is quite unable to follow or accept. For example, he states that,

"The pressure of any part of a body of rotating liquid is not due to its velocity; it would be possible to destroy its velocity and still have the pressure remaining exactly the same as before."

Certainly a liquid cannot rotate without having velocity, and if it does not rotate it has no pressure unless exerted by some other agency.

The writer is indebted to Dr. Timoshenko for a very clear and concise statement of the points of difference. He makes use of two illustrations

to prove that the pressure head and velocity head may be added to give the total head, and his reasoning is correct. He has simply made the old error of assuming that he was describing the usual form of centrifugal pump. In Dr. Timoshenko's illustrative example of the ball moving radially in a groove, (Fig. 34), he calls attention to the increase in the time of action due to the opposing force. The writer does not agree that time of action has anything to do with the work accomplished, since work is merely force times distance and time is not considered. Dr. Timoshenko develops a case in which the total head may very properly be regarded as $\frac{V_2^2}{g}$. He then considers the question of the water flowing radially in the groove opposed by the back pressure of the water in the surrounding case, and concludes that the work done on each pound of water will be exactly the same as before. That this view is not correct can be proved easily by carefully made tests.

Consider an example, as shown in Fig. 45, consisting of a radial piece of pipe so arranged as to revolve about a center at O, with an angular velocity, ω. The outer end of the pipe is plugged and a hole is made in the plug through which water may flow. The pipe is now filled with water and rotated about a center, O, as shown. Assuming a source of supply at atmospheric pressure at the center, water will flow continually through the orifice at the end with a relative velocity, W_2, equal to the peripheral speed, V_2. Thus, the absolute velocity is $\sqrt{2}\ V_2$ and the kinetic energy per pound of water is $\frac{V_2^2}{g}$. This is substantially what Dr. Timoshenko has claimed, and the writer agrees with him in its correctness. It has also been confirmed by tests, as will be shown later. (See page 98, *et seq.*)

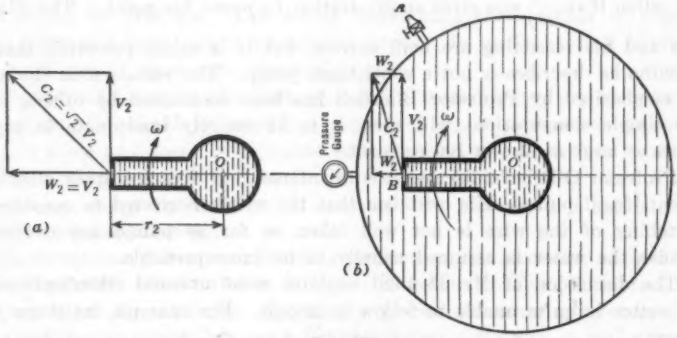

FIG. 45.

Now, assume that the same whirling radial piece of pipe (Fig. 45(a)) is mounted in a concentric circular casing which completely encloses it (Fig. 45(b)). This enclosing case is provided with an outlet through which the discharge may be regulated, as at A. Assume, further, that the entire case and radial piece of pipe are filled with water and that the pressure at the center, O, is atmospheric; also, that the valve at A is closed. The water

in the radial whirling pipe under centrifugal force will try to move out from the center and flow through the orifice at B. However, the space outside is completely filled and, since water is practically incompressible, no flow can take place. Its desire to get out will be communicated to all the particles outside in the case and will appear as a static pressure equal to $\frac{V_2^2}{2g}$ if the water in the case does not rotate with the revolving radial pipe.

A drop of water at Orifice B (Fig. 45(b)) has only a kinetic energy $= \frac{V_2^2}{2g}$ per lb., and that is the only work done on it by the motor which drives the revolving pipe. This work was done during the acceleration period and after it is once up to speed no further work is required except to overcome the various mechanical losses. It is easily seen that the velocity and pressure are (as was stated) "part and parcel" of each other. Either may be regarded as a measure of the energy, but not both. The pressure exists because of the velocity and depends on it. Were there no velocity there would be no pressure (Mr. Donnell to the contrary notwithstanding.)

Now, if the valve at A is opened a little some water will flow out. The pressure in the case will be reduced, and since the back pressure which, before the valve was opened, was just equal and opposite to the head developed by centrifugal force tending to produce flow, is now reduced, water will flow out through Orifice B to replace that flowing at Orifice A. The relative velocity at Orifice B will be due to the difference between the centrifugal head, $\frac{V_2^2}{2g}$, and the back pressure in the case. It will be small if the pressure difference is small and will approach a value, $W_2 = V_2$, if the back pressure is atmospheric. This means that, for all cases of back pressure in this casing, the relative velocity, W_2, will be less than V_2, as shown in Fig. 45(b).

The work done on each pound of water passing through this machine is measured solely by the amount of kinetic energy in the absolute velocity of discharge, C_2. (This is not in agreement with Dr. Timoshenko.) The energy of the water is zero when it enters, and $\frac{C_2^2}{2g}$ when it leaves, the orifice, B; hence the work done is $\frac{C_2^2}{2g}$ for each pound. Fig. 46 (a) shows how the back pressure in the case affects the absolute velocity, C_2, and hence the work done. C_2 (maximum) $= \sqrt{2}\, V_2$ is obtained with zero pressure in the case, and C_2 (minimum) $= \frac{V_2^2}{2g}$ occurs when practically no flow takes place and the pressure in the case is $\frac{V_2^2}{2g}$. This explains why the shut-off head is only $\frac{V_2^2}{2_1 g}$ and not $\frac{V_2^2}{g}$.

The situation may be compared to that shown in Fig. 46(*b*) and (*c*). If the water level is the same in each tank (Fig. 46(*b*)), no flow will take place and practically no work would be required to get a particle of water from one tank to the other. However, in Fig. 46(*c*) the levels are not the same and, hence, flow will occur due to the head, h, as shown. In case a water motor or pump were located in the connecting pipe (Fig. 46(*c*)), power would be obtained from the head, h, or work would have to be done against only that head to get water from the lower to the higher tank. This fact is important. In each case the work done can be calculated by determining the relative velocity, W_2, due to the pressure difference and combining this with the peripheral velocity, V_2, as a vector to obtain the absolute velocity, C_2.

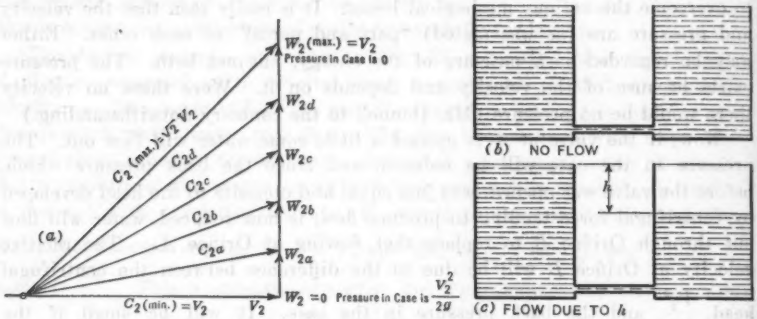

FIG. 46.—EFFECT OF BACK PRESSURE IN FIG. 45(*b*) ON THE RELATIVE AND ABSOLUTE VELOCITIES.

Dr. Timoshenko would say that the work done is always the same and is equal to $\frac{V_2^2}{g}$ no matter what the pressure and hence no matter what the absolute velocity. His idea is that the work done is divided into two parts one to produce the absolute velocity, C_2, and the other to get the water out into the case against the back pressure. Fig. 46(*c*) should make clear this fallacy because, if there is a level difference as shown, flow will take place without any additional expenditure of work. It is difficult to understand how Dr. Timoshenko's claim could be sound mechanically even if it were hydraulically correct for the reason that if the water is to do work against the back pressure in the case the direction of this force must be radial and balanced all around. Since such a force could have no tangential component, it is difficult to understand how it could possibly affect the turning of the wheel which is the only way power could be consumed.

The problem was so clear cut that it was decided to try an experiment which would settle the question absolutely. For this purpose an apparatus similar to that of Fig. 43(*b*) was made up, as shown in Fig. 47. It consisted of a piece of 2-in. pipe to which were connected the two radial arms shown. The pipe passed through stuffing-boxes in each side. It also continued on one

side into an open tank containing water and on the other was connected to a small electric dynamometer. The supply of water to the open tank was arranged so that the water level was maintained a few inches above the opening through which the 2-in. pipe entered. The box was air-tight and was provided with a discharge valve in the bottom and a pipe leading to the compressed air tank at the top. A gauge was also provided to record the pressure in the box.

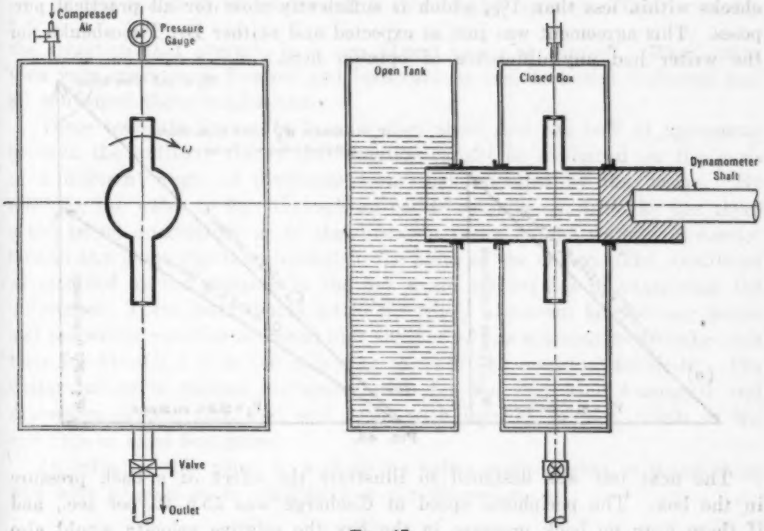

FIG. 47.

It was possible to maintain any desired constant pressure in the box by regulation of the air inlet valve on top and the water discharge valve below. The dynamometer was allowed to run without water in the rotating arms and the "no-load" reading was taken. This consisted of a slight amount of stuffing-box friction and windage. Then water was allowed to flow into the 2-in. pipe and out through the arms. The power required to drive the machine was then observed and corrected for no-load losses. The pressure (if any) was maintained constant during each test. The quantity of water discharged was determined by weighing on an accurately calibrated scale. In this way tests could be made either with atmospheric pressure in the box or higher as desired.

The first tests were made at atmospheric pressure. The final results checked almost exactly with what would be expected under such conditions. The peripheral speed of the end of the rotating arms was 81 ft. per sec. This was found by observing the radius and the rotative speed. According to theory the relative velocity, (W_2), of the water discharged from the orifice should be the same as V_2, or 81 ft. per sec. The absolute velocity would be

$\sqrt{2}\ V_2 = \sqrt{2} \times 81 = 114.5$ ft. per sec., as shown in Fig. 48 (*a*). The head per pound of water would be,

$$\frac{C_2^2}{2g} = \frac{(\sqrt{2}\ V_2)^2}{2g} = \frac{V_2^2}{g} = \frac{81^2}{32.2} = 204 \text{ ft.}$$

The quantity of water discharged was 22.45 gal. per min. The power required to raise 22.45 gal. per min. to a height of 204 ft., would be 1.156 h.p. The power actually measured by the dynamometer was 1.142 h.p. This checks within less than 1%, which is sufficiently close for all practical purposes. This agreement was just as expected and neither Dr. Timoshenko nor the writer had any difference of opinion here.

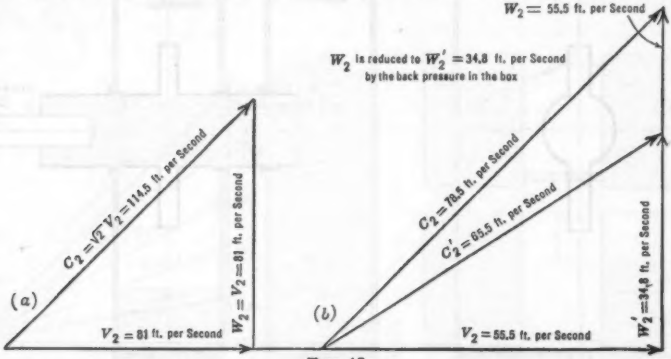

FIG. 48.

The next test was designed to illustrate the effect of a back pressure in the box. The peripheral speed at discharge was 55.5 ft. per sec., and if there were no back pressure in the box the relative velocity would also be 55.5 ft. per sec., and the absolute velocity 78.5 ft. per sec., as shown in Fig. 48(*b*). However, a pressure of 12.6 lb. per sq. in. was maintained in the box during this run. The head due to centrifugal force tending to produce flow is $\frac{V_2^2}{2g}$, or $\frac{55.5^2}{64.4} = 47.9$ ft. This is opposed by a back pressure in the box of 12.6 lb., which is equal to a head of 29.1 ft. The net head producing flow through the orifice is the difference between these two, or 18.8 ft. This head will produce a relative velocity, $W_2' = 34.8$ ft. per sec. If this relative velocity, W_2', is laid off at right angles to V_2 in Fig. 48 (*b*), an absolute velocity, $C_2' = 65.6$ ft. per sec., is obtained. The kinetic energy represented by this is equivalent to a head of $\frac{65.5^2}{64.4} = 66.5$ ft. The quantity of water discharged was found to be 8.88 gal. per min. The power required to lift 8.88 gal. per min. to a height of 66.5 ft., would be 0.1495 h.p. The power shown by the dynamometer was 0.1475 h.p. This agrees within practically 1% and proves absolutely that no work is done against the pressure in the box, as was claimed by Dr. Timoshenko. If he were correct, the power required would have been 0.2150 h.p. instead of 0.1495 h.p. as measured.

In other words, it has been shown by actual tests that the head is not $\frac{V_2^2}{g}$ in such cases, but is a quantity less than that, which may be computed. If the pressure head in the box was increased until it was nearly equal to $\frac{V_2^2}{2g}$, the flow would be reduced to almost zero and the head would approach $\frac{V_2^2}{2g}$, as was shown in the paper and is now verified by test. This is exactly the situation that prevails in a centrifugal pump at shut-off. Many other tests were made with forward and backward as well as radial discharge and all confirmed these conclusions.

These tests are important because they show that the lack of agreement between the ordinary theory and practice cannot be explained on the basis of a different angle of discharge from that intended by the design. By allowing the water to flow through an orifice radially out into the box there could be no uncertainty as to the direction taken by the water. It cannot flow in any other way than normal to the plane of the orifice. The conditions as modified by the pressure in the box alone are capable of explaining the difference. These tests should settle the whole argument beyond any doubt and the writer would recommend that any one who is not convinced make such tests for himself. It is the only way to settle the question definitely. The writer wishes to express his appreciation for the very kind comments and discussion of Mr. Cox, and will await with interest further details of his new type of axial flow pump.

In bringing this paper to a close the writer again wishes to thank those who were so good as to contribute to the discussion.

Paper No. 1698

THE GREAT YANGTZE BAR*

By A. V. Hugo von Heidenstam,† M. Am. Soc. C. E.

With Discussion by Messrs. A. W. Robinson, and R. L. Vaughn.

Synopsis

The object of this paper is to describe the engineering investigations of the Yangtze Estuary for purposes of improving navigation to and from the Port of Shanghai, China. Since the opening of the river to foreign trade in 1842, the volume of shipping entering it has grown enormously, now (1927) amounting to about 16 000 000 British registered net tons per year. Within recent years the draft of ships has increased to a figure at which navigation over the bars of the Yangtze has become difficult. The interests of the Yangtze ports in general and of Shanghai in particular call for improvements.

The engineering problem is one to daunt the most courageous. The bars are many miles in length and the channels 2 or 3 miles wide. The depth in the main channel is 19 ft. at ordinary spring low water, 27 ft. at neap high water, and 31½ ft. at ordinary spring high water. The material is mud, and the bars are bordered by enormous shoals of similar mud, some of which shift and re-form constantly. The water is always heavily charged with silt and while there is a fresh-water discharge perhaps exceeding in maximum value that of any other river in world, its effects are practically neutralized in the estuary by a prodigious tidal flow.

The changes caused by tidal forces in the course of a few days are sometimes greater than from the largest conceivable excavating machinery in many months. The site is fully open to the sea. The main channels, separated by shoals, have cross-sections of about 1 000 000 sq. ft., widths of 3 to 4 miles, and depths in their shallowest sections over the bars of about 19 ft. at ordinary spring low water. There is no solid foundation for training works and their magnitudes would be appalling from a financial point of

view. Under all circumstances a record of the data collected cannot but be of general interest.

A summary is given of the investigations made by the writer, as Engineer-in-Chief, for the Whangpoo Conservancy Board, since 1914, culminating in a special investigation, from 1919 to 1921, as to the possibilities of improving the approaches to, and the facilities in, Shanghai Harbor. This investigation was concluded by the convening of an International Committee of Consulting Engineers, consisting of seven river and harbor experts, who reported at the end of 1921. The principal recommendations made by this Committee included the dredging of the South Channel and the construction of a system of public wharves in the Whangpoo River. This report is still (1927) under consideration by the Central Government.

Some of the difficulties involved in the dredging proposal are noted. An Appendix is also attached, dealing with the principal technical data collected.

Introduction

The problem of improving the sea approaches to Shanghai as here described is most difficult. Shanghai is situated on the Whangpoo River, about 15 miles from its mouth, the river itself forming the harbor (Fig. 1). The Whangpoo enters the estuary of the Yangtze about 30 miles above the main bar of that river, the "Fairy Flats". The depth on the crest of that bar at extraordinary low water is only about 16 or 17 ft.; at ordinary spring low water, 19 ft.; at neap high water, 26 to 28 ft.; and at ordinary spring high water, 30 to 32 ft. There are two other entrances to the Yangtze, but one of these is quite beyond improvement, while the other is similar to the Fairy Flats and more indirect.

The shipping visiting Shanghai has increased to such a volume that, reckoned by tonnage, this city is among the first six ports of the world. Moreover, the drafts of the ships are steadily increasing. Many of these ships have drafts of about 30 ft., and an increase in draft is certain within a few years. A vessel of 30-ft. draft is delayed only occasionally, but those of larger draft would have great difficulty. The deepening of one of the bars, therefore, is indispensable to the future welfare of the Port of Shanghai.

The magnitude of the operation is in itself appalling. Training works of accepted types and of an extent proportionate to the size of the bar might easily cost $50 000 000 (gold). Even so they would not be of such stability as to assure undeniable success. Dredging is only conceivable if the very largest and most efficient modern machines are to be used. The mere surveying and marking out of the site of the works is a very large operation. All these circumstances enhance the technical interest of the investigations already made and the professional opinions given.

History and Record of Reports

In 1876, Messrs. J. de Rijke and G. A. Escher, two Dutch civil engineers employed by the Japanese Government, were requested by the Shanghai

Consular Body to report on the Inner Bar of the Whangpoo River (which has since been eliminated by the works of the Whangpoo Conservancy Board). A supplement to their report included an "Essay on the Fairway from and to Shanghai through the Estuary of the Yangtze."

At that time it appeared from a comparison of the British Admiralty charts issued since 1842 that the South Channel (Fig. 1) was becoming shallow. More recent maps show that this tendency, if at all a fact, ceased subsequently. The authors of this 1878 report believed that the North Channel (Fig. 1) was growing at the expense of the South Channel and that by closing various small crossings and skilfully cultivating a channel between the shoals opposite the mouth of the Whangpoo, a good passage to the North Channel could be developed.

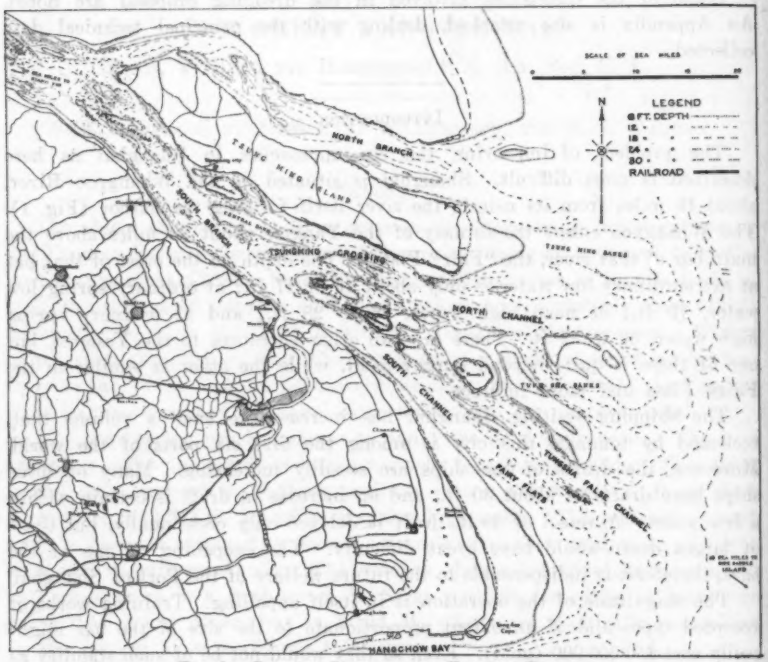

FIG. 1.—GENERAL PLAN OF THE YANGTZE ESTUARY.

It should be noted that the outer bar in the North Channel is usually deeper than that in the South Channel, the real obstruction being an upper bar (Tsungming Crossing). They had in mind a low-water draft of only 15 ft. In their opinion mechanical dredging was impracticable:

"* * * even for assisting only it must prove too expensive in so extensive an estuary. The dredgers, too, as well as the mud scows, would require to be built in a specially costly manner to fit them for navigating rough and dangerous water; but even if they were so constructed, still the number of off days would be very great."

Again,

"Everybody will also understand that any attempt to dredge the estuary of the Yangtze would be throwing money away, and that a single storm would destroy many months' work."

This very definite opinion given in 1876 is probably still true with respect to bucket dredges (which are distinctly suggested by the reference to scows), in spite of the great increase in capacity of dredges. It may not be true, however, of modern suction dredges some of which have a very large output and, by the use of hoppers or pipe lines, become independent of a scow service.

The report has interest as giving a word of warning to Shanghai, but has only a limited bearing on the present problem.

Whangpoo Conservancy Board.—In 1906 the Whangpoo Conservancy Board commenced operations in the Whangpoo with Mr. de Rijke as Engineer. In 1910 certain works near the mouth of the Whangpoo were almost completed, but operations had to be stopped owing to lack of funds. At the end of 1910 Mr. de Rijke was succeeded by the writer, and a re-organization was effected. In the writer's "Project for the Further Regulation of the Whangpoo" of 1911, which work was successfully completed in 1922, attention was drawn to the necessity of watching the behavior of the Yangtze. As part of that project (1912-22), a hydrographic service was established on the Whangpoo, including automatic tide gauges and regular velocity, discharge, and silt measurements. Incidentally, these provided much information as to the Yangtze, as the Whangpoo is really not much more than a tidal "swashway", or large creek, dominated by the Yangtze.

In 1914 the writer recommended that the Board make a special investigation of the Yangtze Estuary, to indicate whether any changes were occurring which might affect the welfare of the Whangpoo, and, at the same time, to make quite clear the condition of the sea approaches to Shanghai. This work was carried on in co-operation with Coast Inspector's Office of the Chinese Maritime Customs, and much hydrological information, in the form of charts (including areas previously unmapped), and tidal, current, and silt data, were accumulated. No specific attempt was made to formulate plans for regulating the estuary, but a working model was built in the hope of reproducing the currents and ascertaining what changes would arise from certain classes of work. Scale difficulties, however, prevented the success of this experiment.

As a result of this investigation, and in order to consider future needs, it was decided to take up the general question of possible improvement. In 1917, by request of the Board, the Vattenbyggnadsbyran, Consulting Engineers, of Stockholm, Sweden, and the writer, submitted a "Report on the Future Development of Shanghai Harbour", which analyzes Shanghai's position in regard to trade routes and includes a definite technical consideration of the approaches. A "Memorandum on a 'Port de vitesse' for Shanghai on, or Canal to, the Hangchow Bay" (see Fig. 1) was appended.

Shanghai Harbor Investigation.—A great deal of interest was created by the publication of this report (of which the definite recommendation was a further and full inquiry), and, in 1919, the Board authorized and commenced

a "Shanghai Harbor Investigation" which was to include as complete a survey as possible and, in addition, projects for improvement of the approach and the construction of harbor works. The work was carried on in three sections under the writer's direction, as follows:

Section I.—Surveys of estuary, etc., in charge of E. C. Stocker, M. Am. Soc. C. E.
Section II.—Harbor designs, in charge of Mr. C. W. Simon.
Section III.—General studies and secretarial, in charge of Mr. H. Chatley.

The delicacy of the approach problem was felt to be such that in addition to the Shanghai investigation two consulting engineers were retained, Mr. C. A. Jolles, of Arnhem, Holland, and Vattenbyggnads-Byran (The Hydraulic Engineering Bureau), of Stockholm.

It was part of the duties of the latter firm to consider also the desirability of making a new approach by means of Hangchow Bay (thus avoiding the present bars altogether). Similarly, Section I was to make (in co-operation with the Chinese Maritime Customs) a full survey of Hangchow Bay (Fig. 1). This survey revealed that the depths in this Bay were just sufficient for the largest drafts likely to visit Shanghai. Thus, the advisability of adopting this method of avoiding the obviously great difficulties of improving the Yangtze depended on two questions:

(*a*) Whether Hangchow Bay was likely to maintain its present depths, or, if not, whether a deep channel could be artificially maintained? and,
(*b*) Whether constructing a first-class ship canal or, as an alternative, a new coast "port de vitesse", with good water connections to Shanghai, was economically practicable?

The Vattenbyggnads-Byran expressed the very definite opinion that Hangchow Bay was slowly but steadily silting up. The survey and comparison with other charts partly confirmed this opinion. As the Bay is quite open and without continuous current channels the possibility of deepening it artificially if required in the future seemed very doubtful.

In the matter of the connection with Shanghai, a ship canal with locks of the Panama Canal type to exclude salt, silt, and tide, appeared prohibitively expensive. The "port de vitesse" in itself was also a matter of great cost and would have a very uncertain relation to Shanghai's peculiar economic welfare.

The Vattenbyggnads-Byran expressed the opinion that the "idea of reaching Shanghai *via* the Hangchow Bay should be definitely given up."

Mr. Jolles, with his long experience on Dutch waterways, was asked to report on the estuary problem only, and expressed the opinion that the bar was due largely to coagulation of the silt by saline flood currents; that the South Channel was the only one for which regulation should be attempted; and that training works would be prohibitively expensive and uncertain of success, but that dredging might be successful. He estimated that 25 000 000 cu. yd. of material might be involved. No "streaming away"* need be anticipated as the silt precipitation will not undergo any change. Drag suction dredges might be

* Removal of mud in excess of the quantity dredged by reason of the current acting on the disturbed bottom.

the only suitable type. He finally suggested dredging work in the channel connecting the "Tungsha Channel" to the South Channel (southwest of House Island, Fig. 1) and in the Tungsha Channel itself, to a depth of 25 ft. below low low water, involving about 12 500 000 cu. yd. of dredging and 900 000 sq. yd. of mattress protection. The cost would be about 22 000 000 Taels (say, $15 000 000); the permanence would be uncertain.

The Tungsha Channel (Fig. 1) is a relatively recent development. The South Channel was formerly wider and then was split by the shoal now termed the Tungsha Spit (Fig. 2). The Tungsha Channel is really part of the former South Channel and for some years it was expected to become eventually the navigation route, usurping the place of the narrowed course of the South Channel. In recent years, however, it has shown no tendency to increase in depth and the bar at its head (which Mr. Jolles proposed to dredge) has shallowed.

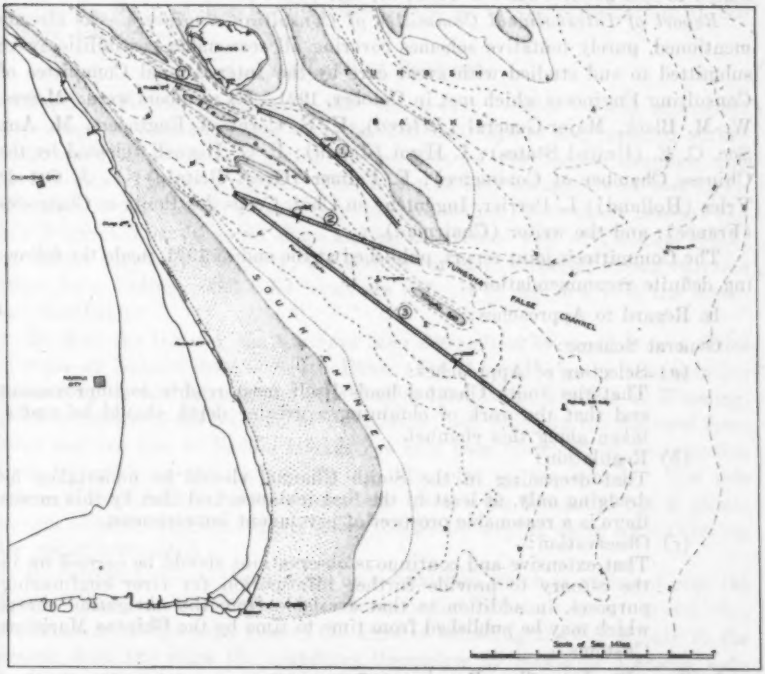

FIG. 2.—THREE LAYOUTS FOR DREDGING PROJECTS IN SOUTH CHANNEL, YANGTZE RIVER.

The Vattenbyggnads-Byran in its report made an elaborate but rather academic study of the shoal movements and concluded that the only permanent tendency is for the deepest channel to swing southward. It held, therefore, that the present South Channel is the most stable of all and definitely recommended dredging along the axis of that channel.

On the basis of the local investigation and studies, the writer, prior to the arrival in Shanghai of the International Committee of Consulting Engineers in October, 1921, prepared a general report on the entire problem (the harbor itself and its approaches) for the use of the Committee, which included plans and estimates for various solutions.

In regard to the estuary, it put forward three alternative dredging projects in the South Channel (Fig. 2):

(1) A cut, 11 miles long, along the thalweg of the Tungsha Channel.
(2) A direct diagonal cut, 9 miles long, between the two channels.
(3) A direct cut, 20 miles long, along the axis of the South Channel.

The net volumes of dredging in the three cases were, respectively: (1) 13 400 000 cu. yd.; (2) 12 500 000 cu. yd.; and (3) 22 000 000 cu. yd.

Suitable harbor works, survey, and dredging craft were included, with five years' operation on whichever of the three layouts might be preferable, estimated to cost about 8 325 000 Taels, or, say, $6 000 000.

Report of International Committee of Consulting Engineers.—As already mentioned, purely tentative schemes covering all reasonable possibilities were submitted to and studied with great care by the International Committee of Consulting Engineers which met in October, 1921. Its members were: Messrs. W. M. Black, Major-General (*Retired*), U. S. Corps of Engineers, M. Am. Soc. C. E. (United States); I. Hiroi (Japan); P. G. Hornell (elected by the Chinese Chamber of Commerce); F. Palmer (Great Britain); P. J. Ott de Vries (Holland); L. Perrier, Ingénieur en Chef, Corps des Ponts et Chaussées (France); and the writer (Chairman).

The Committee's joint report, published at the end of 1921, made the following definite recommendations:

In Regard to Approaches:

General Scheme:

(*a*) Selection of Approaches:
That the South Channel lends itself most readily to improvement and that the work of obtaining a greater depth should be undertaken along this channel.

(*b*) Regulation:
That deepening in the South Channel should be undertaken by dredging only, at least in the first instance, and that by this means there is a reasonable prospect of permanent improvement.

(*c*) Observation:
That extensive and continuous observations should be carried on in the estuary to provide further information for river engineering purposes, in addition to that available from the navigation charts which may be published from time to time by the Chinese Maritime Customs.

In Regard to Immediate Requirements:

(*a*) To carry out forthwith the river engineering observations indicated under the "General Scheme."

(*b*) To make and maintain a channel through the Fairy Flats, developing it gradually foot by foot, to as great a depth and width as required and possible, and to provide as soon as feasible a channel of 600 ft. bottom width for the passage of ships drawing 33 ft. at ordinary neap high water.

The estimate for the work, under "Immediate Requirements", for the improvement of approaches, was as follows:

Capital Expenditure:		
Survey plant	Shanghai Taels	200 000
Dredging plant	" "	4 200 000
Incidental plant	" "	125 000
Total	Shanghai Taels	4 525 000
Annual Expenditure:		
Survey	Shanghai Taels	100 000
Dredging	" "	1 000 000
Total	Shanghai Taels	1 100 000

This plan is still (1927) under consideration by the Central Government and its adoption involves an agreement between that Government and the Diplomatic Body of Foreign Representatives as to the constitution of the Harbor Authority.*

The Present Project†

Survey.—It will be observed that the actual location of the attempted deepening has been left open, with the idea that further and repeated survey work would throw more light on the position of the deepest channels and the stability of the bed masses. This is not as easy as appears at first sight. The river is too wide to permit very exact re-section; permanent beacons can only be erected on the south shore and on the islands west of Tungsha Bank; the depths vary only gradually; the bottom varies in softness; strong currents affect the soundings; and tidal levels are difficult to compute with the necessary exactitude.

To date, the tides on the bar have been determined by reading on a series of poles at Nanhui on the South Bank (Fig. 1) and also by interpolation between an automatic gauge at Side Saddle Islands and another at Woosung, or by temporary poles on some of the islands; but owing to the distance from shore the tide pole at Saddle Islands has only been "leveled" by computation from water slopes—similarly with the tide poles on the islands. The tide poles at Nanhui have been connected by levels with Woosung, but it is not certain whether the high waters across the gently sloping shore out to the bar are really horizontal.

Soundings have also been taken on a lightship, which is anchored over the Fairy Flats and swings over a moderately flat bottom. It is obvious that the accuracy of the tidal rise at the time of sounding the bar is only to the nearest foot, and since the soundings themselves by reason of currents, softness of mud, etc., are probably uncertain by a similar amount, the actual levels of the bottom (Figs. 3, 4, and 5) are in doubt by as much as perhaps 2 ft.

* No criticisms have yet been made by outside parties on the estuary project, except a paper by Mr. Canter Cremers, in the September, 1923, issue of *The Dock and Harbour Authority* (London), in which he expresses the fear that the inward running flood currents will neutralize the dredging by reason of their excess of force on the bed over the ebb currents, due to salinity.

† As outlined by the International Committee of Consulting Engineers, 1921.

Over a large area of the bar the computed values differ only by 1 or 2 ft. in distances of ½ mile. The top, therefore, is practically level, and it is a question whether there is any definite thalweg across it. Longitudinal profiles of the South and North Channels are shown in Figs. 3 and 4. Fig. 5 gives a cross-profile of the estuary at the shallow part (Fairy Flats). Elevations are referred to Woosung horizontal zero (W. H. Z.), an imaginary horizontal plane through the lowest low water at the mouth of the Whangpoo.

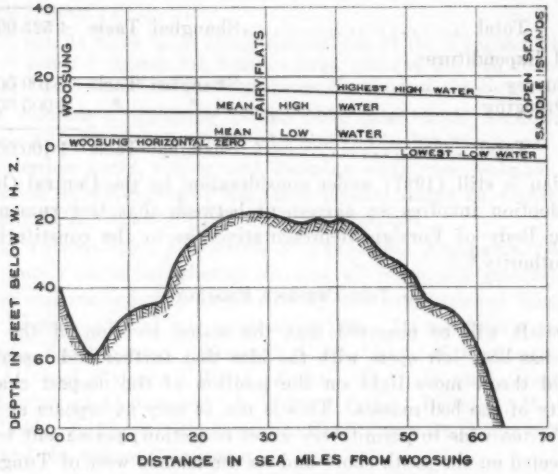

FIG. 3.—LONGITUDINAL PROFILE OF FAIRY FLATS.

A summary of the tide on the Fairy Flats is given in Table 1. At spring tides the tidal currents may be as strong as 6 knots. The silt content may rise to 2 000 parts per million by weight and the salinity of flood currents may be more than one-half that of true sea water.

TABLE 1.—STANDARD WATER LEVELS AT FAIRY FLATS (NANHUI BEACON).

	Water level referred to W. H. Z., in feet.	Rise, in feet.	Depth on crest, in feet.	SEASONAL CORRECTION TO BE APPLIED FOR:	
				January.	July.
Highest high water	18.0	21.8	37.8	.....	.....
Standard spring high water	11.8	15.6	31.6	−0.33	+1.35
Mean high water	9.6	13.4	29.4	−0.62	+1.24
Highest low water	8.6	12.4	28.4	.....	.....
Standard neap high water	7.0	10.8	26.8	−0.10	+1.27
Mean water level	5.4	9.2	25.2	.....	.....
Standard neap low water	3.6	7.4	23.4	−1.22	+0.39
Mean low water	0.8	4.6	20.6	−0.80	+0.81
Lowest high water	0.2	4.0	20.0	.....	.....
Standard spring low water	− 0.0	3.8	19.0	−0.28	+0.28
Lowest low water	− 3.8	0.0	16.0	.....	.....

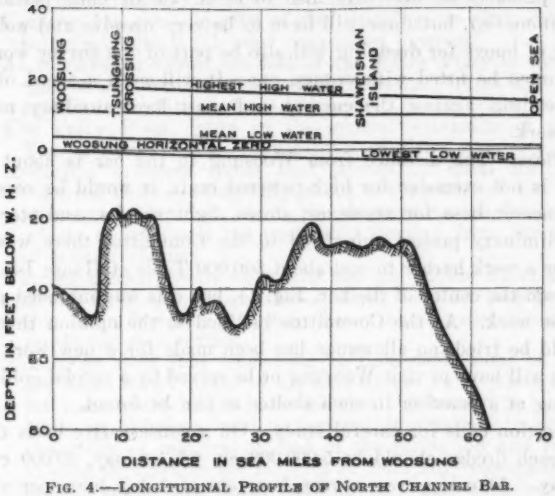

FIG. 4.—LONGITUDINAL PROFILE OF NORTH CHANNEL BAR.

The purchase of a good sea-going survey ship with auxiliary launches, etc., is included in the project. This vessel could repeat soundings with a view to a more rapid determination of progressive changes. By the establishment of numerous temporary tidal stations, it could obtain slightly more precise measurements; but the difficulties are quite serious—the removal or accretion of even 1 000 000 yd. of mud might take place unnoticed.

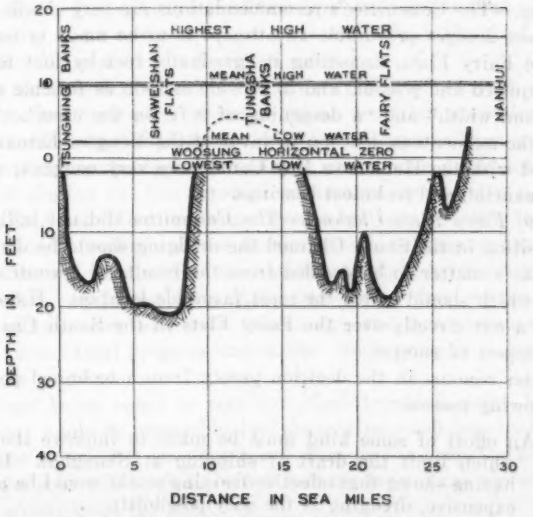

FIG. 5.—TRANSVERSE SECTION OF THE TWO BARS.

It will probably be necessary also to erect one or more permanent tide gauges (automatic), but these will have to be very massive and well founded. The laying of buoys for dredging will also be part of the survey work, so that the vessel must be fitted with cranes, etc. It will need a speed of 10 knots to make headway against the current and must have auxiliary motor craft for shoal work.

Work Base.—The distance from Woosung to the bar is about 30 miles. While this is not excessive for high-powered craft, it would be very desirable to have a nearer base for residence, stores, light repairs, and storm shelter. In the preliminary project submitted to the Committee there was included a design for a work harbor to cost about 500 000 Taels at House Island (about 10 miles from the center of the bar, Fig. 1), but this was intended principally for mattress work. As the Committee inclined to the opinion that dredging alone should be tried, no allowance has been made for a new work base, and the dredges will have to visit Woosung or be served by a special collier capable of bunkering at a mooring in such shelter as can be found.

This question calls for careful study. On a conservative basis the annual output of each dredge should be 5 000 000 cu. yd., or, say, 20 000 cu. yd. per working day. Allowing even a very low rate of 1 h.p.-hour per yd. shifted and 3 lb. of coal per h.p.-hour (includes getting up steam, etc.), the daily coal supply will be at least 30 tons, and more probably 50 tons. The largest drag suction dredge familiar to the writer is the *New Orleans* (Frühling), which has a 3 000-yd. hopper and 300-ton bunkers. For reasons of draft a 2 000-yd. hopper and, say, 200-ton bunkers will probably be the limit for this work, so that each dredge will have to coal about once a week. Oil fuel might be considered.

Dredging.—The Committee's recommendations are very simple. By means of the largest dredges procurable an attempt is to be made to cut a channel through the Fairy Flats, deepening it "gradually foot by foot to as great a width as required and possible and to provide as soon as feasible a channel of 600 ft. bottom width" and "a deepening of 9 ft. on the crest". The reasons leading to the momentous decision in favor of the Yangtze Estuary Approach as compared with the Hangchow Bay Canal were very complex, with various political, financial, and technical bearings.

Choice of Fairy Flats Channel.—The Committee did not indicate exactly in what position in the South Channel the dredging should be done, believing that this was a matter to be decided from the results of a continuous survey of the bar, which should reveal the most favorable location. However, it suggested that a cut directly over the Fairy Flats in the South Channel offered the best prospect of success.

The writer concurs in the decision purely from a technical point of view, for the following reasons:

(1) An effort of some kind must be made to improve the approaches which limit the draft of shipping at Shanghai. Investigation having shown that effective training works would be prohibitively expensive, dredging is the only possibility.

(2) The center line of the South Channel is the most direct navigable course for the majority of the shipping, so that, other things being equal, it is the most convenient location.
(3) As to physical shape, the bed of the Fairy Flats is simpler than that of any other passage, and, therefore, offers the best topographical conditions for improvement.
(4) The Fairy Flats, lying in the general extension of the Lower Yangtze, offers better probabilities of direct scour by the ebb.
(5) Historical evidence shows that permanent shoal formation has occurred more continuously about the mouths of the other two openings rather than about the entrance to the South Channel, which, therefore, is the preferable location from the standpoint of secular change.
(6) Current measurements show that the ebb on the Fairy Flats is as strong as, if not stronger than, that in the other passages. Hence, this site offers the prospect of maximum natural scour and of minimum re-accretion.
(7) Soundings show that from time to time depressions of large area but small depth occur on the axis of the Fairy Flats and persist for some years. This indicates that the bottom is in a state of labile equilibrium, with occasional inclination to scour. The quantities of material shifted in the formation and re-accretion of such depressions are far greater than any reasonable dredging project could cope with, but the fact that such variations of depth do occur suggests that a continuously applied effort on a small area along the line of the strongest currents may co-operate with the scouring tendency of the ebb currents to produce a permanent depression.
(8) These considerations taken conjointly give a reasonable hope that an artificial deepening over a relatively minute fraction of the width of the Fairy Flats would have such a measure of stability as to warrant the attempt to create and maintain it.

Proposed Method of Dredging.—There are two outstanding difficulties: (*a*) The quantity to be removed, which is in the neighborhood of 20 000 000 cu. yd.; and (*b*) the re-accretion that may occur.

There can be little doubt that the slow excavation of a trench to the full depth would form a dead-water pocket in which accretion would be extremely rapid, and a method of dredging that provides a long small cut seems much to be preferred. Since the degree of stability of the sides of the excavation is small, a broad, shallow cut has apparent advantages over a narrow, deep one. On the Taku Bar, near Tientsin, some success has been found with the latter form. So far as the writer is aware the drag suction dredge is the only type that gives the desired results. Ordinary suction dredges (with rotary cutters), or bucket dredges, would not serve the purpose since they cannot work well unless they make a deep and wide lateral cut, the mere volume of which makes rapid longitudinal progress impossible. Such progress is indispensable in order to encourage scour.

Other things being equal, a pipe-line discharge to a point beyond the dredged channel would be preferable, but the marine conditions and the speed required appear to prohibit it. Overboard discharge is open to the objection that part of the mud will be re-deposited over the area of the cut and thereby partly if not wholly undo the work.

The marine conditions suggest that a self-contained hopper dredge will be enabled to work more continuously than a hopper barge arrangement. The decision, therefore, seems to rest exclusively with the drag-suction, self-propelled, hopper-type dredge.

The desired cut increases in length as it deepens, to about 25 miles, but if the shorter shallow depression maintains itself, the stability should increase with the depth, so that the practical question will be rather one of rapidly channeling the bar over a length of, say, 10 miles. If the dredging speed is 3 knots (over the bottom) this means that one through cut might be made in a tidal period (allowing half the time for dumping). If an appreciable result is to be produced in 5 years the annual dredging capacity should be at least 5 000 000 cu. yd., or, say, 2 000 effective cu. yd. per hour (for 2 500 working hours); allowing only one-third the working time for actual dredging, this means a continuous capacity of 6 000 cu. yd. per hour, which would require the largest and most efficient machines yet built. Failure to achieve an output of this size will greatly reduce the possibilities of success unless the natural scour proves very favorable.

The brief details given show the extraordinary uncertainty and difficulty of the problem. Its magnitude appeals to the imagination of every engineer. The Appendix gives further data relating to the estuary.

APPENDIX

General Data

Historical Changes.—Owing to the inaccuracy of early maps there are no precise records of the undoubtedly great changes that have occurred in historic times.

Fig. 6 shows a series of rough maps compiled from old data, which clearly indicate the superior stability of the present South Channel, and the progressive deterioration of the North Branch. The various surveys made since the middle of the Nineteenth Century, the accuracy of which has steadily increased, do not give any distinct evidence as to systematic change in the two main bars; accretion seems to have occurred principally in the regions of the North Branch and Yangtze Cape. Erosion appears to be a purely local phenomenon initiated at concaves.

Tides.—The whole estuary is subject to tidal action. Tidal observations have been made for prolonged periods at Side Saddles (Fig. 7), an island at the extreme north of the Chusan Archipelago in the open sea just off the mouth; at Woosung Forts (Fig. 8), at the entrance to the Whangpoo; and at Kiangyin (Fig. 9), the head of the estuary. Other places have been observed for shorter periods. The annual change of "stage" in the river reduces the tides in the upper part of the Estuary, as shown in Fig. 9. At Kiangyin the mean level has a fortnightly swing.

Tidal Currents.—The currents are quite strong. Maximum flood and ebb velocities of more than 6 ft. per sec. have been observed at a point about 20 miles above Woosung; and on the bar the maximum filament flood velocities at spring tides may be 10 ft. per sec. Outside the estuary there is a distinct clockwise rotary effect and even in the lower parts of the estuary (for example, on the Fairy Flats) the tidal currents move in long flat loops so that there is a transverse (northward) current at slack water.

The non-tidal gradients in the estuary are very small (less than 1 ft. in 10 sea-miles), but the slopes of the simultaneous longitudinal water profiles may be as much as 1 ft. per sea-mile.

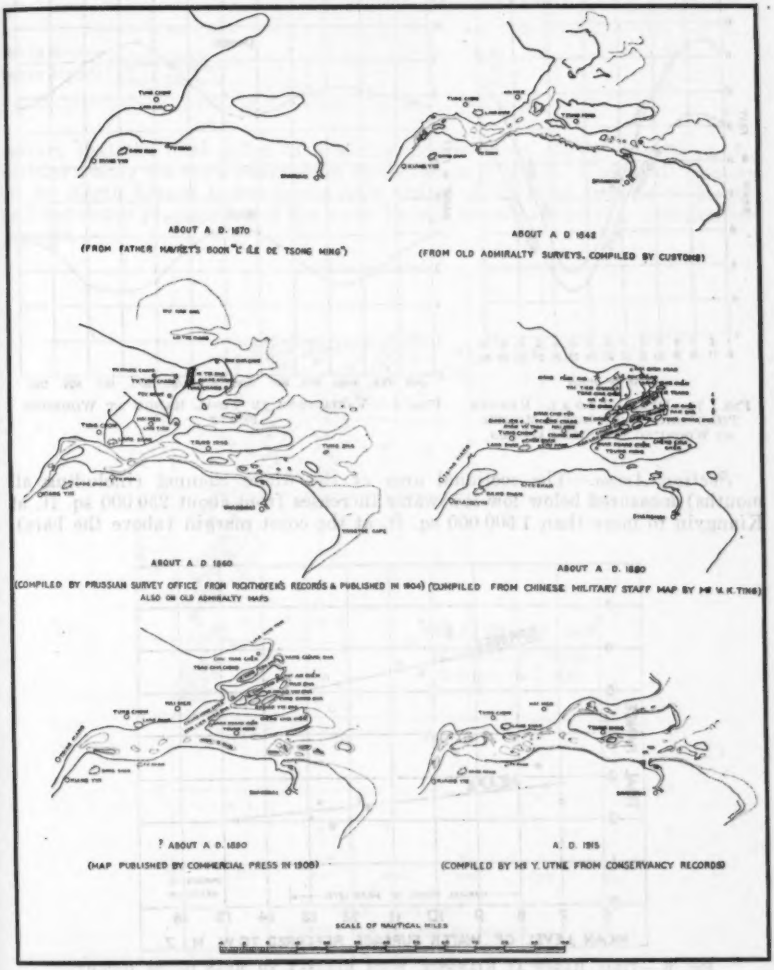

FIG. 6.—SERIES OF HISTORICAL PLANS OF THE ESTUARY.

Velocities.—Owing to the magnitude of the stream the observation of current velocities has not been very exhaustive, but it has been found that in most places the velocity near the bottom is about 60% of the mean velocity and that the mean velocity occurs at about 60% of the depth.

There are great irregularities in the velocity at different depths due to the lack of symmetry of the sections and the tidal-current reversals. The dis-

tribution across the stream shows nothing unusual in spite of the magnitude of the sections.

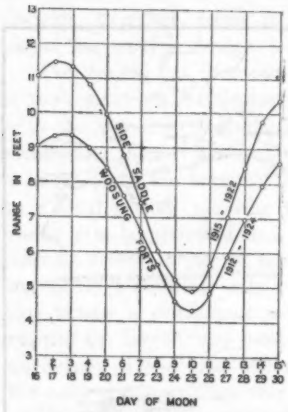

FIG. 7.—MEAN TIDAL RANGES THROUGHOUT THE LUNAR MONTH AT WOOSUNG AND SIDE SADDLES.

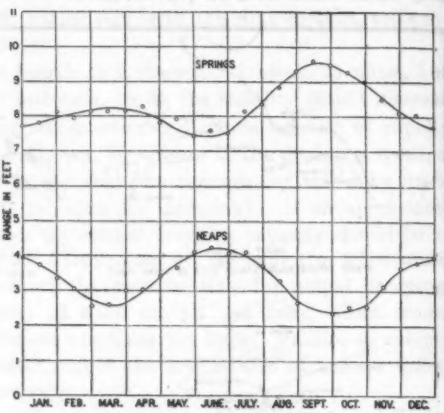

FIG. 8.—VARIATIONS IN TIDAL RANGE AT WOOSUNG FORTS.

Section Areas.—The sectional area of the whole channel (including all mouths) measured below low low water increases from about 250 000 sq. ft. at Kiangyin to more than 1 500 000 sq. ft. at the coast margin (above the bars).

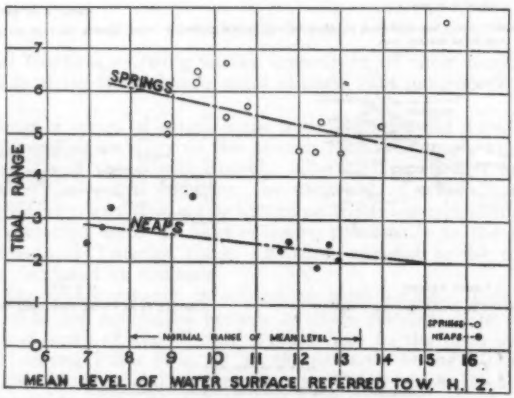

FIG. 9.—TIDAL RANGE AT KIANGYIN, WITH RESPECT TO MEAN GAUGE HEIGHT.

The sectional area below standard spring high water at the coast margin is about 3 000 000 sq. ft.

These areas are divided between the three entrance channels approximately, as shown in Table 2.

Discharges.—It has not been feasible to make a simultaneous observation of the discharge of all three channels owing to the number of large craft required, but from the various individual discharge measurements it appears

TABLE 2.

Channels.		Area below low low water, percentage.	Area below high water, spring tide, percentage.
North Branch		30	33
South Branch	North Channel	40	35
	South Channel	30	30

certain that the total influx of a spring tide is about 250 000 000 000 cu. ft. divided among the three channels in about the ratio, 2:3:3. The small amount in the North Branch is due to the later arrival of the tidal wave at its mouth and the slower propagation of the wave through its rather tortuous and shallow passage.

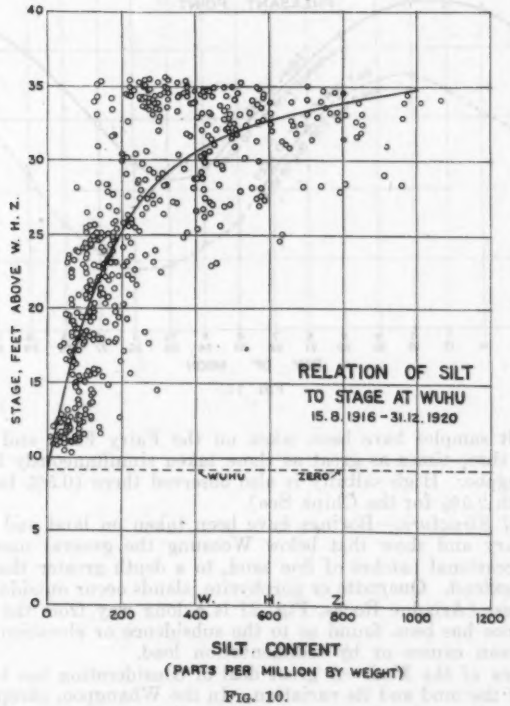

FIG. 10.

Tidal Magazine.—The capacity of the estuary is, of course, equal to the influx and diminishes for spring tides from about 200 000 000 000 cu. ft. at the coast line to 5 000 000 000, or less, at Kiangyin.

Run-Off.—From gaugings in the upper river it has been found that the fresh-water discharge of the river varies from about 250 000 cu. ft. per sec. to more than ten times that amount, averaging about 1 000 000. The maximum is in the late summer and the minimum, in January.

Silt.—Immense quantities of silt are brought down. Fig. 10 shows the silt charge at Wuhu (a point where tidal influence is very small, about 300 miles from the mouth), in relation to the stage of the river, which, of course, varies with the run-off.

In the estuary the tidal currents disturb and keep in suspension a great quantity of silt so that even in the winter, when the supply of fresh silt from the interior is small, the spring tides working in shallower channels develop more velocity and the water has a maximum of turbidity.

Fig. 11 shows the variation of silt with the tidal range at a point in the Whangpoo (Pheasant Point), quite close to the Yangtze.

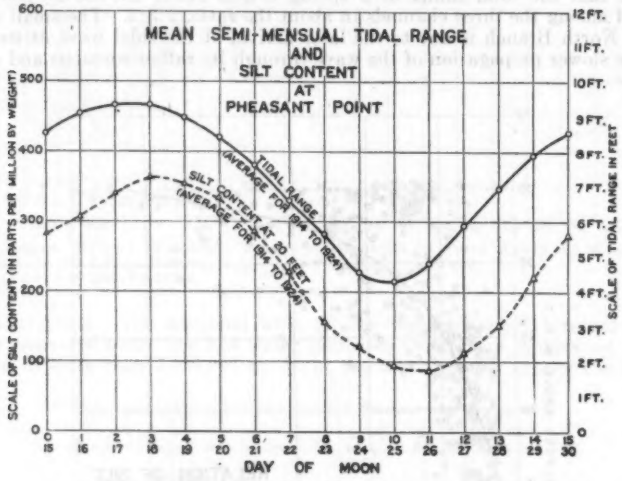

FIG. 11.

A few silt samples have been taken on the Fairy Flats and show values from one to three times as great as those taken simultaneously in the mouth of the Whangpoo. High salinity is also observed there (0.5% to 2.0% which compares with 2.5% for the China Sea).

Geological Structure.—Borings have been taken on land and under water in the Estuary and show that below Woosung the general mass is alluvial mud, with occasional patches of fine sand, to a depth greater than any works are likely to extend. Quartzite or porphyrite islands occur outside the Estuary, but the nearest (Ariadne Rocks, Fig. 2) is a long way from the bars.

No evidence has been found as to the subsidence or elevation of the delta by subterranean causes or by sedimentation load.

Consistency of the Mud.—A great deal of consideration has been given to the nature of the mud and its variation. In the Whangpoo, except in the case of recent accretion, it is a heavy material containing sufficient colloidal matter to make it very firm; but it cannot be regarded as a real clay. Silica predominates as the mineral constituent, and the mud is fairly easily disturbed by a stream of water; but when consolidated it presents considerable resistance to dredging by grabs or bucket dredges. The mud on the Fairy Flats closely resembles that in the Whangpoo.

Meteorological Data.—Ample meteorological data are available. The Fairy Flats is practically in the open sea, being sheltered only on the southwest.

The North Channel Bar is quite in the open. Northwest winds prevail in the winter and the bar is quite choppy during flood current. Southeast winds prevail in the summer and ebb currents are then the more disturbed. Very dangerous typhonic winds may occur in the late summer and autumn. Moderate or smooth weather occurs for about 80% of the time. About 100 hours of fog per year occur on the Fairy Flats and about 400 on the North Channel Bar.

DISCUSSION

A. W. Robinson,* M. Am. Soc. C. E. (by letter).—The writer, having visited Shanghai on several occasions and passed in and out over the bar, is able to visualize the magnitude of the problem and the character of the difficulties so graphically and frankly set forth by Mr. von Heidenstam.

The Board of Engineers' report of 1921 was largely concerned with the development of the Whangpoo as being Shanghai Harbor proper, and with the re-organization which it deemed necessary to enable the Conservancy Board to attack the great problem of deepening the approaches.

The political condition of the Central Government in China makes it hopeless to expect any aid from that source, as is usual in the United States and other countries, and it is, therefore, on the resources and revenues of the Port itself that the Board must depend for its execution and maintenance. Hence, it is of vital economic importance that the capital cost and maintenance charges of the work should not become so great a tax on the commerce of the Port as to burden or defeat the progress and growth of that commerce which it was designed to promote. This means that if dredging the channel is to be attempted, it must be done on a larger scale and at less unit cost than any other similar work in the world.

The Board of Engineers, in reporting on the subject of approaches, stated:

"The Committee is of opinion that deepening in the South Channel should be undertaken by dredging only, at least in the first instance, and that by this means there is a reasonable prospect of permanent improvement."

It also recommended,

"That the harbor authority should proceed to make and maintain a channel through the Fairy Flats developing it gradually foot by foot, to as great a depth and width as required and possible, and to provide as soon as feasible a channel of 600 ft. bottom width for the passage of ships drawing 33 ft. at ordinary neap high water."

This being the decision of this very competent Board of Engineers, the writer will not venture to criticize it or to suggest any alternative. However, there are some very important points to be borne in mind in considering such large-scale dredging plants, and in forecasting the probable results that may be obtained. These points are applicable not only to the work in question, but to all similar works throughout the world. That report was made in 1921, and nothing has yet been done, owing probably to political conditions; but it is presumably becoming more urgent every year.

General Method of Dredging.—In discussing the general method of dredging to be followed, Mr. von Heidenstam is of the opinion that a broad shallow cut has apparent advantages over a narrow deep one, and that the decision seems to rest exclusively with the drag-suction, self-propelled hopper type of dredge. With this the writer concurs, provided the material be suitable. It is better to make a shallow cut quickly across a bar in the direction of the current, in order that it may be self-scouring as far as possible.

* Cons. Engr., Upper Melbourne, Que., Canada.

Dredging on the Mississippi River has been done successfully for many years on this principle with a forward feed type of dredge having a wide suction mouth and anchorage lines up stream. The self-propelling drag-suction type of hopper dredge used for deepening ocean bars at New York and other ports also makes a continuous longitudinal cut, although of narrower width. The sand-pumping hopper dredges on the Mersey River, in England, however, work on a different principle, that of dropping the suction down in one place and making a conical depression as the sand runs in. The hopper is filled easily and quickly by this method, and it is supposed that the net result, after the several pockets thus made have evened out, is entirely satisfactory.

It is supposed that so many cubic yards removed from the channel must have the effect of deepening it. While this is undoubtedly true, it is nevertheless a fact that enormous quantities of sand have been removed from the Mersey without corresponding increase of effective depth. This has been attributed to the shifting nature of the sand, but the writer thinks that pocket dredging in this way offers an inducement for the sand to fill in again, whereas in rapid longitudinal cuts there is not the same tendency, and they are, in a measure, self-scouring. In all these localities the material dealt with is sand.

Character of Material.—This has an important bearing on the success or failure of hopper dredging. Sand, especially coarse sand, is ideal for the purpose as it precipitates quickly in the hoppers, filling them to the top while the water runs off in the overflow. However, sand varies much in coarseness and mud content, and more or less solid matter is washed overboard and lost. In very fine sand mixed with mud, as much as 50% or more may be lost in this way; and in alluvial silt or soft mud only some lumps not broken up will remain in the hopper. This loss may become so great that it would not be profitable to dredge it at all by this method.

At Brunsbuttel, on the Elbe, the silt is so fine and impossible to precipitate that it comes up in the consistency of soup, and when the hoppers are full the dredge goes to sea without any overflow at all. This means that much water is carried as dead load, but it is better than continuing to pump and losing it overboard.

Precipitation of Solid Matter.—Various methods have been tried to increase the precipitation of solid matter in the hoppers, such as baffle-plates and distributing troughs. In muddy material these are only partly successful, and it is obvious that the two essential conditions necessary to precipitate fine material in suspension are time and quiescence. In a dredge hopper these conditions are difficult to obtain. The incoming stream sets up currents and some agitation and time cannot be allowed for slow precipitation. The best that can be done, therefore, is to distribute the delivery into the hopper so that the least agitation will occur, and design the overflows so that the water is removed after the longest interval between the inflow and outflow both as to time and distance.

These conditions can be much better fulfilled in large hoppers than in small. Hence, a very large hopper dredge offers a better opportunity to

reduce the losses in overflow. If the mud will not precipitate in the hoppers sufficiently after pumping, then it will be necessary to consider some other means of filling them.

Type of Drag.—The ordinary form of drag on most of the hopper dredges on the Atlantic Coast (for use in sand) would be quite unsuitable on a packed mud bottom of a nature to require dredging by a bucket or grab. It would simply ride over it and leave a track mark. Such stuff as was picked up and churned by the pump into a fine solution of mud would not precipitate rapidly enough to make a load in any reasonable time.

For such clayey material it would be necessary to excavate it or break it up into lumps suitable to be handled by the pump in such a way that they would not be entirely churned up, but would remain in the hopper. This can be done by a toothed drag or plow having multiple teeth or plowshares, similar to the teeth of a farmer's plow or cultivator. The writer has designed a suction cutter for clay soils, in which multiple cutters or plows are arranged in front of the suction in such a way that all the pump has to do is to pick up the loose material. The cutters are constructed so that if any tooth strikes a snag it will drop back and ride over the obstruction.

Grab Type.—The grab or clamshell type of dredge is well suited for soft clay and the wear and tear and mechanical losses are less than with the pump type. A series of grabs could be arranged on the dredge which could load the hoppers with no loss by overflow and at any desired capacity rate. With electric distribution of power, oil-engine generated, the problem would be simplified and good economy obtained.

Economy of Large Units.—After the dredging the problem is one of transporting and dumping at sea. It is well-known that large vessels are more economical than small, both in propelling power and operating costs. The limiting factors in ocean vessels are draft of water and time of loading.

Table 3 was prepared by the writer for another paper.* It shows the comparative economy of cargo vessels of 2 500 to 25 000 tons dead weight capacity.

TABLE 3.—Comparative Economy of Cargo Vessels.

Dead weight capacity, in tons	2 500	5 000	10 000	15 000	20 000	25 000
Length of vessel, in feet	215	300	430	510	590	675
Beam of vessel, in feet	36	44	58	68	72	80
Draft of water, loaded, in feet	22	25	28¼	32	34	36
Speed, sea-miles per hour	11	11	11	11	11	11
Indicated horse-power	1 460	1 900	2 800	3 750	5 000	6 000
Coal per hour, in pounds	2 920	3 600	5 000	6 380	7 350	7 950
Coal per 100 ton-miles, in pounds	10.6	6.5	4.5	3.9	3.3	2.9

The dimensions given may be varied, of course, to suit different designs. For instance, if less draft is required the hull may have more length and beam; but the comparison is sufficient to illustrate the great saving in coal consumption in the larger sizes. Thus, a vessel of 2 500 tons consumes 10.6 lb. of coal per 100 ton-miles at 11 knots, while a vessel of 25 000 tons only consumes 2.9 lb. per 100 ton-miles at the same speed. In other words, a given

* "Economy in Ocean Transportation," by A. W. Robinson, *Proceedings*, Eng. Inst. of Canada, February, 1919.

amount of cargo is carried in the larger vessel with 27% of the fuel, and a saving of 73%, with intermediate sizes in proportion.

Size of Plant.—As to size and capacity of such a dredging plant, the writer does not offer any opinion at this time, except to state the possibilities. In the present case the limiting depth of water of 18 ft. could be exceeded at high tide and after the channel has been partly deepened. The vessel, therefore, might be built to carry, say, half load at 18 ft. and full load at 22 or 24 ft., which would permit the use of a vessel of 15 000 tons.

Stability of Channel.—The question of the stability of the completed channel would remain to be proved by time, whether the initial dredging were on a large or a small scale. A tenacious mud would apparently offer greater stability than sand or silt, and it is probable that maintenance costs would not be great. A comparison of annual surveys would indicate the present rate of change.

Report of Board of Engineers.—Perusal of the report of the Board of Engineers mentioned by the author discloses a difference of opinion as to procedure.

One member stated:

"I differ in being of opinion that the data available at present are not sufficient to justify me in making the dredging a definitive scheme of improvement. I recommend the carrying out of an experimental dredging before taking up the actual dredging work, in order to ascertain the feasibility of the latter, and under favorable circumstances, the amount of work needed for the maintenance of a deep water channel on the bar."

The other six members stated,

"The experimental dredging recommended will prove to be futile and it would be unsafe to base any conclusions on the success or otherwise, of the results which might be obtained thereby. They consider it dangerous to follow this proposal for the reason that failure to effect anything approaching permanent deepening would create the impression that a satisfactory channel over the Fairy Flats cannot be produced by dredging. They believe on the contrary, that there is no reasonable doubt about providing a greater depth by dredging, and that the depth so obtained can be maintained by the same means. The one condition they wish to lay down is that the dredging operations should be on a really extensive scale."

The writer thinks that there is some ground for both these contentions. On the one hand some experimentation would seem to be essential to determine the behavior of the material under actual conditions of dredging; the rate of precipitation in a hopper, if pumping is used; the losses in the overflow; the best type of excavating or plowing drag suction to be used; and, generally, whether sufficient material could be retained in the hopper to make the pumping method feasible. If it could not, a test of some other method should be made.

The material on the bar is described as "mud, fairly easily disturbed by a stream of water, but when consolidated presenting considerable resistance to dredging by grabs or bucket dredges." The author does not state whether any experiments have been made to determine the points mentioned.

On the other hand such an experimental plant would prove nothing as to the general results, in deepening the channel or its permanence, but it would

certainly yield useful data. The writer, therefore, is inclined to agree with the Minority Report as to the necessity of obtaining data on which to base a sound design suitable to the conditions before embarking on any large expenditure.

With these data obtained, there is no doubt that a seaworthy dredging plant, that could deal with the large quantities involved at a low cost, could be designed and built with every assurance of success.

R. L. VAUGHN,* ASSOC. M. AM. SOC. C. E. (by letter).—Under the conditions outlined in this clear and interesting paper, any one experienced in problems of this kind would probably agree that the most promising line of endeavor would be by dredging. Training works appear to be almost out of the question: First, on account of their magnitude and cost; second, because of construction difficulties; and, third, because of doubts concerning their efficacy and permanence. Quite often under such circumstances jetties merely push the problem a little farther seaward, so that, with improved equipment available, the tendency in the United States has been more and more to rely on dredges to create and maintain channels over ocean bars.

Hydraulic hopper dredges are best adapted to a sandy material. With silts, from 5 to 10 yd. are often pumped overboard for every yard retained in the hoppers. The net results on the channel will be excellent, however, provided there is a current to carry away the material thus placed in suspension. Using a certain special type of suction head, remarkably satisfactory results have been obtained in moderately stiff mud. Where the distance to the dumping grounds has been relatively short, costs as low as $0.03 per cu. yd. (hopper measurement) have been achieved, this figure being exclusive of capital and administrative items.

With anything approaching a moderately stiff clay, so far as the writer is aware, drag-suction equipment has been a miserable failure. It hardly seems possible, in a location consisting of shifting mud flats, that there should be any trouble from this source. However, the material is described as being very firm, although it cannot be classed as a real clay. It is further stated that considerable resistance is presented to grab or bucket dredges. A first-class bucket dredge is capable of excavating very hard material. Any substance which presents a marked resistance to such a tool might well prove impossible for a drag suction.

There seems at least a possibility that the pipe-line dredge has been dismissed without giving it sufficient consideration. The outstanding objection to the use of such equipment in the present instance is the exposure to rough water. It is quite true that a pipe-line dredge could not be operated in such a location satisfactorily if held in position by spuds. It might be entirely feasible, however, to dig on wires.

Another difficulty would be with the pipe line itself, which would need to be of special and rugged design. So far as the writer knows, no equipment which would exactly meet the present condition has ever been built, for the

* Cons. Engr., San Francisco, Calif.

reason that it would be quite expensive and that there was little or no demand for it; but there is no evident difficulty that could not be overcome.

The author states and the writer agrees that, other things being equal, such a tool would be preferable. One important possibility is that the material, if it is anywhere near as stiff and sticky as the description indicates, would pile up at the end of the pipe line to a considerable extent, thus forming a bank alongside the channel. Such a bank would be subject to attack by wave action, but, nevertheless, it would remain a very distinct shoal, and tend to perform the function of a training wall, for a considerable period.

One of the great advantages of a pipe-line dredge is that when it is working at all it is working continuously. Except when interrupted by serious storms, a properly designed plant under the given conditions should be able to work 22 actual pumping hours per day, 25 days per month (if shut down on Sundays). The author states that the weather is moderate and the water calm 80% of the time throughout the year. If there should be a 20% loss of time due to rough weather, this time could be partly used for plant repairs and maintenance, giving an actual pumping time of 440 hours per month, or about 5 200 hours per year.

A dredge of the seaworthy characteristics required could easily be designed to have a capacity of 4 000 cu. yd. per hour, giving a capacity of 20 000 000 cu. yd. per year. Such output may appear fantastic to one not familiar with the latest developments in plant of this kind, but it is not much beyond the range of the writer's own personal experience. For instance, he has seen 2 000 cu. yd. per hour pumped through 1 500 ft. of floating 22-in. pipe line, the material being a mixture of 60% stiff mud and 40% broken oyster shells, which is a combination not particularly easy to pump. This particular dredge had about 1 200 h. p. (900 kw.) on the pump shaft.

Even should the capacity be grossly over-estimated, due to lack of familiarity with the material and the local conditions, still two such units would certainly be able to greatly exceed this annual output, if they could be used at all. A unit such as is contemplated, together with all its attendant auxiliaries, could be built in the United States for a cost probably under $1 000 000. In this country the operating cost of such a unit, exclusive of capital and administrative charges, but including maintenance and renewals, should not exceed $50 000 per month. These expenditures, both capital and operating, are materially below those given by the author.

With such an increase in the dredging capacity possible, much of the force would be lost from the argument that the cut should be deepened gradually and uniformly throughout its entire length. Of course, there would be considerable silting in the cut, but probably not enough to affect seriously the problem. Certainly, also, a part of the material pumped would find its way back into the excavated channel, but not as great a part of the actual quantity pumped as would be the case with a hopper dredge.

Many practical details of such a dredging plant would require special study for solution. One of the most important elements would be the pipe line and the method of controlling it. The line should have as little excess

buoyancy as possible, as one with a large excess of flotation would pound itself to pieces in a seaway. The effect of the strong currents on the floating line should also be carefully considered; likewise the method of holding and moving it. Doubtless some of the floats would go aground on the spoil-bank, but with the large range of tide the line should float at high water and could be shifted ahead at that time. The moorings to hold a large dredge on a mud flat should be given special consideration; likewise the means for shifting—always remembering that these operations must be carried on regularly in rather rough water. For anything like satisfactory running time it would be necessary to re-fuel while dredging, which would probably preclude the use of anything but oil fuel. It is suggested that, for power, first consideration be given to a direct-connected Diesel drive for the pump, and Diesel-electric drive for the cutter, swinging engines, and auxiliaries.

The writer has been encouraged to advance his present suggestion by a consideration of the depths of water that seem to exist in the vicinity. A greater part of the area over which it is desired to dredge appears to be protected somewhat by a rather extensive stretch of comparatively shallow water to seaward. Under such conditions a very nasty choppy sea may exist, one quite dangerous to small craft, but different from the heavy destructive surf which may be encountered where there is deep water in the immediate vicinity of a shoal. If there should exist in the locality in question the heavy breaking seas to be found at times in such places as San Francisco Bar, Eureka Bar, or Humboldt Bar, on the Pacific Coast, for instance, then only a highly mobile plant, such as a self-propelled hopper dredge, could be considered. It might be that a combination of the two tools would give the best solution, a self-propelled dredge for use on the outer part of the bar where the exposure is greatest, and a pipe-line machine for use farther in where the expanse of shallow water had broken up the heavier seas.

In any case the advent of a typhoon is an entirely different matter. The approach of such a storm can be detected, and retirement of all plant should be made to the most sheltered spot within reach. This would necessitate the services of a very able sea-going tug which should be available at all times. No dredge that the writer can imagine could successfully ride out a typhoon while lying on the bar.

Paper No. 1699

RE-DESIGNING CATAWBA STATION FOR SERVICE ON A LARGE TRANSMISSION SYSTEM*

By W. S. Lee,† M. Am. Soc. C. E.

With Discussion by Messrs. H. A. Hageman, H. V. Joslin, T. H. Hogg, and W. S. Lee.

Synopsis

This paper describes the re-design and re-construction of the first hydro-electric power station of the Duke Power System in the Carolinas, now (1927) comprising twelve water-power and six steam-power plants of an aggregate installed capacity of 749 925 kv-a., feeding a transmission system of approximately 3 000 miles of electric circuits.

This plant, located on the Catawba River near Rock Hill, S. C., had an original installation of eight rope-driven generators of 5 600 kw. total capacity. The head of water was 23 ft. Operation of the plant began in 1904, and power was transmitted at 11 000 volts to adjacent territory. After twenty years' operation of the plant, it was decided to raise the dam 47.6 ft., and the reconstructed plant is now operating under a maximum head of 70 ft. The new power-house installation consists of four vertical-shaft, water-wheel-driven generators of 60 000 kw. total capacity. The current is stepped up to 100 000 volts for transmission.

Since the beginning of the Twentieth Century the electric light and power industry has developed rapidly and a modern hydro-electric system now consists of a group of stations of various kinds, which may be described, as follows:

First.—Stations that use the fall and run of the river.

* Presented at the meeting of the Power Division, Asheville, N. C., April 21, 1927.
† Vice-Pres. and Chf. Engr., Duke Power Co., Charlotte, N. C.

Second.—Stations that use the fall and run of the river plus a small amount of storage, taking care of the night and Sunday flow and perhaps of minor weekly fluctuations of the flow of the river.

Third.—Stations that have a large storage capacity and are used as a valve or outlet to supply the deficiency in power of other stations during low-water seasons.

In addition to the hydro-electric stations, the present large power system usually comprises a number of steam-power stations which, preferably, are located at, or in proximity to, industrial centers so as to reduce the losses in transmitting the power to the points of delivery. They have various efficiency ratings, depending on the time they are intended to be operated in conjunction with the hydro-electric plants, and they may be divided into the following classes:

1.—Plants designed to operate intermittently and during low-water periods; termed "stand-by plants".

2.—Plants designed to operate twelve months of the year and capable of supplying a constant amount of power; termed "base plants".

Finally, by interconnecting the trunk lines of the transmission systems of large independent power companies operating in adjoining districts, energy can be transferred from one district to another in a so-called super-power zone, the principal object being to insure a reliability of service and to make possible a more effective utilization of the water power from streams having different characteristics of flow.

The Duke Power System, in the Piedmont Section of the Carolinas, is now (1927) operating twelve water-power plants and six steam-power plants which may be grouped as follows:

	Installed capacity, in kilovolt-amperes.
A.—Run of River Hydro-Electric Stations:	
Greatfalls	30 000
Dearborn	56 250
Total	86 250
B.—Hydro-Electric Stations with Storage Ponds:	
Lookout Shoals	22 800
Rocky Creek	30 000
Cedar Creek	56 250
99 Islands	22 500
Total	131 550
C.—Hydro-Electric Stations with Large Storage Reservoirs:	
Bridgewater	25 000
Rhodhiss	31 875
Mountain Island	75 000
Catawba	75 000
Fishing Creek	37 500
Wateree	70 000
Total	314 375

FIG. 1.—GENERAL VIEW OF THE OLD CATAWBA PLANT.

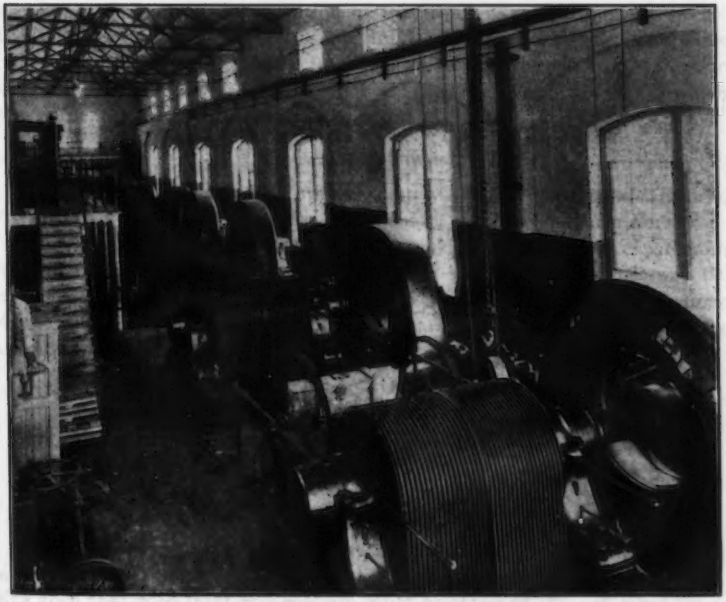

FIG. 2.—INTERIOR VIEW OF OLD CATAWBA STATION.

	Installed capacity, in kilovolt-amperes.
D.—Stand-by Steam Stations:	
Greenville	8 000
Greensboro	8 000
Total	16 000
E.—Base Steam Stations:	
Tiger	37 500
Mount Holly	45 500
Eno	31 250
Buck	87 500
Total	201 750

These power stations, of an aggregate installed capacity of 749 925 kv-a., feed into a transmission system consisting of approximately 3 000 miles of circuits, of which more than 50% are 100 000-volt, steel-tower lines. These power lines serve a territory approximately 350 miles long and 150 miles wide, and the trunk lines are interconnected with the transmission systems of three independent companies all of which operate in the Southeastern Power Zone comprising the States of North Carolina, South Carolina, Georgia, Alabama, and Tennessee.

In 1904, when the Catawba Power Company, now forming part of the Duke Power System, began operation of the 10 000-h. p. development on the Catawba River at India Hook Shoals, 6½ miles north of Rock Hill, S. C., three 11 000-volt pole lines, of 28 miles total length, carried the electric current to the Towns of Rock Hill and Fort Mill, S. C., and Charlotte, N. C., which latter point was 18 miles distant from the power plant.

Old Catawba Station

The first plant of the Duke Power System was called the Catawba Station (Fig. 1), and contained eight horizontal-shaft, rope-driven generators, four of 750 kw. each, and four of 900 kw. each, making a total rated capacity of 6 600 kw. (Fig. 2). The speed of the horizontal-shaft, triple turbines was 110 rev. per min., and that of the three-phase, 60-cycle, 11 500-volt generators, 300 rev. per min. The normal head of water at the station was 23 ft. and the guaranteed efficiencies were, as follows:

	Efficiency, percentage.
Turbines	80
Generators	94
Rope drive	94
Over-all efficiency	70.7

The highest flood on record at that time was 27.1 ft. above normal tail-water level, and the generator floor was 1 ft. higher, the station arrangement being such that good light and cool air could be obtained through windows on both sides of the power house.

The impounding structure of the plant consisted of a curved spillway, 585 ft. long, of standard ogee type, built of bulk concrete masonry, with an

average height of 34 ft. above the bed-rock foundation. An earth dam, 400 ft. long, with slopes riprapped on both sides, was rebuilt and raised after the July, 1916, flood, when the river discharge exceeded the 1901 flood by 100 per cent.

The drainage area of the Catawba River at the station is 3 085 sq. miles, the pond area was 1 800 acres, and the available storage capacity, 202 000 000 cu. ft. Before the large storage reservoirs were built on the Upper Catawba River, the stream carried large volumes of silt in suspension during flood stages, a considerable amount being deposited in the Catawba pond, so that after twenty years' operation of the plant barely the night low-water flow of the river could be stored when the plant was not operated 24 hours.

Following the July, 1916, flood, the Duke Power Company built three large storage reservoirs on the Catawba River above the station for the purpose of impounding the high waters of the Upper Catawba River for use during periods of low water on the Lower Catawba. This resulted in a large increase of uniform flow at the Catawba Station and the question arose whether additional machinery should be installed and the old plant overhauled; whether the dam should be raised so that the water would back to the tail-race of the Company's, Mountain Island Station, 25 miles farther up stream, thus creating another large storage reservoir; or whether an entirely new power house should be built and the old power plant representing a value of approximately $1 000 000, scrapped.

A topographic survey of the entire storage basin was then made, and it was found that for a development of 70-ft. head, which called for a raising of the old spillway 47.6 ft. above the top of the flash-boards, the superficial area of the full reservoir was 12 455 acres and the available storage capacity 10 300 000 000 cu. ft. considering a 30-ft. draw-down. In view of the fact that this storage was available not only for the new Catawba Station, but also for the existing stations of the Duke Power Company, on the Lower Catawba River, having a combined mean head of 250 ft., authority was given, in August, 1924, to raise the old dam and to build a new power station.

Designing Features of New Plant

As shown in Fig. 3, the new station is on the left side of the river, looking down stream, and the lower part of the south end of the substructure is built against the retaining wall for the old earth fill. The developed length of the new spillway is 802.93 ft. measured between centers of flood-gate piers. Referring to Fig. 4, the spillway contains eleven steel flood-gates, 45 ft. wide by 30 ft. high, and one smaller gate, 19 ft. wide and 25 ft. high. The curved section of the spillway, 168.52 ft. long, contains no flood-gates and the top is at Elevation 570.0, corresponding to the top of the flood-gates when in closed position. The space occupied by the masonry supporting gates, Nos. 9, 10, and 11, and the small gate, contains the substructure of the old power house.

The raised spillway follows the same alignment as the old spillway and the new masonry is built on top, against the down-stream face of the old masonry, as indicated on Fig. 5. Three 12 by 12-in. drains running along the rollway of the old structure are formed in the new masonry and are provided with 12 by 12-in. side outlets, at 55-ft. intervals, by which any seepage water from the

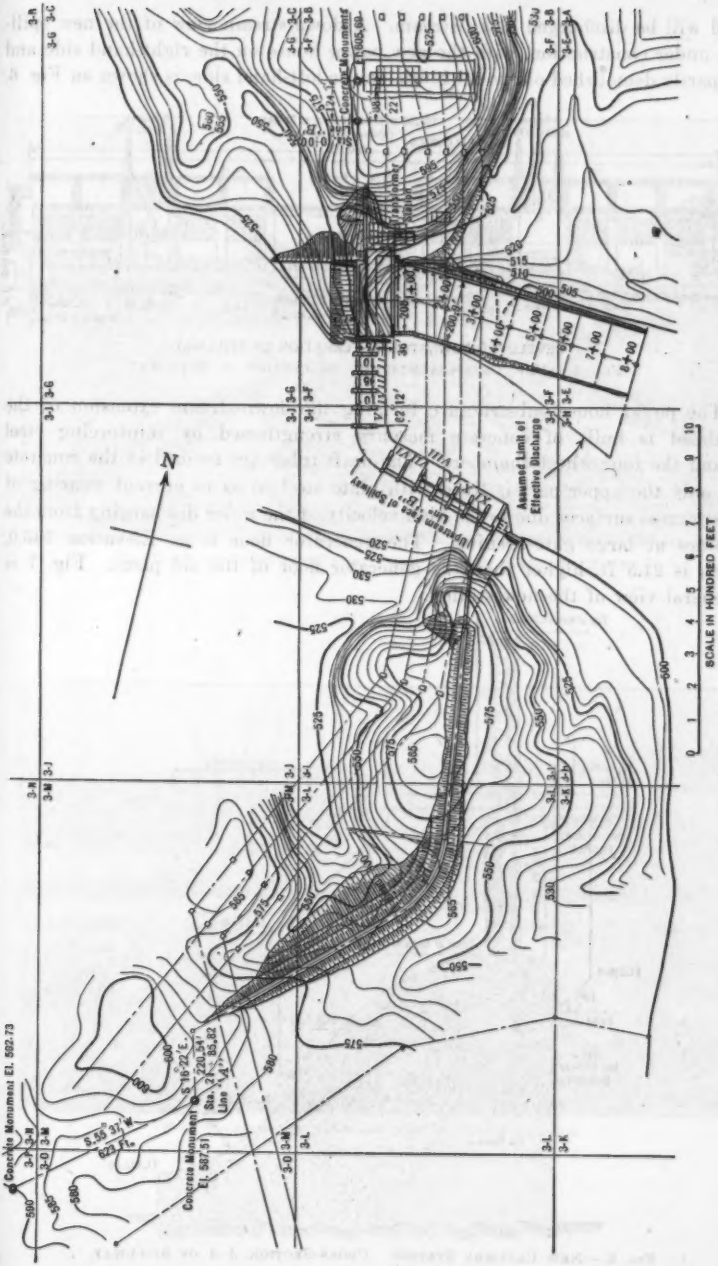

FIG. 3.—GENERAL PLAN OF NEW CATAWBA STATION.

pond will be discharged down stream. A down-stream view of the new spillway under construction, with the new power house on the right-hand side and the partly demolished old power house on the left-hand side, is shown on Fig. 6.

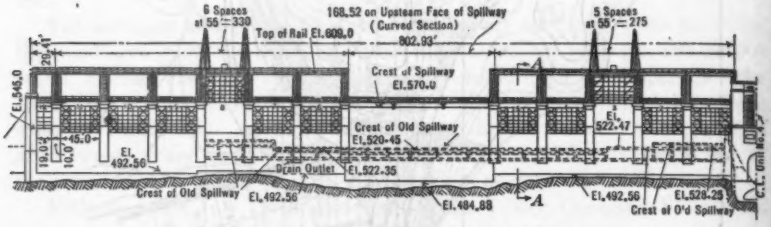

FIG. 4.—NEW CATAWBA STATION. ELEVATION OF SPILLWAY.

The power house substructure forming the down-stream extension of the bulkhead is built of concrete masonry strengthened by reinforcing steel around the four wheel chambers. The draft-tubes are formed in the concrete and only the upper part is lined with plate steel so as to prevent wearing of the concrete surfaces due to the high velocity of the water discharging from the turbines at large gate-opening. The generator floor is at Elevation 545.0, which is 21.5 ft. higher than the generator floor of the old plant. Fig. 7 is a general view of the new station.

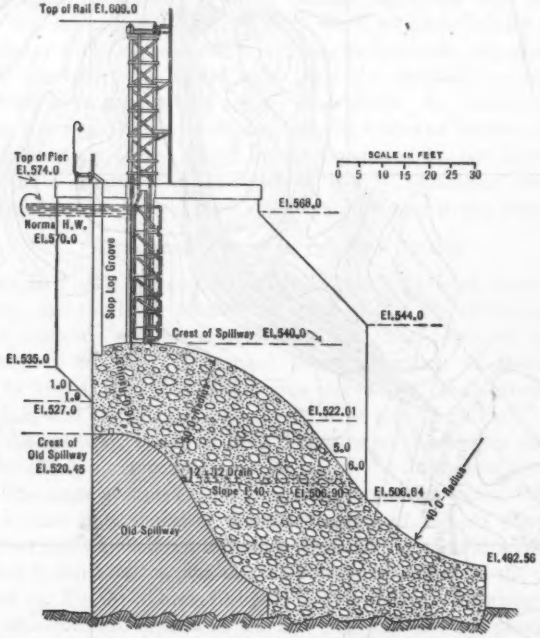

FIG. 5.—NEW CATAWBA STATION. CROSS-SECTION *A-A* OF SPILLWAY.

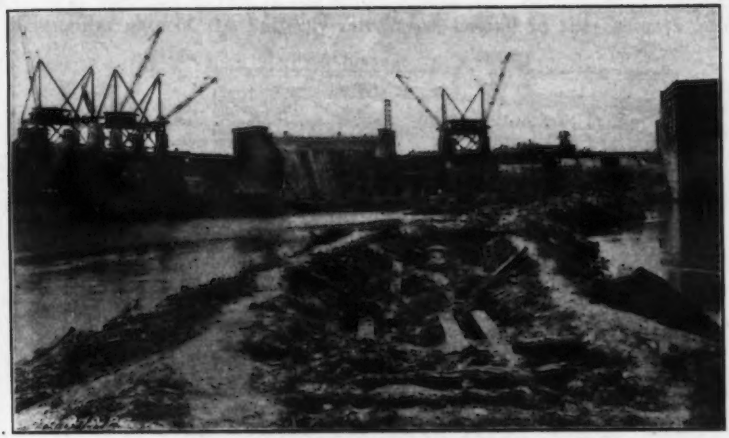

FIG. 6.—NEW SPILLWAY UNDER CONSTRUCTION, CATAWBA PLANT.

FIG. 7.—GENERAL VIEW OF NEW CATAWBA STATION.

The rack structure at the up-stream face of the power-house bulkhead is built of reinforced concrete and structural steel, the spacing of the rack bars being 4½ in., center to center. The intake to each turbine flume consists of two 18 by 25-ft. openings formed in the concrete masonry. Each opening contains a rectangular gate of the butterfly-valve type, having in the center a cast-

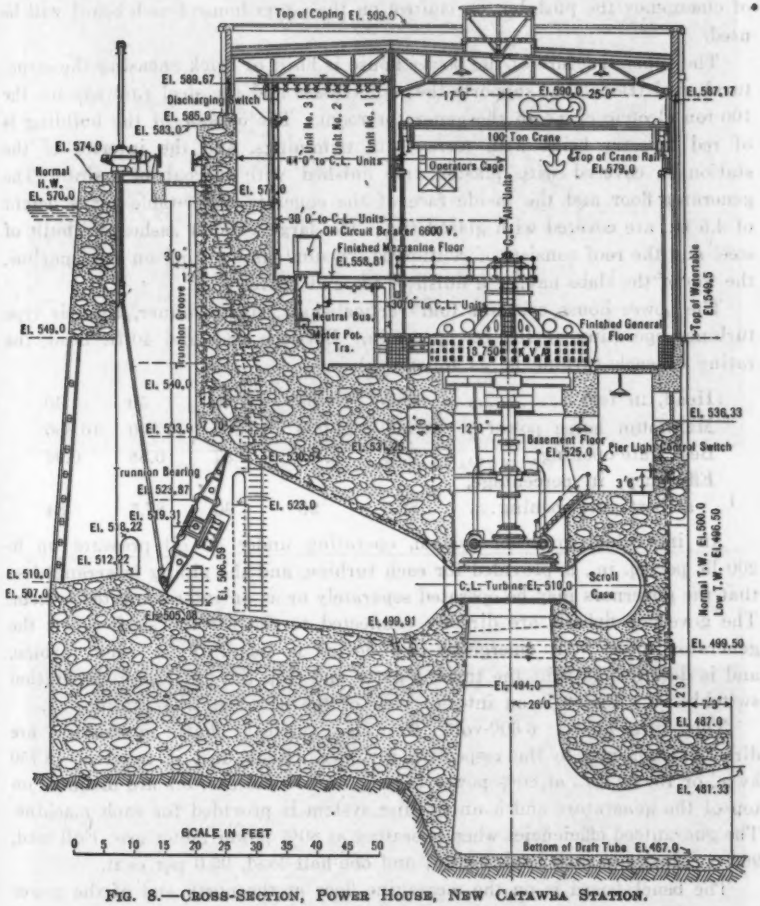

FIG. 8.—CROSS-SECTION, POWER HOUSE, NEW CATAWBA STATION.

steel girder, 3 ft. deep and 2 ft. 8 in. wide, with bronze-bushed trunnions, 28 in. in outside diameter and 20 in. long, at each end. The wings of cast iron are firmly attached to the girder by machine bolts and shrink rods. A built-up cast-iron wall-frame securely anchored to the masonry is provided with machine-finished surfaces at its lower half at which point the surfaces of the gate and wall-frame come in direct contact. The upper half of the wall-frame has machine-finished beveled faces conforming to similar surfaces of the gate. The slot between the upper half of the gate and the wall-frame is sealed by a

set of brass flaps attached to the up-stream side of the frame. Each gate is operated by an individual, completely enclosed, electrically operated hoist on top of the power-house bulkhead, as shown in Fig. 8. A gate-position indicator is provided on top of the hoist. Normally, the head-gate motor will be operated by means of a push-button control system on top of the bulkhead and in case of emergency the push-button control on the power-house bench-board will be used.

The superstructure of the power house is built of brick encasing the structural steel frame that supports the roof trusses and the steel runways for the 100-ton electric crane in the generator room. The outside of the building is of red tapestry brick with terra cotta trimmings, and the interior of the station is covered with plaster and finished with a coat of paint. The generator floor and the inside face of the concrete water-table for a height of 4.5 ft., are covered with glazed tile. The large window sashes are built of steel and the roof consists of reinforced gypsum slabs resting on steel purlins, the top of the slabs having a finish of tar and gravel.

The power house contains four vertical-shaft, single-runner, Francis type turbines operating at 100 rev. per min. Between 68.5 and 40-ft. head, the rating of each turbine is, as follows:

Head, in feet	68.5	65	60	50	40
Maximum horse power..	22 500	21 000	19 000	14 800	10 600
Best gate-opening.....	0.85	0.86	0.87	0.88	0.96
Efficiency, in percentage, at best gate-opening...	89.5	90	90	87.5	84

An individual governor system, operating under an oil pressure up to 200 lb. per sq. in., is provided for each turbine, and the piping is arranged so that the governors may be operated separately or as an interconnected system. The governor flyballs are directly connected to the turbine shaft below the generator rotor. An emergency-stop device is installed for each turbine, and is designed to shut the turbine gates and stop the unit from the station switchboard. Fig. 9 is an interior view of the new Catawba Station.

The three-phase, 6 600-volt, 60-cycle, vertical shaft generators are directly connected to the respective turbines. Each unit is rated at 18 750 kv-a., or 15 000 kw., at 80% power factor. Individual exciters are mounted on top of the generators and a unit oiling system is provided for each machine. The guaranteed efficiencies when operating at 80% power factor are: Full load, 96.3%; three-quarters load, 96.0%; and one-half load, 95.0 per cent.

The bench-board is on the mezzanine floor at the north end of the power house. Through four water-cooled, outdoor-type, transformers of the same capacity as the generators the current is stepped up to 100 000 volts and then fed into the transmission system of the Duke Power Company. A view of the outdoor transformer station nearing completion is shown in Fig. 7.

The tail-race is 800 ft. long, and if the four units are operated at seven-eighths gate-opening and under 65-ft. head, the discharge is 12 000 cu. ft. per sec. Under these conditions the mean velocity of the water in the smallest tail-race section is 4.0 ft. per sec.

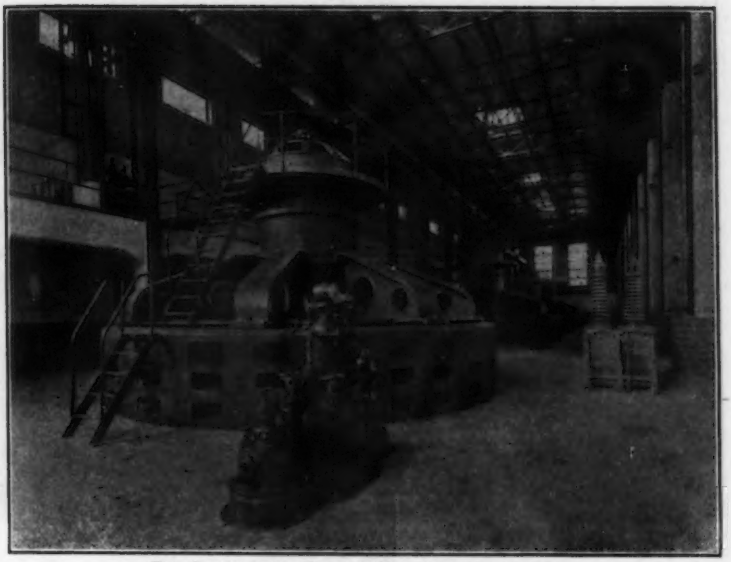

FIG. 9.—INTERIOR VIEW OF NEW CATAWBA STATION.

FIG. 10.—VIEW OF CONSTRUCTION TRESTLE ON TOP OF OLD SPILLWAY, CATAWBA STATION.

Construction Features of New Plant

As part of the construction program, the old Catawba Station was to be kept in operation until the first machine in the new power house was ready to be started under a reduced head. It was known that high water was likely to occur at any time of the year, calling for the least obstruction to the spillway during the construction period. It was decided, therefore, to build a steel trestle on top of the old spillway, carrying two lines of standard track and a runway of 32 ft. 3-in. gauge, to accommodate three traveler cranes for use in the construction of the new masonry, as shown in Fig. 10.

The steel bents forming part of the construction trestle were spaced on 27½-ft. centers, and the top of the rail was 26 ft. above the crest of the main section of the old spillway. By this arrangement the track stringers and girders forming the top part of the bents could be located above the seat of the flood-gates at Elevation 540.0, thus permitting an easy removal of the heavy steel members after the masonry was laid. The legs of the steel bents were embedded in the new masonry. Each traveler crane consisted of two stiff-leg derricks, with individual hoisting engines mounted on top of a portal of steel construction, capable of handling a load of 10 tons per boom at a radius of 80 ft. and of 20 tons per boom at a radius of 40 ft.

As it was required to complete the new power house before the dam was raised to its full height and the flood-gates were installed, the work of excavating the foundations and of laying the masonry for the power house bulkhead and substructure was arranged so that the old earth fill on the north side of the river could be used as a temporary dam. As seen in Fig. 11, this necessitated the removal of nearly the entire down-stream portion of the old fill. However, neither heavy rainfalls nor high waters which might have caused slides and delayed the completion of the power-house substructure, occurred during this critical period. A traveler crane served in the construction of the concrete masonry and the placing of the turbine parts embedded in it. This crane was similar to those described previously, but with runways on top of a set of wooden trestles located immediately below the down-stream face of the new power-house substructure.

The crusher and concrete mixer plant (Fig. 12) was about ¼ mile below the power-house site. The primary crushing was done by a 48 by 60-in. jaw crusher and the secondary crushing by four No. 6 gyratory crushers. The rated capacity of the plant was 200 tons of 2½-in. ring stone per hour. The cement house was designed to handle cement in bulk, and the framework for the mixer plant was structural steel, constructed so as to allow the steel to be re-used on similar jobs elsewhere. The concrete was mixed in two 2-yd. tilting mixers and delivered to the site in bottom dumping buckets. All the concrete was deposited in place by gravity. Typical elevations of the crusher and mixer plant and of the cement-handling plant are shown in Fig. 13.

Construction of the new plant was commenced in August, 1924, and the co-ordination of the work done was such that, on August 8, 1925, the old Catawba Station could be shut down and Generator No. 1 in the new station put on the line two hours later. The old station was then dismantled and the new plant was entirely completed at the end of December, 1925.

DISCUSSION

H. A. HAGEMAN,* M. AM. SOC. C. E. (by letter).—The re-development of the power site on the Catawba River at India Hook Shoals twenty-three years after the original project was put into operation, is an excellent example of the possibilities that exist in modernizing old hydro-electric plants.

It shows the opportunities that are open to the engineer to make use of his skill and experience in creating a new development that will produce power and energy from the water more efficiently than formerly. Many water-power developments that have been in operation over a long period of years, have antiquated power-generating equipment that is uneconomical from the standpoint of output and maintenance as compared with present-day hydro-electric machinery. The hydraulic structures of an old development, such as the dam, head-works, water conduits, and power station, may be in good condition but the machinery for transforming the potential energy of the stream into electric current is often inadequate if the maximum amount of power and energy is to be obtained.

The re-development makes a much greater utilization of the stream flow than formerly and permits a large increase in the production of power and energy with considerable gain in efficiency. The increased capacity and energy output is due to the larger storage that has been created, the greater head used, and the higher efficiency of the modern hydro-electric generating and transmitting equipment.

The increase in head from 23 ft. to a maximum of nearly 70 ft. emphasizes the advantage resulting from a condition often encountered on Southern and Western rivers, of the absence of extensive construction in the river valleys. Fear of the oft-recurring floods and various other considerations have caused the inhabitants to do most of their building on high ground back from the river and to reserve the river-bank meadows for agricultural purposes. This results in a much lower flowage cost, when a material rise in water level is made, than is usually found on Northern or Eastern streams. Another distinct advantage to water-power development on many of the Southern streams is that the railroads, except in the mountains, generally follow the higher land of the divides and cross the river valleys instead of following the river bank, as is usual in the Northern and Eastern States.

During the period between the construction of the old and the new developments described by the author, considerable progress was made in the art of hydro-electric power generation and in the transmission of electric energy in large quantities. Probably the greatest advance was in the design of hydro-electric machinery; more particularly the water-wheel equipment, in the use of direct-connected vertical shaft units, and in the elimination of inefficient mechanical power transmission. It is also true that the improvement in the methods of analyzing stream flow, greater economy in the design of hydro-electric structures, and more efficient power trans-

*Chf. Hydr. Engr., Stone & Webster, Inc., Boston, Mass.

mission over long distances, have contributed to the progress realized. In view of this statement a comparison of the hydraulic features of the old and the new Catawba developments might be of interest.

The new station contains only one-half as many units as the old one, while the combined rated capacity is increased from 6 600 kw. to 60 000 kw. The new units are of the single, Francis runner, vertical-shaft type, each direct-connected to the generator, while the old units were of the horizontal-shaft type with triple Francis runners, each water-wheel unit delivering its power to the generator through a rope-drive. The over-all efficiency of the old units is stated as being 70.7%, while the combined efficiency of the new units is about 87%, an increase of 23 per cent. The generating equipment in the old station required about 0.73 cu. ft. per sec. to produce 1 kw., while in the new development, with the increase in efficiency and in head, the same result is obtained from about 0.20 cu. ft. per sec. under the maximum head, beside the large increase in output due to greater use of storage.

It is interesting to note that valves of the butterfly type, for water control, are used in the inlets to the new units. This type of valve has been used in water-power developments for a long time, but it is only within the last few years that it has been improved so that it could be used for large openings without excessive leakage. There is a great diversity in the type of control mechanism used and in the devices adopted to reduce leakage. It is understood that the Duke Power System has several installations of large butterfly valves, using the spring brass flaps attached to the up-stream side of cast-iron wall-frames to secure water-tightness. It would be of considerable interest to know how these have worked out in service, both as regards water-tightness and as to whether there has been any trouble from material lodging on these flaps. It would also be of interest to know the amount of power necessary to operate these gates under different conditions of flow, using the tension-rod type of control mechanism. The use of the direct-connected flyballs and of complete individual units in the governor system is typical of present practice.

It is evident that the flood conditions have been very severe on the Catawba River, since although the generator floor of the old plant was placed 28.1 ft. above the normal tail-water level, and 1 ft. higher than the maximum previously recorded flood level, the flood of 1916 submerged the station with a flow 100% greater than the previously recorded maximum flood. This seems a good reason for making the new generator floor level 21.5 ft. higher than the old floor level, or nearly 50 ft. above the normal tail-water level. This excessive flood condition is probably one explanation of the use of the very large flood-gates, 45 ft. long by 30 ft. high, although there may be other reasons for selecting these large gates in place of a greater number of smaller ones.

From the data given in the paper, it is noted that the usable storage has been increased from about 5 000 acre-ft. to about 236 000 acre-ft. This new storage changes the power and energy aspect of the possibilities at this site. Formerly, there was only sufficient pondage available to enable the flow to meet the daily load factor of the station, but now there is a large

regulated flow available, which can be used efficiently during periods of drought.

The lack of natural lakes and storage basins on the rivers in the southeastern part of the United States makes all artificial storage especially valuable, and the relative increase in the primary flow of the stream is often much greater than with an equal amount of additional storage developed on rivers with equal drainage areas in the Northern States.

The development and use of the large storage basins must have a considerable effect on the peak floods of the river and must be a valuable asset to all property owners along the lower valley.

It has been stated that large quantities of silt have been carried by the stream during high-water periods before the development of storage reservoirs. Any definite data regarding the lessened quantity of silt carried with the present storage conditions, or the rate of deposition of silt in the various storage basins, would be valuable. It is understood that this river is used for water supply in several instances. There must be considerable benefit from having clearer water.

The growth of the system load has apparently been very rapid, requiring frequent increases in power facilities, and this particular re-development may be taken as a notable achievement of present-day practice.

The tremendous increase in the size of single units that manufacturers are able to build, has given a great impetus to re-development of old plants. The use of the present modern reaction and propeller type runners, efficient vertical thrust bearings, improved draft-tubes, and large control gates, have all been factors contributing to the construction of more efficient and larger single units. Some of the points mentioned are illustrated by the following hydro-electric developments.

At the Garvin's Falls Plant of the Manchester Traction, Light, and Power Company, of Manchester, N. H., on the Merrimack River, the old plant consisted of six horizontal-shaft, triple-turbine, direct-connected units, under 30-ft. head. These were installed about 1900, and two units had new horizontal-shaft runners installed about 1920. In 1924, the four old, 800-kw., horizontal units were removed and two new vertical-shaft, propeller type turbines with direct-connected generators were installed. These new units are 3 000 and 4 000 kv-a., respectively. They increased the station capacity 50% with a corresponding increase of only 15% in the quantity of water required. The turbines are equipped with plate-steel Hydraucone draft-tubes, direct-connected governor flyballs, and adjustable lignum-vitæ guide-bearings.

In connection with this re-development, the plant at Kelley's Falls, on the Piscataquog River, was built over from a two-unit, horizontal-shaft, rope-drive plant, very similar to the Catawba Plant, to a single-unit, automatic, vertical-shaft, propeller type, direct-connected plant.

Another instance of the utilization of the power available under a very low head by means of propeller type runners is the Green Island, N. Y., development of Henry Ford and Son, Incorporated. This plant has a normal head of 13 ft., which is considerably reduced during high water, and contains

four 2 000-h.p. wheels, having 4-blade runners 156 in. in diameter, in a siphon flume setting.

A recent development containing modern, vertical shaft, Francis turbines, each 25 000 h.p., under 112-ft. head, and direct-connected to alternating-current generators, is the Bartlett's Ferry development of the Columbus Electric and Power Company. These units have elbow type draft-tubes.

An interesting example of the application of a butterfly valve for use as a head-gate to a water-wheel unit will be found in the Conowingo development now (1927) under consideration for The Susquehanna Power Company. Each water-wheel unit, which will have a rated capacity of 54 000 h.p. at full gate and 89-ft. head, will be equipped with a vertical shaft, cast-steel butterfly valve, 27 ft. in diameter, provided with specially designed rubber sealing devices. These valves will be the largest ever constructed and will be located directly at the entrance to the scroll-cases. Before selecting this type of valve a careful investigation was made of all types of head-gates with a view to securing the most satisfactory installation from the standpoint of cost and operation. The valves, as installed, will insure the least leakage of any type of gate under the particular conditions. They will be operated from the power-house floor and can be installed or dismantled by the main station cranes. This type of valve has permitted the most economical power-house design.

H. V. Joslin,* M. Am. Soc. C. E.—There is no question but that terracing the arable land would be of advantage to the power companies in that it would diminish silting in their reservoirs; but the speaker does not think missionary work of this nature among the farmers by agents of the power companies would pay for itself for some time to come.

Mr. Lee mentions the flood of 1916, when the river discharge was twice as much as had been heretofore recorded. This flood was considerably greater per square mile of drainage area on the Catawba than it was on the Pee Dee, where the Blewetts Falls Station of the Carolina Power and Light Company is located. The drainage area at the latter point is about twice that at Catawba, and, after data were received from the Southern Power Company of the discharge at Catawba, preparations were immediately made by the Carolina Power and Light Company to strengthen the Blewetts Falls dam and power house in anticipation of a similar flood.

It was discovered that in the event of such a flood the power house itself would probably float, and it was decided to anchor it to the rock below by drilling several holes about 35 ft. long through the concrete, and grouting reinforcing rods into place. Tripod drills of the largest type were used, and steel was obtained from Norway. Several of the holes had to be drilled through the generator-room floor through which a number of conduits had been placed, presumably according to blueprints that were available. Special precautions were taken to avoid hitting these conduits, but without success, and had it not been for the fact that the plant was idle most of the time, due to lack

* Engr., Carolina Power & Light Co., and Affiliated Cos., Raleigh, N. C. Mr. Joslin died November 3, 1928.

of water, the job would doubtless have cost considerably more. The water shortage was caused by the filling of the reservoir of the Tallassee Power Company farther up the river.

There has not been any flood in the river since, that has approached that of 1916 in intensity, and, inasmuch as since that time three large storage reservoirs have been built above Blewetts Falls, there will probably be no opportunity to test the efficacy of this anchorage. Mr. Lee's paper is very valuable, particularly at this time when, due to the great increase of efficiency in modern turbines and generators, many of the older hydro-electric plants are becoming obsolescent and sooner or later will require drastic remodeling. Probably not all of them will be rebuilt as completely as was the Catawba Station.

T. H. Hogg,* M. Am. Soc. C. E.—Hydro-electric problems in Ontario, Canada, are somewhat different from those in the region to which this paper applies. High flood flows are not experienced as frequently, and more extensive lake systems tend to equalize the flow. To take a specific example: on one of these river systems the drainage area is between 9 000 and 10 000 sq. miles, and lake systems thereon are so extensive as to permit almost complete regulation over a 5-year low-water period. The total run-off per square mile is less than in the South, amounting to 0.6 to 1.3 cu. ft. per sec. in this system.

There are some features of the paper that are of special interest in connection with the present situation in Ontario, as similar problems of load growth and of re-design and rehabilitation of plants are to be met. This is particularly true of the Niagara System, which covers the southwestern part of the Province and is fed by plants situated at Niagara Falls. The Hydro-Electric Power Commission controls three of the four large developments on the Canadian side of the river there; that is, the Toronto Power Plant (having a capacity of 150 000 h.p.), the Ontario Power Plant (180 000 h.p.), and the Queenston Plant (550 000 h.p.). The first unit of the Queenston Plant came into service in the spring of 1922. Nine units are now installed, and in December, 1926, the plant carried a load of 540 000 h.p.; that is, an increase in load of this same amount had taken place in the five years since the plant went into service. It will be seen from this that the problem of providing for increasing loads is strikingly similar to those outlined by the author.

Problems of design are somewhat different from those of the Catawba Station. The Toronto Power Plant was one of the first built at Niagara Falls, and, while the gross head is about 180 ft., the operating head, on account of large draft-tube and tail-race tunnel losses, is only approximately 135 ft. The efficiency of the development, based on the gross head, is less than 50 per cent. At Queenston the over-all efficiency is 91%, based on a 305-ft. head. In other words, Queenston delivers 30 h.p. per sec-ft. of water used, and the Toronto Power Plant delivers less than 10 h.p. International agreements fix the quantity of water that may be used to develop power, which means that to obtain additional power it will be necessary to curtail the output of the low-head and low-efficiency plants and use the water thus released more

* Chf. Hydr. Engr., Hydro-Electric Power Comm. of Ontario, Toronto, Ont., Canada.

effectively. This, within a short time, may compel the shutdown of the Toronto Power Plant, unless re-design and rehabilitation can materially modify its water economy.

Changes in the Toronto Power Plant made recently have reduced operating costs. The thrust-bearings in use formerly were of the oil-pressure type, operating at a pressure of 350 lb. per sq. in. These have been replaced by Kingsbury bearings, resulting in an annual saving of $15 000.

Certain operating records from Queenston may be of interest. This plant now (1927) operates on a load factor close to 90% for the whole year. The output amounts to 8 500 000 kw-hr. per day, and the writer believes that in the next two or three years this amount may be increased to 9 000 000 kw-hr.

One of the important operating problems on the Niagara River plants is that of ice control and disposal. The Niagara River is, of course, an open river at all times, but it carries enormous quantities of ice, which appears first about the middle of December and is sometimes present as late as the first of June. Ice flow during April and May, however, is not a menace on account of the high air temperature.

Protective equipment at the plant intakes, such as curtain-walls, overflow weirs, and ice runs, is used, and removes as much of the river ice as possible; but at the Queenston Plant, between the intake and the power house, there is 4½ miles of river section of canal, and 9 miles of excavated section. In addition, there flows into the river section the Welland River, about 45 miles long, which drains the country to the west of the Niagara River. Thus, even if all the Niagara River ice is excluded from the intake, it becomes necessary to cope with the ice formed in the Welland River and the long canal. As a matter of fact, the protective measures at the Queenston intake do exclude practically all the river ice, but at the Toronto Plant a considerable quantity of frazil and slush ice passes directly into the penstocks. The greater part of the ice reaching the head-works at Queenston, that is, the ice formed in the canal, is also of the same type, together with a comparatively small quantity of cake ice. The quantities of ice are so great that if it were not cared for in some way the plants would be shut down in an hour or two. In the first year of operation at Queenston, when the intake works were not complete, large quantities of ice gathered and at times curtailed the plant output appreciably, but since 1925 interruptions to the extent of a single kilowatt have not occurred.

If an attempt were made to by-pass the ice by means of the ice chute, which is provided at the end of the forebay, there would be a considerable abstraction of water that has been drawn through the canal, and a power loss of perhaps 30 000 or 40 000 h.p. The alternative is to allow the ice to pass through the turbines, and this has been done, obviating any curtailment of load. The advantages are so great that in the writer's opinion there is no question as to its being the proper solution.

The same method of disposing of the frazil and slush entering the Toronto Plant is followed there. The racks are removed, as otherwise they would quickly become clogged with ice and shut off the flow to the penstooks.

Too much emphasis can be placed on the necessity of keeping ice out of the plants. With the large machines now available, wheel passages are not readily blocked by the ice flowing in the rivers, and little danger can be involved in the method of operation outlined.

W. S. LEE,* M. AM. SOC. C. E. (by letter).—In the case of the Catawba Station the dam was raised and the power house was rebuilt, thereby obtaining a higher head, a greater utilization of the stream flow, and an increased efficiency due to improved design of the plant and equipment. While it is true that not all the older hydro-electric plants will be rebuilt as completely as the Catawba Station, the time will come when all the water powers of economic value are developed and the rehabilitation of the older plants must be considered if only for the reason of increasing the over-all efficiency and reducing the operating costs.

Mr. Hageman inquires as to the use of large flood-gates for the new Catawba development. The length and alignment of the old power house and spillway determined the effective length of the new spillway, and in order to take care of the extreme flood discharge it was necessary to consider flood-gates of such large dimensions. The wide openings have also the advantage of offering no restriction to large débris and trees which may be carried by the river at periods of high water.

As to the sealing devices for the head-gates, there is some slight leakage, but the drain provided at the lowest point of each turbine flume is more than ample to take care of this flow.

In the storage reservoirs of the Duke Power System no systematic quantitative measurement of silt deposited during high-water periods was made, and, therefore, no definite data are available.

UNUSUAL ENGINEERING FEATURES OF AN IMMENSE THEATRE BUILDING*

By R. McC. Beanfield,† Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Theodore Belzner, Fred A. Noetzli, A. Floris, Laurence J. Waller, and R. McC. Beanfield.

Synopsis

Some of the outstanding features of Al Malaikah Temple, at Los Angeles, Calif., are:

Combination pin and riveted balcony truss, 168 ft. span, weighing 250 tons;
Steel balcony cantilevers with a 45-ft. over-hang;
Stage with double asbestos fireproof curtain, probably the largest constructed to date (1927);
Reinforced concrete stage roof arches supporting steel gridiron which functions as a tie for the roof arches;
Seating capacity of 6 550 in orchestra and balcony;
Reinforced concrete proscenium arch, clear span of 100 ft.;
Auditorium steel roof trusses, one end on rollers, each weighing 60 tons; span, 192 ft.;
Banquet hall reinforced concrete roof arches, span, 90 ft.;
Ventilating system supplying 750 000 cu. ft. of air per min.; and
Stage switchboard and main chandelier, probably the largest yet constructed.

General Description

The Al Malaikah Temple in Los Angeles, commonly known locally as the Shrine Civic Auditorium, is the new home of the ancient Arabic order, Nobles of the Mystic Shrine. It is located at Jefferson, Royal, and Thirty-second Streets, the site of the old Shrine Auditorium destroyed by fire on January 12, 1920.

FIG. 1.—AIR VIEW, AL MALAIKAH TEMPLE, AUDITORIUM IN FRONT, BANQUET HALL AT LEFT.

FIG. 2.—VIEW OF INTERIOR OF THEATRE, SHOWING ABSENCE OF COLUMNS. CHANDELIER IS 22 FEET IN DIAMETER, GIVING IDEA OF SIZE.

The Temple occupies nearly 3 acres (Fig. 1), and may be divided into three units, as follows: The Auditorium, or theatre (Fig. 2), with facilities for housing the various Shrine organizations, such as Patrol, Band, Chanters, etc.; the Banquet Hall (Fig. 4), with a large basement for public exhibition purposes; and a kitchen wing, with facilities for serving large banquets. (See floor plan, Fig. 3.)

The construction throughout is reinforced concrete, except the roof trusses over the Auditorium, the trusses supporting the balcony, and the gridiron over the stage, which are steel.

The Auditorium

The Auditorium Section of the Temple is 200 ft. wide and 294 ft. deep, including the stage. It consists of a reinforced concrete frame with exterior concrete curtain-walls. The roof is constructed with a reinforced concrete joist system, which is supported on structural steel purlin beams connected to the steel roof trusses.

The Auditorium on the south side contains ample dressing-room facilities, including suites for stars. Large dressing rooms for male and female choruses are located in the basement under the stage. The musicians have a rest room and locker facilities. All the dressing rooms are efficiently ventilated and have shower baths.

The Potentate, Divan, Veterans, and various auxiliary organizations of the Shrine, such as the Patrol, Chanters, band, etc., are provided with complete facilities on the second floor on the south side of the Auditorium, which include a kitchen and large dining room.

The Pavilion

The north wall of the Auditorium is equipped with steel rolling fire doors, so that it can be shut off entirely from the Banquet Hall when desired. The large Banquet Hall, or Pavilion, contains 101 000 sq. ft. of floor space, including a large basement used for exhibition purposes; also, ground and second floors with a surrounding cantilevered balcony. There are two adjoining kitchens and serving rooms of capacity large enough to accommodate 10 000 people. The reinforced concrete roof of the Banquet Hall (Fig. 4) is supported on a series of beautiful reinforced concrete Saracenic arches, having a clear span of 90 ft.

The entire ground floor of the Pavilion is finished with white maple flooring, laid on a patented floor filler, called "Nailcrete". The Pavilion is used for art exhibits, civic expositions, and large balls. It has a clear ceiling height of 17 ft. in the basement, where machinery or automobile displays can be installed. Automobile ramps are provided from the Thirty-second Street front to this level. The basement is ventilated by a forced circulating system, the foul air being exhausted at the floor level in order to accommodate automobile exhibits.

The Stage

From a theatrical viewpoint, the Auditorium is one of the largest constructed to date (Fig. 2). Its stage, 72 ft. deep and 192 ft. wide, one of the

largest in the world, was designed to give ample room for the elaborate rituals of Shrinedom, as well as for grand opera and great theatrical spectacles. The orchestra pit can accommodate 200 musicians. The proscenium opening (Fig. 5) has a clear span of 100 ft. and a height of 37 ft. at the crown. The main floor seats 3 200, and the balcony, 3 350. With the exception of 22 seats behind balcony columns, the entire audience has an unobstructed view of the stage. The stage has a seating capacity of 1 700. It will be noted that the balcony seating exceeds that of the main floor.

Balcony Trusses

Preliminary designs and estimates were made for three different systems of truss framing under the balcony (Fig. 6). Scheme *C* was recommended as being the most practical, economical, and rational because:

1.—It contained less tonnage.
2.—Only two steel columns were required as compared to four in other designs.
3.—It contained fewer auxiliary trusses than the others.
4.—It was easier to erect, having fewer units and simpler connections.
5.—There were fewer complications relative to deformation, due to simplicity and the omission of secondary units.
6.—The over-hang of the cantilever trusses, from the main supporting truss, was practically the same, tending to provide uniform deflections in the cantilever trusses, which condition was very desirable, considering the reinforced concrete balcony deck construction.
7.—The entire design was rational, and involved no extraordinary features.

The main balcony risers and treads are reinforced concrete, supported by eight steel cantilever trusses (Fig. 7), having a minimum over-hang of 45 ft., which, in turn, are supported by a main balcony steel truss (Figs. 7 and 8). This truss is, doubtless, the largest steel balcony truss yet constructed for the purpose. It weighs nearly 250 tons, and has a clear span of 168 ft. It is of interest that the balcony truss columns were located to displace a single seat on each side of the Auditorium nearest the aisles adjacent to the walls (shown at *a*, Fig. 3), instead of outside the Auditorium walls, which arrangement would have increased the span 20 ft. The obstructed view for a few seats is relatively unimportant as compared with the increased difficulties in design and greater cost if 20 ft. had been added to the span of the main balcony truss.

As it is necessary to have sufficient clearance through the center part of this main truss for the balcony exit passageways, pin joints and eye-bar diagonals were used instead of the usual built-up members and riveted joints with larger gusset-plates. Riveted joints were used where practicable to obtain general stiffness. Where pins were necessary, nickel steel was chosen particularly to reduce the size of the pin-holes in the lower chord.

Steel Stresses

To avoid excessive moments and restraint due to the large angle of rotation in the truss, a pin-column joint was used. An analysis of the column joint based on a coefficient of friction of 0.25, indicated that the column must

resist moment due to pin friction before the pin could rotate. Few data are available relative to the friction of pins in steel trusses. This coefficient (taken from Professor Föppl) is, at best, only an approximation for this condition.

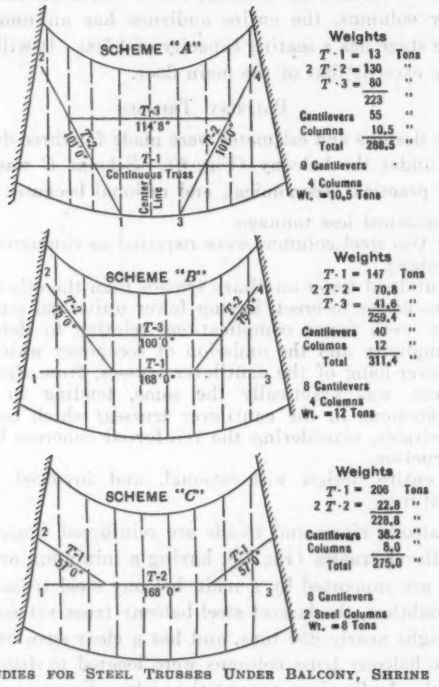

FIG. 6.—STUDIES FOR STEEL TRUSSES UNDER BALCONY, SHRINE AUDITORIUM.

Except for the stresses, the design of the balcony truss was based on the report of the Society's Special Committee on Specifications for Bridge Design and Construction.* The stresses recommended by the American Institute of Steel Construction were adopted. The stresses used for nickel-steel pins were 36 000 lb. per sq. in. in the extreme fiber for bending, 30 000 lb. per sq. in. for bearing, and 20 000 lb. per sq. in. in shear.

SECONDARY STRESSES

Due to the unprecedented size and unusual design of the main balcony truss, *T*-2, with its combination pin-and-riveted connections, a careful analysis of the secondary stresses was made. The computed restraining moments at the pin joints were rather uncertain as the coefficient of friction of the nickel-steel pins was an unknown factor and had to be assumed.

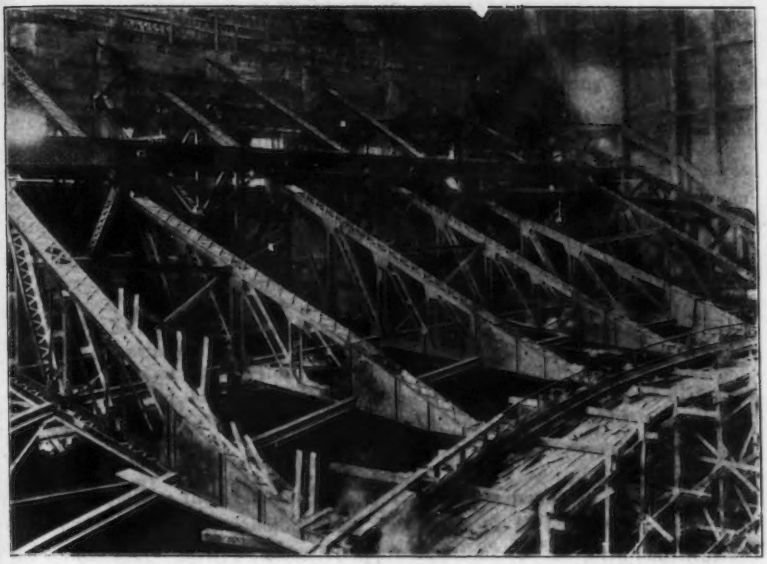

FIG. 7.—BALCONY TRUSSES CANTILEVERED FROM MAIN TRUSS, *T*-2, JACK TRUSS, *T*-1, AT RIGHT, SUPPORTS TWO CANTILEVERS.

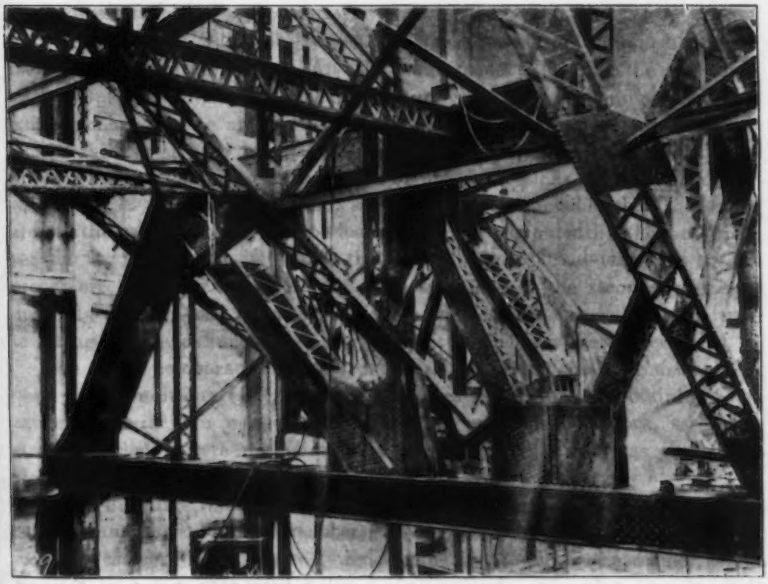

FIG. 8.—DETAIL OF MAIN BALCONY TRUSS, *T*-2, SHOWING PIN CONNECTION TO JACK TRUSS, *T*-1, AL MALAIKAH TEMPLE.

An adaptation of Mohr's semi-graphical analytical system, by Mr. G. A. Maney,* was selected by the writer for calculating the secondary stresses. Maney's arrangements of Mohr's methods are much simpler, more concise, and involve less time than other commonly accepted methods.

Only approximate results to determine probable localized excessive stress conditions were expected, on account of the modifying effects of various conditions, such as the following:

(1) Change in the primary stress distribution due to changes in the section of members (particularly at joints), to gussets and splice members, and also to fabrication conditions.
(2) Effects of changes in moments of inertia in members between joints.
(3) Variation between the theoretical length of a member between axial intersection points and the actual length between gussets.
(4) Elastic deformation of the gusset-plates, initial slip, and distortion of the rivets, and degree of frictional resistance between riveted plates.
(5) Unknown frictional resistance of pin joints.

In computing the deformations in the various members, the gross areas were used, no allowance being made for details or for changes in section at the connections. Mohr's successive approximations (to the third substitution) were utilized, which gave results accurate enough for all practical purposes. All computed secondary stresses were checked by another method of calculations to results within 5 per cent.

A maximum of 24 000 lb. per sq. in. was allowed for combined stresses, including secondary stresses. An effort was made to modify the secondary stresses due to dead load conditions by lengthening and shortening the various truss members in the amount of their respective deformations, which necessitated the use of hydraulic jacks, steamboat ratchets, and tapered drift-pins to force the members into their riveted or pin connections. As the dead load was about 72% of the total load, and as it was improbable that the entire area of the balcony would ever be loaded with the computed live load of 75 lb. per sq. ft., the seats being fixed, the writer deemed it advisable to try, by proper erection methods, to eliminate in some degree the secondary stresses due only to dead load conditions. While considerable force had to be used to spring the various members into place, little difficulty was experienced.

Due to the comparatively small deformations of the truss members under dead load conditions (Fig. 9), and the impracticability of obtaining such extreme accuracy in measurements in the structural shop work, secondary stresses probably were not eliminated to the desired extent, as subsequent strain-gauge measurements have indicated.

Some difficulty was encountered with hand-reaming. Due to large holes (1⅛ in.) and thick built-up members, it was difficult for the reamer crews to keep the reamers steady, there being a tendency to wobble the reamer, which resulted in a few over-sized holes.

* "Secondary Stresses and Other Problems in Rigid Frame," *Bulletin*, Univ. of Minnesota, March, 1925.

Balcony Truss Erection

Some doubt had been expressed regarding the ability and facilities for manufacturing the large truss near-by. Its successful fabrication and erection by a Los Angeles contractor (The Llewellyn Iron Works) was an achievement that created considerable local pride.

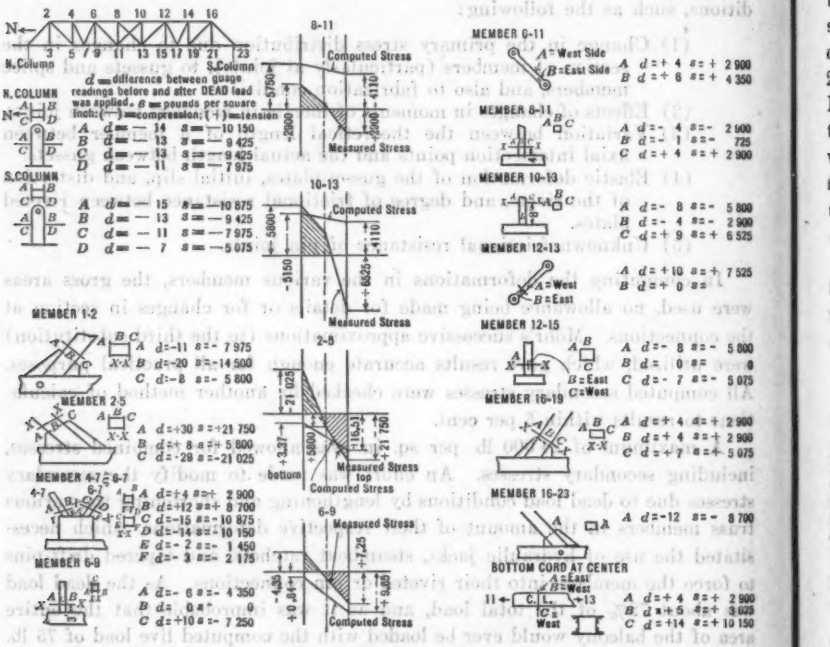

Fig. 9.—Strain-Gauge Investigations, Main Balcony Truss, T-2, Al Malaikah Temple.

This balcony truss was delivered to the job in sections, the largest (center lower chord section) weighing 47 tons and being 80 ft. long. The truss was erected on a steel substructure consisting of the same members as were used in the falsework for the roof trusses. The lower chord sections were first set on the camber screw-jacks. The web members were next placed, followed by the top chord sections.

No unusual difficulty was experienced in forcing the various members into their connections, and the pins were driven home without any undue effort. Prior to riveting, at least 30% of the holes in the connections were bolted tightly. No trouble was encountered in driving the 1-in. rivets (some with a maximum grip of 5¾ in.) by ordinary pneumatic hammers, with 120-lb. air pressure. Comparatively few rivets were rejected. The 1-in. rivets known as "swell-neck" rivets, were tapered a full ⅛ in. for 1 in. along the shank, starting at the head.

The taper on large rivets helped materially to fill the holes completely, particularly in over-reamed holes. In general, they resulted in fewer loose rivets, especially where the rivet grip was large.

The general layout of the balcony framing is shown in Fig. 10. The jack trusses, *T*-1, tend to equalize the over-hang of the cantilever trusses, which project a maximum of 45 ft. beyond the main balcony truss. It was desirable to prevent excessive and unequal deflections of the structural steel trusses supporting the balcony, particularly the cantilevers, and the possibilities of cracking and otherwise shearing the relatively thin monolithically finished 2½-in. slabs and narrow 5-in. risers of the reinforced concrete balcony framing. Hence, it became necessary to design and arrange the balcony trusses so that their deflections would be relatively uniform and slight. Deflections of the various trusses were carefully computed by Williot diagrams and checked analytically. The maximum computed deflection of the cantilever trusses under dead load was ¾ in. (Truss *B*).

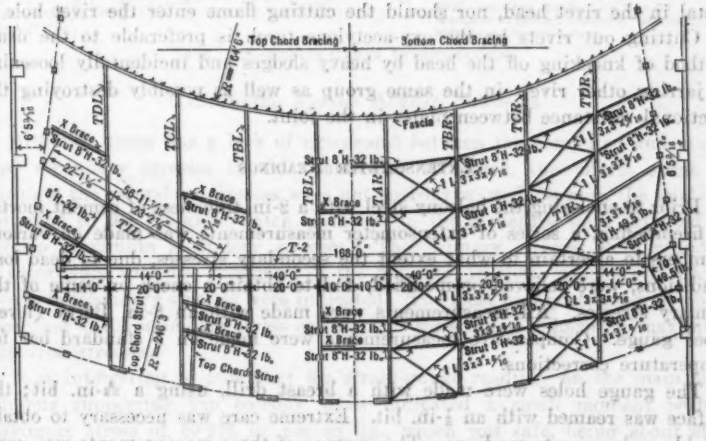

FIG. 10.—BRACING FOR BALCONY TRUSSES.

The cantilever balcony trusses were cambered for dead load by offsetting the rivet holes at the fulcrum connections in the gusset-plates on the main truss or the jack trusses, as the case may be, the top holes being set back and the bottom holes brought forward. The rivet holes in the gusset-plates at the fulcrum connecting the cantilever trusses to the main truss or jack trusses were drilled and reamed in the field after the cantilever trusses had been supported in their proper cambered positions by cables with turnbuckles secured to the roof structure. In adjusting the cantilever trusses to their proper camber the milled joint at the heel or fulcrum in the bottom chord was displaced so that the abutting faces in the joint were not in proper contact. This was corrected in a very satisfactory manner by filling the gap with electrically welded metal.

Electric Welding

Electric welding was found to be an excellent method for obtaining full metal-to-metal contact where milling of inclined surfaces cannot be made uniformly tight. The joint should be properly scarfed to allow the metal to be fluxed or built in to the inner side of the joint. Electric welding does not overheat, and possibly injure, the adjoining metal as will often result from the use of the oxy-acetylene torch in such operations.

Cutting Out Rivets

Where rivets had to be removed the oxy-acetylene torch was used to good advantage to burn off the button of the rivet. This operation, however, should be performed only by a mechanic experienced in using the torch, otherwise the metal in the joint may be injured. The cutting flame should be applied to the side of the rivet head at right angles to, rather than parallel with, the shank of the rivet. It is not always necessary to burn off all the metal in the rivet head, nor should the cutting flame enter the rivet hole.

Cutting out rivets by the oxy-acetylene torch is preferable to the usual method of knocking off the head by heavy sledges and incidentally loosening or jarring other rivets in the same group as well as possibly destroying the frictional resistance between plates in the joint.

Extensometer Readings

Prior to enclosing the balcony steel with a 2-in. thickness of cement mortar as fireproofing, a series of extensometer measurements was made on various members to ascertain to what extent the secondary stresses, due to dead load conditions, were relieved or modified, and to obtain a check on some of the primary stresses. All measurements were made with an 8-in. Berry (lever-type) gauge. Comparative measurements were made on a standard bar for temperature corrections.

The gauge holes were made with a breast drill, using a $\frac{3}{32}$-in. bit; the surface was reamed with an $\frac{1}{8}$-in. bit. Extreme care was necessary to obtain reliable and accurate readings. The average of three measurements was used. A slight difference in pressure on the points of the gauge when applying the extensometer produced considerable variation in the readings. The points on the gauge seemed to have too great a taper, being about 60 degrees. Points with sharper tapers, about 30°, and smaller gauge holes, properly reamed, doubtless, would give more accurate readings.

Readings to the number of 360 were taken on the balcony truss. Due to obstructions and inaccessibility, it was impossible to obtain complete extensometer readings on all truss members, and at many desirable points, to obtain the maximum secondary stresses. However, sufficient strain-gauge measurements were taken to demonstrate, in a practical way, what members were under maximum stresses. From the results obtained it appears that the stresses in the members varied considerably over the cross-sections, and that the maximum measured stress was well within safe limits.

The measurements indicated that the results of the field methods to modify the computed secondary stresses were rather uncertain, possibly due to relatively small deformations and inaccuracy in shopwork, and that the calculated secondary stresses did not fully agree with the measured stresses (Fig. 11). Doubtless this was due to the several modifying effects already mentioned, which are not subject to analytical calculations.

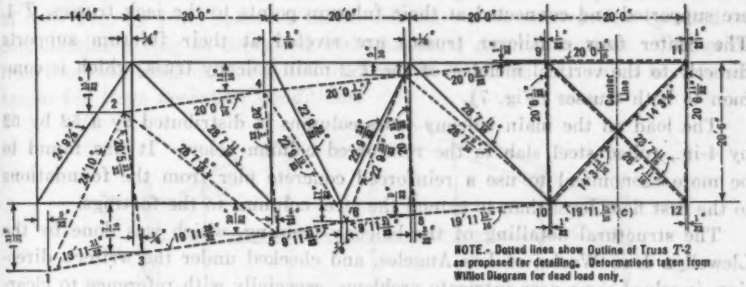

FIG. 11.—STRAIN-GAUGE INVESTIGATIONS.

CALCULATED *Versus* ACTUAL STRESSES

Although there was a lack of agreement between the computed and measured secondary stresses in this particular structure, the efforts spent to calculate the secondary stresses were not entirely wasted, because the analysis indicated to the designer which members in the structure were expected to develop maximum secondary stresses. The primary stresses were reduced, in accordance with the judgment of the designer, in those members in which excessive secondary stresses were indicated. The most highly stressed members according to the secondary stress calculations were found to have the maximum measured stresses.

It is interesting to note that the strain-gauge readings on the main steel columns supporting the balcony truss indicated a small moment with a maximum stress of 10 875 lb. per sq. in., which was safe, being about 30% greater than the computed stress. These columns were designed with a very low unit stress, 8 500 lb. per sq. in., to allow for increased stresses due to bending and other causes, which could not be computed accurately. Each of these columns is braced near its top by three 10-in. H-struts to the reinforced concrete wall structure. Note the variation in stress distribution on the section shown in Fig. 11.

BALCONY DESIGN

Truss *T*-1 is attached at one end to the main balcony truss by a pin connection in a large steel casting resting on a built-up stool between the web members of Truss *T*-2 (Fig. 8). The other end is supported on a reinforced concrete wall column. The chords of Truss *T*-1 consist of two 15-in. channels, with 8-in. Bethlehem H web members. The bottom chord

in the end panel section of the balcony truss, *T*-1, was composed of two 8-in. standard eye-bars to avoid clearance difficulties. The pin joint connecting Truss *T*-1 to the main balcony truss, *T*-2, eliminated any possibility of excessive restraining moments due to the varying deformations of the connected trusses.

There are eight cantilever trusses (Fig. 10), four of which are directly supported and connected on the main balcony truss, *T*-2; the other four are supported and connected at their fulcrum points to the jack trusses, *T*-1. The center four cantilever trusses are riveted at their fulcrum supports directly to the vertical member of the *T*-2 main balcony truss, which is common to both trusses (Fig. 7).

The load on the main balcony truss columns is distributed by a 52 by 52 by 4-in., rolled steel slab to the reinforced column below. It was found to be more economical to use a reinforced concrete pier from the foundations to the first floor level than to extend the steel columns to the footings.

The structural detailing of the balcony framing, which was done by the Llewellyn Iron Works, of Los Angeles, and checked under the writer's direction, involved some very intricate problems, especially with reference to clearances. That only two minor errors, due to changes in plans, occurred in the field erection is an accomplishment worthy of mention.

In order to stiffen the ends of the cantilever trusses and reduce their deflections to a minimum, a double web plate girder section was used, as shown in Fig. 7. During erection, the plate girder sections were given a camber by offsetting the rivet holes in the bottom chord in the joint connecting them to the open web section of the truss. The chords were built of 8 by 3-in. angles, latticed and placed 1 ft. 3 in., back to back, which width added to the lateral stiffness. The anchor, or wall, ends of the cantilever trusses were secured to anchor-bolts on top of reinforced columns.

Special attention was given to the design of the general bracing throughout the balcony framing. The cantilever trusses were sway-braced in horizontal and vertical planes by angle cross-bracing and struts in the form of bents, as indicated in Fig. 10. The cantilevers and jack trusses assisted materially in bracing the main balcony truss in addition to the four horizontal boxed latticed struts which braced the upper chord to the rear wall (Fig. 8). The four exits passing through the main truss were supported by hanger rods anchored above in the concrete deck of the balcony.

To avoid any possibility of the concrete balcony cracking along the Auditorium walls, due to deflections of the supporting trusses, a construction joint was placed in the concrete deck, midway between the Auditorium wall and the adjacent cantilever trusses. Although the balcony has been loaded to capacity several times, no cracks in the concrete decking have been observed to date.

The local building ordinance required a full live load test of the balcony, which was accomplished by using metal plaster barrels filled with water. After the test the water was siphoned from the barrels.

Unusual Stage Construction Features

The stage roof arches, eight in number, are spaced 22 ft. on centers. One end of each of the center arches is supported by the proscenium arch wall. The arches were designed as partly fixed (Fig. 12). Turnbuckles were placed in the bars near the west wall to develop equal stresses in the two channels that form the horizontal tie and to produce a small amount of initial stress in the tie prior to stripping the forms. The gridiron floor proper consisted of flats 4-in. by ⅜-in., spaced 7 in. on centers, which construction resulted in considerable saving as compared with the usual channel sections. The gridiron floor was designed for a live load of 100 lb. per sq. ft., which has proved ample for stage operating conditions.

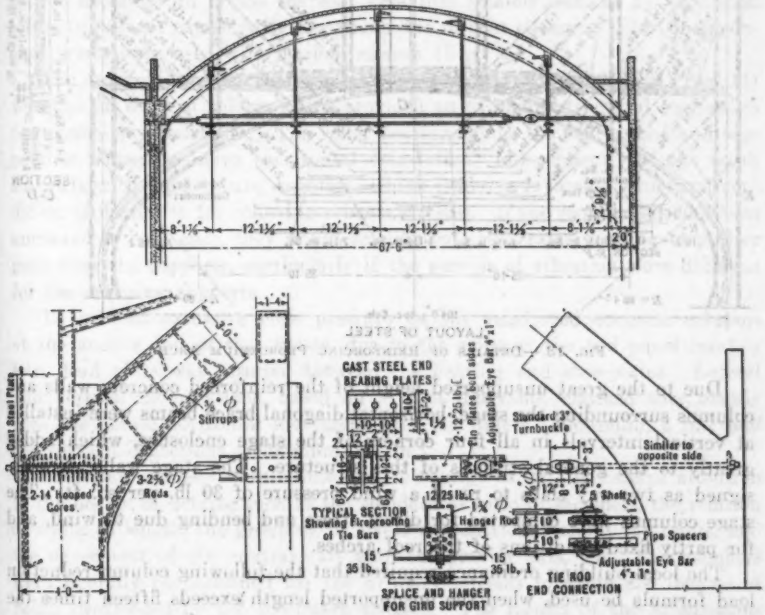

Fig. 12.—Stage Roof Arches.

The stage roof arches were poured in one continuous operation, commencing from each springing line and working simultaneously and symmetrically toward the crown. The arches and the beam system were poured up to the under side of the roof slab. By casting the arched roof slab with concrete having a slump of 2½ in., cover boards were found to be unnecessary. The roof arches were cast with a concrete having the proportions of 1 part cement to 4.5 parts aggregate.

The proscenium arch (Fig. 13), has a clear span of 100 ft. This arch was computed as a girder with partly restrained ends. Particular attention was given to diagonal tension stresses, which were resisted by diagonal bars

(Fig. 13). In order to increase the lateral stiffness, pilasters were placed in the web under each roof arch similar to the stiffeners in plate girder construction. A flanged head, or tee, in the top of the proscenium girder also adds to its lateral stiffness.

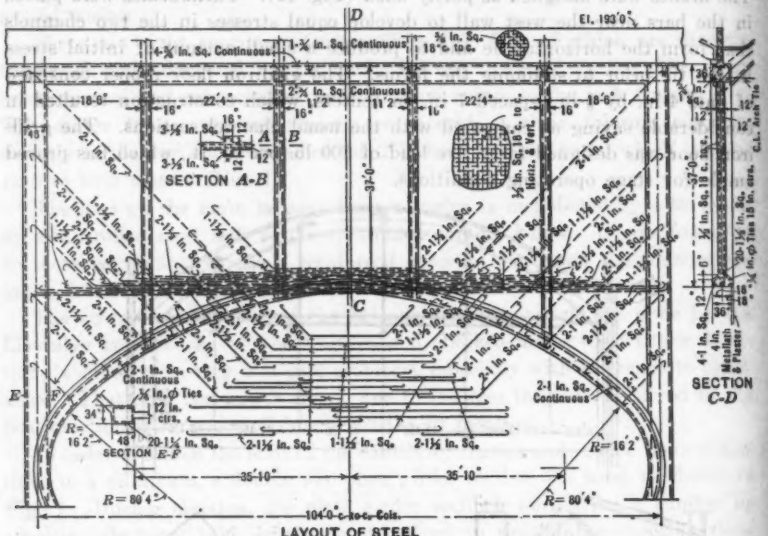

FIG. 13.—DETAILS OF REINFORCING PROSCENIUM ARCH.

Due to the great unsupported height of the reinforced concrete walls and columns surrounding the stage, horizontal diagonal brace beams were installed at vertical intervals in all four corners of the stage enclosure, which added greatly to the general stiffness of this structure. The stage walls were designed as two-way slabs to resist a wind pressure of 30 lb. per sq. ft. The stage columns were computed for direct stress and bending due to wind, and for partly fixed conditions of the roof arches.

The local building ordinance required that the following column reduction load formula be used, when the unsupported length exceeds fifteen times the least diameter:

$$P' = P\left(1.6 - \frac{L}{25\,D}\right)$$

in which,

P' = permissible load.
P = permissible load due to ordinary column formula.
L = unsupported length.
D = least dimension of core.

The stage floor was designed for a live load of 250 lb. per sq. ft. The framing consists of standard steel I-beams supporting a wood-joist system. All steel connections were bolted so that any particular section of the floor could be removed readily without affecting the adjacent parts.

Auditorium Roof Trusses

The structural steel roof trusses over the Auditorium (Fig. 14), each weighing 60 tons, have a clear span of 192 ft. It will be noted that these trusses are supported on reinforced concrete columns.

The Auditorium proper was constructed with double walls on each side to resist earthquake forces and provide duct space for the ventilating systems. The inner walls of the Auditorium are metal lath and plaster, supported by reinforced concrete columns and beams. This skeleton frame forms a system of braced bents with the outer walls and columns which support the roof trusses (Fig. 15).

Due to the large area of the Auditorium and the long-span roof trusses, it was necessary to divide the roof area into smaller sections by expansion joints to prevent excessive deformations due to heat changes. Elastite expansion joints were used with marked success (Fig. 15).

The south ends of the roof trusses were anchored; the north ends (Fig. 14) were set on nests of rollers. This provided an excellent structural connection for earthquake resistance. The roller bearings allow the center roof and supporting trusses to move (horizontal translation) independently of the north supports with temperature variation, which is also a favorable structural condition of flexibility for relieving seismic stresses. If the roof trusses had been anchored at both ends, they would act like battering rams, tending to pull or push over the supports, particularly if the periods of vibration were different for the opposing supports.

To prevent excessive edge pressure on the reinforced concrete columns at the anchor end of the trusses, due to the slope at the end panel joint, a $\frac{1}{8}$-in. lead plate was inserted between the bearing and shoe-plates. Lateral and vertical deformations, based on Williot diagrams, checked very closely with the actual horizontal movement over the rollers (maximum, $\frac{3}{4}$ in.) and the vertical deflections (maximum, $2\frac{1}{16}$ in.).

Secondary stresses were eliminated, to a large extent, by careful attention to the design of details, such as the slenderness ratio of members, the relation of width to length, the grouping of rivets concentrically about the joints, and the agreement of the neutral axis with the gravity axis, etc. The members were liberally proportioned for the primary stresses to avoid the danger of being overloaded by the secondary stresses. The results of the calculations indicated that the combined primary and secondary stresses did not exceed 21 000 lb. per sq. in. Because of the relative low secondary stresses, it was not deemed necessary to attempt to eliminate them by shop or erection methods.

The steel roof trusses were erected in pairs from a movable substructure (Fig. 14), consisting of braced steel bents bolted together and resting on rollers over timber cribbing. After all the roof trusses were erected, the movable steel substructure was dismantled and its members were used in the temporary supports for erecting the main balcony trusses.

The roof trusses were first assembled in the shop to the proper cambered positions, reamed, and match-marked. The trusses were erected by sections. The bottom chord was assembled first on the camber blocks of the movable

substructure, then the web members were installed, followed by the top chord sections. All members were bolted tightly with at least 30% of the rivet holes in the joints bolted. A great saving in the roof steel (about 14 tons) was effected by using a cantilevered purlin system, with alternate double cantilever and suspended members.

The computations relative to cantilever purlins are based on full uniform load conditions, in which case the most economical cantilever projection is 0.1465 of the distance between the trusses. For partial loading, the maximum moment due to uniform loads would be increased 20 per cent.

Pavilion Roof Girders

The continuous reinforced concrete girders, supporting the Banquet Hall roof, were designed as a part of a fixed frame (Fig. 16). The soffits of the roof girders (Fig. 4) were curved to represent Saracenic arches, which added to the depth of the girders over the interior columns where large negative moments existed, and presented a very pleasing architectural appearance. It will be noted that the balcony cantilever girders tended to reduce the moments in the columns. The rear, or wall, columns were required to resist an uplift. The anchor arms of the continuous girders were projected through and above the roof (Fig. 16), being hidden from the interior.

Foundations

The footings were located in a tight gravel stratum. A maximum of 8 000 lb. per sq. ft. was adopted as the safe bearing pressure. However, this maximum pressure was modified. The foundation having the largest ratio of live, to dead, load was selected and proportioned for the combined dead and live loads. The dead load on this footing was divided by the area thus formed, and the new reduced unit pressure was used for the dead loads on the foundations.

Considerable economy was obtained by combining the exterior retaining walls with the continuous footings, particularly under the east exterior wall of the stage. The area of steel for resisting the tension stresses, due to large moments in the footings, was reduced to a great extent, as the advantage of a relatively much larger moment arm was obtained by locating the positive moment steel in the upper part of the retaining wall. This is practically monolithic with the footing. The spread, or T-shape, of the footing provided adequate compression area.

Construction Plant

The contractor's construction plant and system of operation were of unusual interest. The concrete had to be distributed over an area of about 3 acres, which necessitated a gravity distributing system and central mixing plant. The distributing tower and concrete plant were located in the center of the stage, and the main distributing tower, a few feet in front of the proscenium arch.

Various reasons influenced the selection of the stage as the most practical location for the distributing tower and concrete plant. The mixer was centralized, which, to a large extent, equalized distribution of the concrete. The

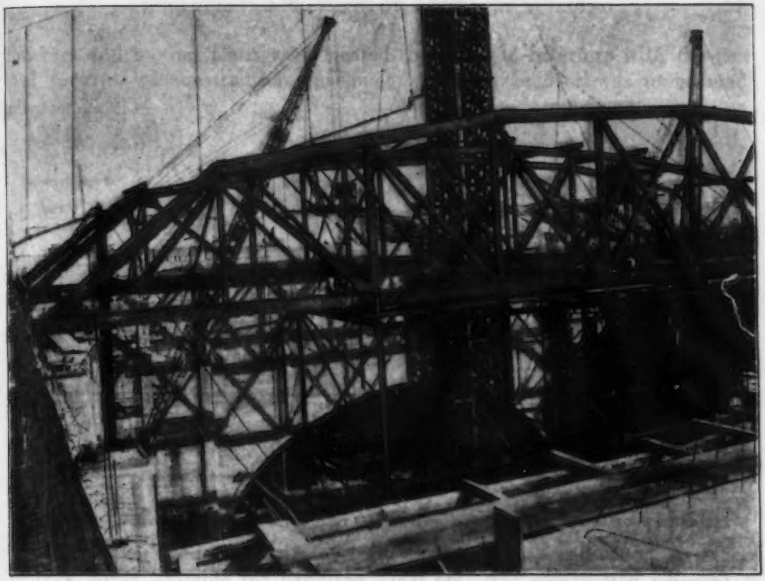

FIG. 14.—ROOF TRUSSES, ROLLER END SHOWING MOVABLE STEEL FALSEWORK, AL MALAIKAH TEMPLE.

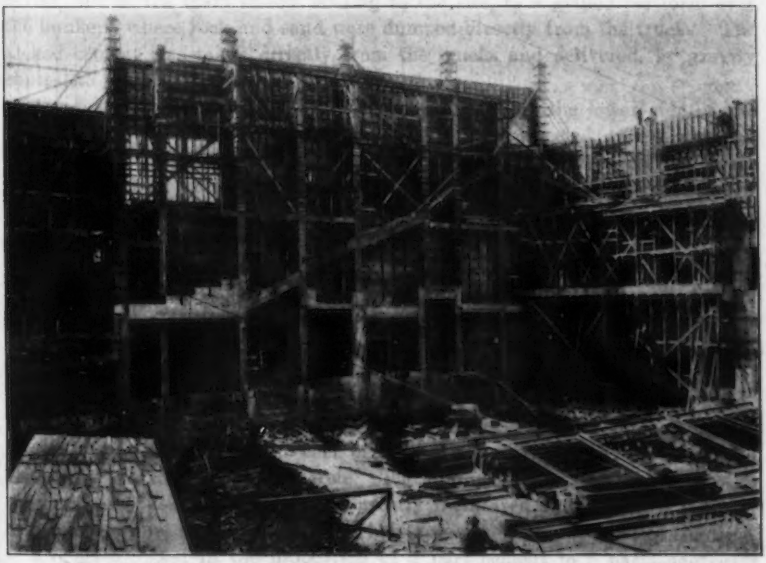

FIG. 15.—VIEW OF INNER WALL FRAMING AND SOLID EXTERIOR SIDE-WALL, AL MALAIKAH TEMPLE.

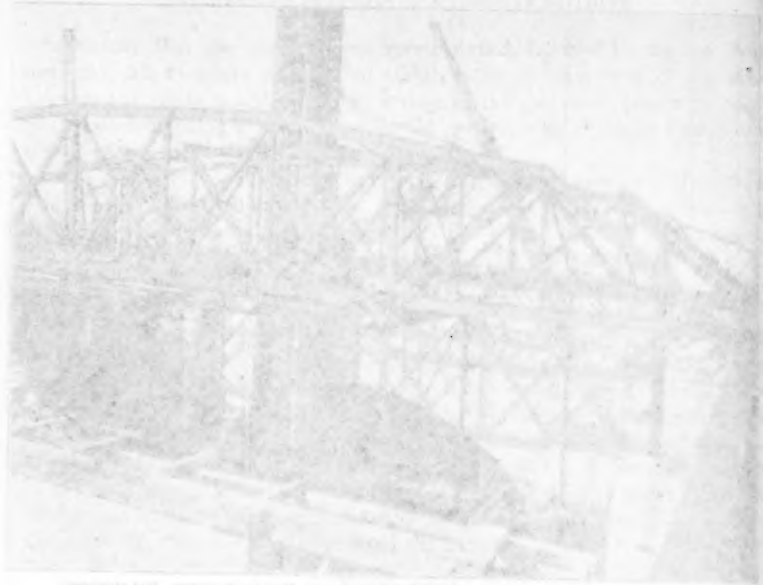

bunkers and mixing plant were located so as not to interfere with the general progress of construction, inasmuch as the stage floor was to be made removable.

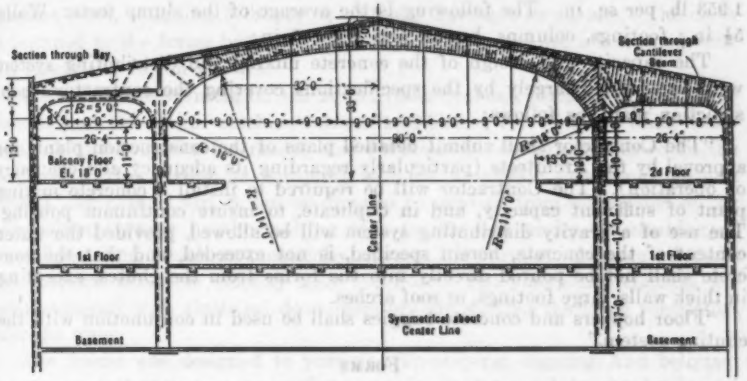

FIG. 16.—CROSS-SECTION OF BANQUET HALL, SHOWING CONTINUOUS ROOF GIRDERS.

The bunkers had a capacity of 1 000 cu. yd. of rock and sand. A cement storage house, suitable for handling 3 000 bbl., was constructed adjacent to the plant. For truck delivery of materials a ramp was built from Jefferson Street, one of the main streets leading to the site, to a grilled platform over the bunkers, where rock and sand were dumped directly from the trucks. The sacked cement was taken directly from the trucks and delivered, by gravity chutes, to the storehouse.

Sand and gravel were fed from short spouts along the lower side of the bunkers into regular concrete buggies, which were wheeled an average distance of 20 ft. to the mixer hoppers, and dumped. The concrete aggregate was measured by volume in the concrete buggies. It required three buggy men to feed each mixer when operating at full capacity. The mixing water was controlled by an automatic water tank.

To prevent interruption, due to possible break-downs in the construction plant while casting important structural units for which continuous pouring was necessary, a duplicate plant was specified and installed. This consisted of a two-compartment hoisting tower to which was attached two 1-yd. sliding distributing hoppers and two 1-cu. yd. Smith mixers. The main distributing tower was 238 ft. high. Two tail towers, each 100 ft. high, were built about 300 ft. each from the main hoisting tower; a 1½-in. plow steel cable, 1 500 ft. long, was laid over the hoisting tower to each of the tail towers to support the Lakewood chutes for distributing the concrete. The duplicate plant, in addition to its protection in case of an emergency, greatly facilitated and expedited the general construction, as both mixers and hoists were kept in use most of the time.

Concrete mixed in the proportion of 1 part cement to 6 parts aggregate was used throughout, except in the stage roof arches, columns, and roof arches of the Banquet Hall. All roof arches were cast with a 1:4.5 concrete, and the columns supporting the roof arches of the Banquet Hall were poured with a 1:3 mix.

The strength of the concrete was controlled by mechanical analysis and by slump and compression tests. For the 7-day compression tests, 1:6 mix, the average of 119 tests was 1 155 lb. per sq. in.; and for 190 tests at 28 days, 1 953 lb. per sq. in. The following is the average of the slump tests: Walls, 5½ in.; footings, columns, beams, and slabs, 5 in.

The capacity and design of the concrete mixing and distributing system were determined largely by the specifications covering the contractor's construction plant, as follows:

"The Contractor shall submit detailed plans of the construction plant, for approval by the Architects (particularly regarding its adequacy and efficiency of operation). The Contractor will be required to install a concrete mixing plant of sufficient capacity, and in duplicate, to insure continuous pouring. The use of a gravity distributing system will be allowed, provided the water content of the concrete, herein specified, is not exceeded, and that the concrete shall not be poured directly into the forms from the chutes, excepting in thick walls, large footings, or roof arches.

"Floor hoppers and concrete buggies shall be used in conjunction with the chuting system."

Forms

The specifications covering the design and erection of form work, contained several paragraphs which represented considerable thought and experience. These specifications read in part:

"In proportioning forms and centering concrete shall be treated as a liquid of its full weight for vertical loads and three-fourths of its weight for horizontal pressures.

* * * *

"Timber supports must be designed so that the number of joints in side-grain compression shall be reduced to a minimum on account of the low bearing value of timber across the grain.

"Care must be taken to prevent lateral displacement of vertical posts due to radial pressures from arch rings, by providing proper longitudinal bracing.

"Vertical supporting members, posts, struts, etc., must have butt-joints or end grain bearing and fish plates. Fish plates shall not be permitted to transmit vertical loads. Scabbing of horizontal supporting members to vertical supports will not be permitted.

* * * *

"An additional rise in the centering of arches of $\frac{1}{800}$ of the span shall be provided for shrinkage and settlement of the forms and supports.

"In constructing centers for arches no reliance shall be placed on spiking, but all main members shall be bolted together at joints.

* * * *

"The design and construction of all form work shall be subject to the approval of the Engineer, and no concrete shall be deposited on or in said form work prior to such approval; but such approval shall not be deemed cause for claims for damages or extension of time in case of failure of said form work, nor will it relieve the Contractor from furnishing forms which will produce acceptable work. All such approved plans and descriptions of said form work shall thereupon become a part and parcel of these plans and specifications."

Fireproof Curtain

The asbestos stage curtain is one of the largest in the world, weighing approximately 9 tons. It consists of a rigid steel frame composed of six hori-

zontal latticed trusses 14 in. deep at the center and braced vertically by latticed angle struts extending the entire height of the curtain.

The steel curtain frame is covered on each side with wire-woven, 95% pure, asbestos cloth, weighing 3 lb. per sq. ft.* and having wire inserts. The cloth is fastened to the frame by half round strips, which, in turn, are secured with tap screws, 12 in. on centers.

The curtain is operated on ten 20-in., roller-bearing, machine-turned, cable sheaves and two 24-in. machine-turned head-blocks, set on large roller bearings. A 10-h.p. motor for raising and lowering the curtain is located in the basement. The curtain is equipped with an automatic emergency closure control. In case of fire, it can be dropped by gravity from either side of the proscenium opening by the melting of a fusible link or by the slashing of a small cut line, which automatically releases the curtain. A large oil dashpot prevents excessive velocity near the floor. The emergency controls are interconnected with electrical door operators for opening the large ventilators over the stage.

The frame was designed to prevent side-swaying, sagging, and bellying, due to unequal air pressure on the two sides, and to withstand a horizontal lateral pressure of 5 lb. per ft., with a factor of safety of 2, without binding on the smoke-pocket guides. The lateral pressure is based on a temperature of 750° Fahr. on the Auditorium side and 1 600° Fahr. on the stage side, with 15-min. exposure.

The curtain has an unbalanced weight sufficient to cause it to drop by gravity with a frictional factor of 1 in 32 sec. As designed, the whole curtain descends as a unit, making its entire unbalanced weight effective in dropping.

The stage scenery equipment (Peter Clark System) consisted of 100 counterweighted sets, operated on T-bar tracks, about 4 in. on centers. A bridge located along, and cantilevered from, the rear wall of the stage provides the facilities necessary for painting the exceptionally large scenes.

The Acoustics

The acoustics of the Auditorium was the subject of much thought. Detailed study was given the correlation of size and shape to prevent objectionable reverberation. The selection of lime plaster for finishing the interior wall surfaces assisted, to some extent, in absorbing the sound. The great hung canopy and the surrounding ceiling, with its numerous broken surfaces, were treated so as to subdue undesirable reflection without losing any of its architectural beauty. All the seats were upholstered and the aisles carpeted. Not only was this in keeping with the luxuriousness of the appointments, but it also served further to prevent acoustical defects.

As a result, normally, stage programs can be heard without difficulty in the rear seats of the balcony, a distance of 235 ft. However, this was considered too great a distance for the average human voice, or subdued music, to carry successfully. Consequently, it was deemed advisable to provide an amplifying system.

* Same as tested by the U. S. Bureau of Standards, Washington, D. C., in its curtain tests.

Public Address System

In keeping with the high standards utilized throughout this edifice, it was desired to obtain the most comprehensive and complete system available, as well as one that would faithfully amplify, transmit, and reproduce the program. To meet these requirements, a Public Address System was installed by the Graybar Electric Company.

It is used for many and varied functions. In addition to reproducing speech and music from the stage of the Auditorium, it provides a means for "piping" the program from one room to another, thus caring for overflow meetings. This Public Address System is also used for amplifying in the large ballroom, for reproducing radio programs when used in conjunction with a radio receiving set, for paging throughout the building, and for cab calls.

To provide these features, it was necessary to install in and about the Temple a total of 46 projectors or horns, 25 microphone outlets, and 24 observer stations. A special control room, adjacent to the Exhibition Hall, was used for housing the amplifying and radio receiving equipments and auxiliary apparatus. The microphone outlets were installed at strategic points throughout the building for conveying, to the amplifying system, such programs as it is desired to reproduce throughout the building itself, or to transmit over the air through a radio broadcasting station.

Similarly, observer positions were provided for watching the performance of the loud speaker equipment in each particular room. A telephone circuit, between these positions and the control room, enables the observer to advise the operator if corrections are required. The power used for operating this system is obtained from the regular alternating-current house supply and is adjusted to the proper voltage by a vacuum tube rectifier system.

Since the Auditorium is thus equipped, it is not necessary to request front seats in order to enjoy the program. There are no panels to hinder the view, the projectors being carefully concealed in the proscenium arch 42 ft. above the stage. They reproduce the program so that those in the rear seats can hear as well as those in front.

Heating and Ventilating

The heating system consists of three Birchfield welded, low-pressure boilers, set in battery with Fess oil burners. Each boiler has a capacity of 30 000 sq. ft. of radiation. The Auditorium and Banquet Hall are heated and ventilated by a forced-air circulating system.

The majority of people who visit this edifice are so impressed with the lavishness of its appointments, that they are apt to take for granted the perfect air conditions that prevail without realizing the great engineering skill that made such conditions possible. The average layman would be astounded to know that, in order to insure perfect ventilation, it is necessary to handle 43 254 000 cu. ft. of air per hour. This enormous quantity is distributed by 12 Sturtevant ventilating fans, of various sizes, located at strategic points throughout the building. To the Auditorium alone 14 838 000 cu. ft. is supplied, and correspondingly large quantities are furnished to dressing-rooms under the stage, the Banquet Hall, basement, etc.

The Auditorium is ventilated by the up-draft system (Fig. 17), wherein the air is forced into plenum chambers under the seats and thence through mushroom outlets into the room. An exhaust air system, with outlets in the ceiling under the balcony and in the ceiling of the Auditorium, draws the vitiated air up past the breathing zone and exhausts it to the outside. The up-draft system for a building of this type is much superior to the so-called down-draft system, wherein the air enters the ceiling and is sucked out under the seats. In the up-draft system the laws of Nature are utilized as the heated air rises, which assists the exhaust system in its work. A very important point in favor of the up-draft system is the quick elimination of smoke, especially during the Shrine ceremonials.

The incoming fresh air is heated by large units of Aerofin heaters which are automatically controlled by thermostats set in the various rooms. The stage is amply heated to compensate for differences in temperature between the Auditorium and the stage area, thus eliminating the great drafts that usually occur when the curtain is raised.

Decoration

The architectural treatment of the entire structure is Saracenic, with the Moorish motif predominating. Rare beauty marks the ceiling of the Auditorium (Fig. 2) with its jeweled tapestry canopy reflecting the blue of an Arabian sky. The tapestry effect on the huge plastered canopy with its large ropes (9 in. in diameter) of cast plaster, is so realistic that many have believed that this immense ornament was constructed of real tapestry and fibered ropes.

The whole effect of the interior of the Auditorium is heightened and magnified by a gloriously beautiful envelope of Oriental filigree work and daring color schemes (Fig. 5), which is truly Saracenic in design. The Saracens were celebrated for their decorative art, in which the Oriental love for display and color demanded a certain luxuriousness, that is reflected through the interior treatment.

A great deal of decoration was applied directly to the concrete beam and wall surfaces, which were tinted and stenciled, producing a very striking and interesting effect, particularly on the roof arches in the Pavilion (Fig. 4).

The concrete exterior of the entire building was treated with California stucco of a light buff color, applied with an air brush and producing a durable coating of a pleasing uniform texture. The exterior ornamentation consists of polychromed tooled synthetic limestone, composed of crushed limestone and Portland cement.

Electric Lighting

In the center of the suspended canopy is hung a magnificent chandelier, 22 ft. high and weighing approximately 5 tons (Fig. 2). It contains 500 electric bulbs, arranged to produce 64 color combinations, all controlled by dimmers on the stage switchboard. There are fifty-one 1 320-watt circuits, nine 150-watt lamps to each circuit, and three emergency circuits. To each of the four colors—red, white, blue, and amber—there are twelve circuits.

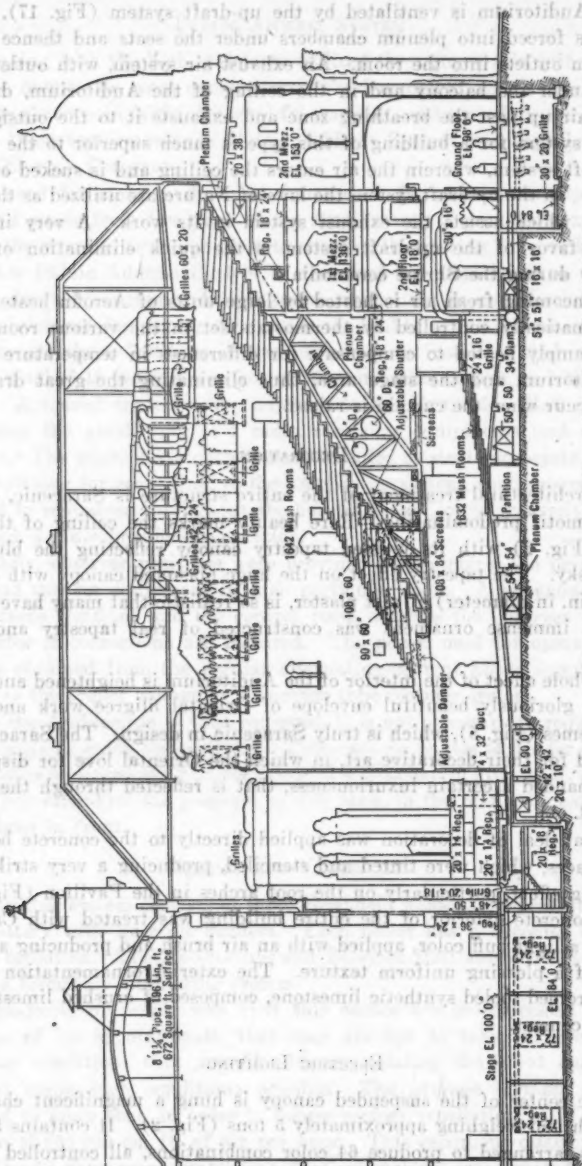

FIG. 17.—LONGITUDINAL SECTION OF AUDITORIUM, SHOWING UP-DRAFT SYSTEM OF VENTILATION.

The chandelier is constructed with a structural steel frame connected to the steel ceiling supports by pin joints, to allow the fixtures to swing during seismic disturbances. Access to the fixture for lamping and cleaning is provided by a portable ladder extending through a trap-door in the ceiling.

The entire lighting system is unique. Hundreds of concealed lights of varying colors, together with the large chandelier and other minor fixtures and all the stage lighting equipment, are controlled by one of the largest stage switchboards in the world. This switchboard, manufactured by the Hub Electric Company, is 28 ft. long and 12 ft. high, weighs 16½ tons and contains 298 dimmer plates of the Ward Leonard selective remote control. The dimmers run the full length of the board. By a system of roller-bearing mountings, a full length of dimmer can be controlled by a master lever.

Two separate electric services enter the building, connecting to two separate transformer vaults. A 100-kw. transformer set is installed for direct current for use on the stage.

Miscellaneous

A total of 30 275 cu. yd. of concrete were poured, and 2 308 000 board-ft. of form lumber was utilized. About 1 550 tons of reinforcing steel and 1 100 tons of structural steel were used.

The following shows the amount of each contract, and the total cost of the building:

Excavating	$38 520.00
General construction	1 214 452.00
Plumbing, heating, ventilating, and sprinklers	190 000.00
Electric wiring	109 532.00
Switchboard	41 939.00
Elevators	21 570.00
Electric fixtures	38 641.00
Decorating and painting	68 000.00
Fixed seating	50 000.00
Stage equipment	60 984.00
Finish hardware	13 140.00
Public Address System	16 246.00
Organ	35 000.00
Sign lights	1 295.00
Estimated cost of store fronts	8 000.00
Estimated cost of kitchen equipment	8 500.00
Total	$1 915 819.00
Architects' fees and miscellaneous small items	140 000.00
Total cost of building alone	$2 055 819.00

Mr. John C. Austin was the Architect, and Edwards, Wildey and Dixon, the General Contractors. Thomas Haverty Company furnished the heating, ventilating, and plumbing systems. The writer, as Chief Engineer for the Architect, was responsible for the structural design and the design of the heating and ventilating systems.

DISCUSSION

THEODORE BELZNER,* AFFILIATE, AM. SOC. C. E. (by letter).—The author states that "a slight difference in pressure on the points of the gauge when applying the extensometer produced considerable variation in the readings". During 1913 and 1914, a comprehensive series of extensometer investigations was made on the important truss members at the main towers and legs of the Brooklyn intermediate towers, during the strengthening of the end spans of the Williamsburgh Bridge, in New York City.

A 20-in. Howard extensometer, with 55° tapered points, was used, and the writer does not recall such variations as the author indicates, except in cases where the pressure on the strain-gauge was not properly applied. When the pressure was always placed directly over the contact points and firmly held against the member to be measured, there could not possibly be any spring of the various parts in the strain-gauge, causing variations in the readings.

The gauge holes in the steel members were drilled with a hand ratchet, using a No. 57 combination drill bit with a 60° countersink. After the holes were drilled, the edge between the countersink and drilled holes was removed with a 55° center punch by tapping it with a hammer which, in turn, formed a conical seat to receive the points of the strain-gauge. A pointed aluminum rod, a small cedar stick, and some absorbent cotton were used for cleaning the holes before taking any readings. By using the aluminum rod, the softness of the material prevented any injury to the holes. The gauge holes were cleaned out at each reading.

The writer agrees with the statement concerning the reamed holes, and believes that with careful and accurate preparation, the application of proper pressure on the strain-gauge, and the extreme care taken by the author should have resulted in more accurate readings with the equipment used on the theatre building.

Detailed descriptions of precise extensometer investigations made on the Hell Gate Arch Bridge† and the writer's discussion of the Niagara Railway Arch Bridge,‡ may be of interest in connection with this paper.

FRED A. NOETZLI,§ M. AM. SOC. C. E. (by letter).—The design of the theatre building described by Mr. Beanfield involved some very unusual features. Especially noteworthy are the balcony truss of 168-ft. span, the balcony cantilevers with a 45-ft. overhang, the reinforced concrete proscenium arch of 100-ft. span, and the reinforced concrete frames over the Banquet Hall, having a center span of 90 ft.

The writer had the privilege of being connected with the design of some of the structural parts of the building, particularly those of reinforced concrete. In the original plans there were provided for the Auditorium roof, two hinged reinforced concrete arches with horizontal ties spanned between the arch abutments. This type of construction would have involved some espe-

† *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), pp. 1047–1051.

‡ *Loc. cit.*, Vol. LXXXIII (1919–20), pp. 2004–2005.

§ Cons. Hydr. Engr., Los Angeles, Calif.

cially interesting features, but steel construction was subsequently used, as described in detail by the author.

The proscenium arch (Fig. 13) is supporting, among other loads, the concentrated vertical reactions of four of the stage roof arches. Considerations from the architectural point of view prohibited the use of a horizontal tie to take the large thrust of this arch. On the other hand, the columns supporting the arch could not economically be constructed with sufficient lateral stiffness and strength for carrying this thrust. Consequently, the most economical solution appeared to be the design of this "arch" as a girder and for this purpose the great depth available for the girder (37 ft. at the center and about 60 ft. at the supports) was very desirable. Nevertheless, there were twenty 1½-in. bars necessary for the bottom reinforcement at the center of the span. The diagonal tension was taken care of by a combination of bent-up bars and stirrups.

The author's computation of the secondary stresses in the steel balcony truss are of special interest. These studies indicated a way of eliminating part of the theoretical secondary stresses by proper erection methods. Such a procedure has been used very successfully also for other types of structures, especially bridge arches in which the effect of rib-shortening was partly compensated for by putting the arches under initial compression by means of screw-jacks and, subsequently, effecting the closure of the arches.

Mr. Beanfield's efforts to check, with extensometer readings, the theoretical stresses in important structural members is commendable. Information on the size of secondary stresses in such structures is especially desirable. It is to be hoped that such strain measurements will also be made to serve as a guide in the design of future structures.

A. Floris,* Esq. (by letter).—The most interesting part of this structure is doubtless the Banquet Hall. Unfortunately, however, the author's statements with regard to this important part of the design are lacking in detail to such an extent that it is difficult to understand clearly the intentions of the designer.

The structure (as shown in Fig. 16), represents a rigid frame which, due to the absence of hinges or other design features eliminating bending moments, is statically indeterminate to a high degree. Obviously, to analyze such a complicated structure is practically not feasible and for this reason some simplifications must be introduced.

In such cases it is always possible, by a proper arrangement of hinges and other features of design, to divide the structure into secondary frames, beams, and columns the analysis of which is an easy matter. The structure (Fig. 18) may be divided into a two-hinged frame that supports the beams from the outside columns as well as the simple beam within the middle span. Also, it could be assumed to consist of two superimposed frames with two hinges each. The upper frame, with a tie-rod connecting two hinges, would be similar to that suggested first and the lower frame would be composed of the two columns and the straight beam within the middle span. Formulas for the solution of these frames are available elsewhere.†

* Los Angeles, Calif.

† "Rahmenformeln," by A. Kleinlogel, Berlin, 1925.

The solution of the latter subdivision results in reducing the bending moment of the beam in the middle of the lower frame. The same result can be obtained if this beam (Fig. 18) is fixed to the columns of the frame. In order to reduce the statically indeterminate quantities in such a case, a hinge is inserted in the top of the roof (Fig. 19) which simplifies the calculations appreciably.

FIG. 18.

If the loading is symmetrical, the system thus formed is statically indeterminate in the second degree. This assumption as to the loading corresponds fairly well to the actual conditions with the exception, perhaps, of the wind pressure acting on the frame. In this building, however, the influence of wind seems to be negligible.

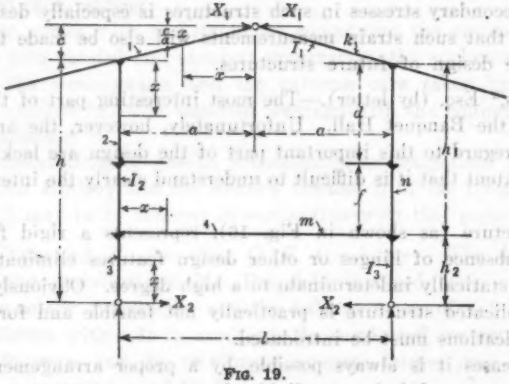

FIG. 19.

In the case of a symmetrical loading, the horizontal thrusts, X_1 and X_2 (Fig. 19), are taken as the unknown quantities. Then, if only the work done by the bending moments is considered, the equations of least work* are:

$$\frac{\partial u}{\partial X_1} = \int \frac{M}{E I} \frac{\partial M}{\partial X_1} d s = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

$$\frac{\partial u}{\partial X_2} = \int \frac{M}{E I} \frac{\partial M}{\partial X_2} d s = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

* "Die neueren Methoden der Festigkeitslehre und der Statik der Baukonstruktionen," H. Müller-Breslau, Leipzig, 1924, p. 96; see, also, "Mechanics of Internal Work," I. P. Church, N. Y., 1910, p. 63.

Denoting by M_0 the bending moment of the statically determinate frame for a given loading, the following moments and their derivatives for the various elements of the frame are obtained (see Fig. 19):

Element 1:

$$M = M_0 - X_1 \frac{c}{a} x; \frac{\partial M}{\partial X_1} = -\frac{c}{a} x; \frac{\partial M}{\partial X_2} = 0$$

Element 2:

$$M = M_0 - X_1 (c + x); \frac{\partial M}{\partial X_1} = -(c + x); \frac{\partial M}{\partial X_2} = 0$$

Element 3:

$$M = M_0 - X_2 x; \frac{\partial M}{\partial X_1} = 0; \frac{\partial M}{\partial X_2} = -x$$

Element 4:

$$M = M_0 - X_1 (c + h_1) - X_2 h_2; \frac{\partial M}{\partial X_1} = -(c + h_1); \frac{\partial M}{\partial X_2} = -h_2$$

Using these expressions, Equations (1) and (2) take the final form:

$$X_1 \left[2 \left\{ k s \frac{c^2}{a^3} \int_0^a x^2 \, dx + n \int_0^{h_1} (c + x)^2 \, dx \right\} + m (c + h_1)^2 \int_0^l dx \right] + X_2 m h_2 (c + h_1) \int_0^l dx = \alpha$$

$$X_1 m (c + h_1) h_2 \int_0^l dx + X_2 \left[2 \int_0^{h_2} x^2 \, dx + m h_2^2 \int_0^l dx \right] = \Gamma$$

or,

$$X_1 \left[2 \left\{ k s \frac{c^2}{3} + n c h_1 \left(c + h_1 + \frac{h_1^2}{3c} \right) \right\} + m (c + h_1)^2 l \right] + X_2 m h_2 (c + h_1) l = \alpha \quad \ldots\ldots(3)$$

and,

$$X_1 m h_2 (c + h_1) l + X_2 h_2^2 \left(\frac{2}{3} h_2 + m l \right) = \Gamma \quad \ldots\ldots(4)$$

in which,

$$s = \sqrt{a^2 + c^2}$$

$$\alpha = 2 \left[k s \frac{c}{a^2} \int_0^a M_0 x \, dx + n \int_0^{h_1} M_0 (c + x) \, dx \right] + m (c + h_1) \int_0^l M_0 \, dx$$

$$\Gamma = 2 \int_0^{h_2} M_0 x \, dx + m h_2 \int_0^l M_0 \, dx$$

and,

$$k = \frac{I_3}{I_1}; n = \frac{I_3}{I_2}; \text{ and } m = \frac{I_3}{I_4}$$

The frame was made statically determinate by removing the roof hinge (without connecting the separated parts) and also putting the right column on rollers (Fig. 20).

The integrals in Equations (3) and (4) depend on the loading and must be determined in each case separately. The final results are (Fig. 20):

Loading (*a*).—For a unit load, p, uniformly distributed over the entire span of the roof (cantilevers excluded),

$$\alpha = \frac{p\,a^2}{4}\left[k\,s\,c + 2\left\{n\,h_1\,(2\,c + h_1) + m\,l\,(c + h_1)\right\}\right]$$

$$\Gamma = m\,h_2\,p\,a^3$$

Loading (*b*).—For a unit load, p, uniformly distributed over the entire span of the beam:

$$\alpha = m\,(c + h_1)\,\frac{pl^3}{12}$$

$$\Gamma = m\,h_2\,\frac{pl^3}{12}$$

Loading (*c*).—For a loading due to the cantilevers of the roof:

$$\alpha = -\mu_1\left[2\,n\,h_1\left(c + \frac{h_1}{2}\right) + m\,l\,(c + h_1)\right]$$

$$\Gamma = -\mu_2\,m\,h_2\,l$$

in which, μ_2 is the moment of these cantilevers over their supports.

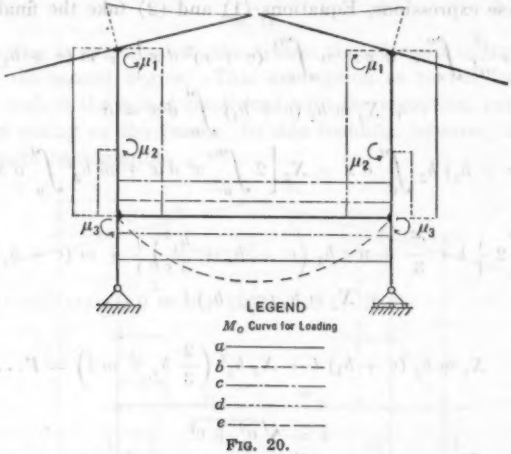

FIG. 20.

Loading (*d*).—For a loading due to the cantilevers or brackets above the elevation of the beam (for the inner brackets or cantilevers):

$$\alpha = \mu_2\left[2\,n\,f\left(c + d + \frac{f}{2}\right) + m\,l\,(c + h_1)\right]$$

$$\Gamma = \mu_2\,m\,h_2\,l$$

in which, μ_2 is the moment of the cantilevers over their supports. For the outer brackets the sign of μ_2 in the last two equations must be reversed.

Loading (*e*).—For a loading due to the brackets at the elevation of the beam:

$$\alpha = \mu_3\,m\,(c + h_1)\,l$$

$$\Gamma = \mu_3\,m\,h_2\,l$$

in which, μ_3 is the moment of these brackets at their supports.

If the influence of an unsymmetrical loading is to be considered, the rigid frame is statically indeterminate to the third degree. For the third unknown —the vertical component of the roof hinge—it is necessary that a third equation similar to Equations (1) and (2) be used.

For those who do not favor statically indeterminate structures, the frame represented in Fig. 18 can be made statically determinate by inserting a hinge in the top of the roof as is shown in Fig. 19. The result is a three-hinged frame, the analysis of which is well known.

LAURENCE J. WALLER,* M. AM. SOC. C. E. (by letter).—The author has written a concise and yet complete description of a building which was designed primarily to achieve structural economy. The design of this structure is a refreshing change from the current procedure in architectural engineering. As a general rule the architect first develops a building rather thoroughly in accordance with his ideas of architecture. The engineer is then called in and invited to support the building in such spaces as the architect has not seen fit to utilize in his treatment. The resultant structure is, of course, a compromise between engineering design and architectural concession. In this instance from very necessity the building was handled, from its inception, as an engineering problem. The architectural treatment was subordinated to the engineering requirements, and, indeed, it consists of little more than a refinement and decoration of the structure.

In a larger sense, this structure has added nothing new to architectural engineering. There are no features inherently novel in the design. It is worthy of consideration, however, in that its conceptions are fundamentally sound. Two main considerations govern the design: (1) Selection of the materials best adapted to the specific requirements; and (2) refinement of engineering design to secure maximum efficiency from the materials chosen.

In a balcony of this magnitude steel framing is decidedly indicated. The large cantilever length would definitely predicate such construction even if considerations of head-room and exit clearance did not demand it. In connection with the roof, the chief desideratum was to erect a structure which would be light and which would not exert a large bending moment on the long columns that support it. Steel trusses on rollers met the requirements very satisfactorily. Throughout the remainder of the structure, the requirements were not so severe, and reinforced concrete was chosen as being adequate for the construction involved and considerably cheaper than steel. As indicative of the economy of construction attained, attention is called to several features which may be of service in similar structures.

In the wall footings, the height of the wall below the first floor was used as a moment arm in the continuous wall footings. This procedure is in accordance with the probable stress distribution and is highly efficient.

The rigid frame construction in the Banquet Hall is the most economical type of structure and has the additional merit of producing a very graceful architectural effect. Unfortunately, statically indeterminate structures are

* Cons. Engr., Los Angeles, Calif.

comparatively little used in the United States. There is a mistaken feeling that this type of construction involves laborious and protracted engineering calculations. In some instances this, of course, is true. Literature of the rigid frame has been developed to such an extent, however, that, in general, a rigid frame design is as simple as a statically determinate problem. More serious consideration should be given to this form of construction since it is almost invariably highly economical and pleasing in appearance.

The cantilever purlin system is a construction much in vogue in Europe. There seems to be no good reason why its use in this country should not become more general. As against a bending moment of $\frac{WL}{8}$, the cantilever system can be arranged to secure a moment of $\frac{WL}{10.45}$ in the end spans and $\frac{WL}{16}$ in all interior spans. This is a saving not to be regarded lightly. The system is applicable to floor construction and has been used by the writer in that connection with notable economy. It is particularly applicable to long-span floor construction, where its use not only achieves economy, but also decreases the depth of a floor system to a minimum not otherwise attainable.

R. McC. Beanfield,* Assoc. M. Am. Soc. C. E. (by letter).—Considering the scope and valuation of the building industry comparatively little descriptive and practical data, relative to the actual design and construction of structural frames, particularly those involving statically indeterminate problems, has been published. Many theories have been advanced and discussions written about the design of building structures, but practical descriptive matter of value, covering the actual design, construction, and tests of such structures, is woefully lacking.

With this thought in mind the writer submitted his paper with the hope that, in the solution of his problems (some of which were rather unusual), he would contribute some practical data of value to those interested in structural design and economies of building construction.

Mr. Waller calls attention to the fact that the building was treated, from its inception, as an engineering problem to which the architectural treatment was more or less subordinated. By the very nature of the structure, with its unusual long-span elements, it consisted, to a large extent, of purely engineering problems. On the other hand, the esthetic treatment was not without its difficulties, and these were solved efficiently and economically by the architect. The desired efficiency was produced by 100% co-operation between engineer and architect, and resulted in many economies in the actual construction of the building.

Is it not really a fact that many modern buildings express false conceptions of architectural beauty—particularly of strength and stability—by the illogical use of decorated veneers, arches, and beams that do not seem to have substantial supports, and by other deceptive motifs belying strength and supporting beauty?

In the "Shrine Civic Auditorium" the architect expressed the large structural units which, for the most part, were exposed, as elements of architectural

* Cons. Engr., Los Angeles, Calif.

beauty. An arch is always more pleasing than a straight soffit beam. Why not use more concrete arches as real supports, thereby obtaining 100% use of the concrete, whereas only about 38% is actually utilized in a reinforced concrete beam? Why resort to the use of plaster when the natural surface of the concrete can be treated, or decorated, with excellent results and more economically, as was done in many of the structural elements of this building?

Special attention is directed to Mr. Waller's statements, namely,

"* * * (1) Selection of the materials best adapted to the specific requirements; and (2) refinement of engineering design to secure maximum efficiency from the materials chosen."

It is an exception rather than a rule, that the structural engineer is not permitted to use his judgment in the selection of the most efficient materials for a specific purpose. The arbitrary policy of dictating that this or that material must be used throughout the structure tends toward considerable waste of money.

Without the use of the elastic theory it would have been practically impossible to design most of the large structural units with any degree of safety or economy, because many of the structural elements were statically indeterminate in varying degrees. Reinforced concrete, owing to its monolithic characteristics and the fixed conditions and continuity at the joints, involves more or less statically indeterminate problems, which should be solved by the application of proper methods based on the elastic theory. It will avail nothing to ignore the stern fact that arbitrary and illogical rules, as adopted in most municipal building codes, will serve as a panacea for the design of such structures. There is ample information and precedent now available to those who will interest themselves in modern statics.

Mr. Waller emphasizes the methods of designing continuous wall footings wherein considerable economy is obtained by locating the tension steel high up in the wall above the footing proper. Mention is also made of the economy involved in the cantilevered purlin system, which can likewise be applied to floor systems.

Mr. Noetzli's discussion has supplemented the paper with several interesting features of the structural design, particularly the proscenium arch. Enlarging on his suggestions relative to extensometer readings, the writer strongly advocates the measurements of deformations in large and important structural elements of a building, especially of statically indeterminate reinforced concrete frames. For example, it would be enlightening to know the magnitude and effect of secondary stresses in long-span reinforced concrete trusses, several of which have been constructed within the past five years. The measurement of stresses in rigid frames, verifying theoretical assumptions, would do much to create increased confidence in, and the more extensive use of, such structures.

Relative to extensometer readings Mr. Belzner states:

"When the pressure was always placed directly over the contact points and firmly held against the member to be measured, there could not possibly be any spring of the various parts in the strain-gauge, causing variations in the readings."

The personal equation of the operator has much to do with the accuracy of strain-gauge readings. Applying equal, vertical pressures on two points 8 in. apart, sometimes in difficult positions, by one man, is easier said than done. Unless the pressures are exactly vertical over the contact points a variation in the deformation read is certain. For this reason an average of three measurements was taken.

To read deformations accurately by extensometers requires considerable technique and varies for different types of strain-gauges. More published data on the technique of strain-gauge measurements would be of considerable assistance to the profession.

Mr. Floris submits a commendable discussion relative to the solution of the rigid frames supporting the Banquet Hall roof. His suggestions relative to the use of hinges and the avoidance of fixity by brackets at the column joints, at the first and second-story girders, in order to reduce to a minimum the statical indeterminate conditions, are noteworthy and lead to a definite determination of all stresses in the frame. On the other hand, the value of the rigidity of the structure, as a whole, must not be overlooked for conditions that are produced by seismic disturbances. With slight variations in the seismic oscillations a series of loosely jointed beams and columns would act as battering rams, resulting in much probable damage to the entire structure.

The writer's analysis of the stresses in these frames assumed the main columns to be hinged at the second-floor level, with hinges at the outer supports of the roof girders, thus obtaining a frame statically indeterminate in one degree—that of the horizontal reactions at the column hinges. Other parts of the frame, below the column hinges, were designed on the basis of relative rigidities.

The solution of the three-hinged frame, as suggested by Mr. Floris, is quite novel and instructive. The method of analysis is given in detail and contains general formulas for the most practical loading conditions.

That the writer has been repaid for his efforts is reflected in the assistance he has been able to render others desiring data involved in the solution of some of the problems presented in his paper.

Paper No. 1701

ADVANCES IN WATERWAYS ENGINEERING DURING A HALF CENTURY*

By W. M. Black,† M. Am. Soc. C. E.

With Discussion by Messrs. C. L. Hall, De Witt D. Barlow, and W. M. Black.

Synopsis

A review of the progress of waterways engineering must include statements of advances made both in the science and in the art of engineering. Since an engineering problem is solved best when the desired results are obtained in the least time and at the least cost, progress in engineering is measured by the improvement of methods and the reduction of costs. The art of engineering is very old. It is questionable whether more noteworthy examples will ever be produced than those exemplified in the pyramids and temples of Egypt, the irrigation works known to ancient peoples, the aqueducts of Rome, or the walls and canals of China.

Modern engineering can boast of great triumphs, but the advances made have been mainly in plant and methods causing reductions of time and costs. In this paper, the writer will not be able to treat this subject from the world-wide viewpoint which it deserves. He will simply try to show some of the progress made in waterways engineering in the United States.

Science of Waterways Engineering

Researches into the laws governing the flow of water in streams date back through the centuries, but it is hardly too much to claim for Humphreys and Abbot that present knowledge of stream flow is largely based on their pioneer work in the Mississippi, carried on during the middle of the Nineteenth

* Presented at the meeting of the Waterways Division, Philadelphia, Pa., October 8, 1926, and published in October, 1927, *Proceedings*.

† Maj.-Gen., U. S. A. (*Retired*); Engr. (Black, McKenney & Stewart), Washington, D. C.

Century. Since then, engineers of both Europe and America have continued the research until, to-day, formulas are available by means of which the discharges of streams can be determined with a fair degree of accuracy. The relation between rainfall and stream discharge is yet under investigation. Many data have been collected and tentative formulas proposed. The complexities which this subject presents are well shown in papers published by the Society.

The question of flood control has also received wide consideration by American engineers and has been the subject of papers and discussions before the Society. The Assouan Dam, in Egypt, and the work of the Miami Conservancy Commission, in Ohio, are notable examples of works constructed to this end during the past fifty years. The relation of deforestation to river floods has been widely discussed, notably by Chittenden,* Burr,† and Townsend.‡

The action of side channel spillways has been well discussed§ by Julian Hinds, M. Am. Soc. C. E. The efficacy of such spillways in controlling flood heights is under trial in the Sacramento River, California, and is being studied for the Mississippi River by a Board of Engineers.

The effects of a regulated flow from storage reservoirs in maintaining navigable depths in the Mississippi River above Lake Pepin, and in decreasing flood heights, have been under observation and record since 1880, when the reservoir project was authorized, affording a material increase in exact data on this important branch of waterways engineering.

The volumes, movement, and heights of floods in the Mississippi River have received prolonged study by the members of the Mississippi River Commission and their assistants, and to-day it is possible to predict, for points on the lower river, the height which will be attained by a flood wave passing St. Louis, Mo., or Cairo, Ill. The phenomenon of the increase of the velocity of flood wave propagation over that of flood river current, slight in shoal water, but great in deep reaches, has been studied and announced. Another important addition to waterways engineering knowledge, is the better understanding of the courses followed by the filaments of water of a river in their progress through a bend, and the better understanding of the processes of bank erosion and bar formation obtained therefrom. The important functions of bends in a river which flows through an alluvial plain are also now better appreciated. "Boils" in the deep water of bends and the cause of the formation of the "mud lumps" near the mouth of a river like the Mississippi, are yet under study. The general principles of waterways engineering as now generally accepted, have been ably outlined by Townsend.‖ Progress has been made in the study of tidal action in rivers and estuaries and in canals which join two bodies of water in which tidal action exists. Parsons' study of the tides and their action

in the Cape Cod Canal,* Marmer's studies of the tides and their action in New York Harbor,† and the report of Zeskind and Le Lacheur on those of Delaware Bay and River,‡ give valuable data. The best study of this subject known to the writer is that of L. Bonnet, Engineer and Director of Ponts et Chaussées, Belgium, on tidal action in the Scheldt River,§ in which the magnitudes of the action of the various tidal phenomena in any reach of the river are shown to be functions of the tidal energy entering that reach, and formulas are given by which, for any proposed change in the channel capacity of the reach, the corresponding change in the tidal phenomena can be predicted within reasonable limits of accuracy. This subject is now being studied on the Chesapeake and Delaware Canal.

The great developments of the past half century in irrigation and in hydro-electric production have led to increased knowledge of the principles governing works constructed for these purposes, but these subjects are beyond the scope of this paper.

The formation of an up-stream undercurrent of salt water at and near the mouths of the Mississippi River, when the main river current is not reversed in direction, was first investigated by Lt. Col. E. J. Dent, Corps of Engineers, U. S. A., M. Am. Soc. C. E., and described‖ by Col. C. McD. Townsend, U. S. A. (*Retired*), M. Am. Soc. C. E. The subject of bottom salt-water undercurrents was also studied in 1921-22 by Capt. (now Major) A. P. von Deesten, Corps of Engineers, U. S. A., Assoc. M. Am. Soc. C. E., in the Sabine-Neeches Waterway, Texas.¶ The action of a lock between an upper fresh-water pool and a lower pool of salt water, in pumping salt water into the upper pool, has been studied at the Charles River Lock, Boston, Mass., and the Gatun Locks of the Panama Canal. There have also been made many studies of the effects of storm wave and current action on sandy coasts.**

The causes and effects of upward water pressure on dam foundations and the measures necessary to overcome this pressure have been widely investigated. Many studies have been made of the stresses in arches and particularly in the arch of a single arch dam, under the supported pressures.

All these studies form additions to the science of waterways engineering.

Art of Waterways Engineering

The past fifty years have produced notable advances, largely due to increased knowledge of the properties of materials, to the use of electricity for power and light, to the development of steam and internal combustion engines, and to the great improvement of machines thereby made possible.

Although concrete in one form or another has been in use for centuries, its wide application to all classes of structures is less than fifty years old, and this wide use is largely due to the employment of steel in reinforcement. As a result of this use, the properties of concrete and the action of the reinforcement have received extended study, with the development of numerous formulas for practical application. A recent advance has been in the development of alumina cements which attain their strength in a short time after setting.

Hydrographic Surveying.—Aeroplane photography has greatly facilitated the work of hydrographic surveying. By its aid, extended surveys can now be made periodically with relatively small expenditures of time and money, and changes in the course of a stream, or in a coast line, noted and their cause studied.

The use of drags or sweeps in determining navigable depths and discovering submerged obstructions has become general and the sweeps themselves have been improved in form.

The first sweep designed to cover large areas rapidly was devised by Capt. S. S. Leach, Corps of Engineers, U. S. A., and used by the U. S. Lake Survey in 1893-95.* Subsequently, in 1902, it was greatly improved by F. C. Shenehon, M. Am. Soc. C. E., then Principal Assistant Engineer of the Lake Survey.† As developed, the sweep can cover a swath 2 000 ft. wide. In 1908, the maximum day's work of one sweep covered 5 sq. miles.‡ The use of the sweep was adopted by the U. S. Coast and Geodetic Survey about 1904. In a recent survey in Alaska, the Coast and Geodetic Survey party was able to cover 65 sq. miles in one day's work.§ The construction and operation of the wire drag and sweep are described in recent publications of the U. S. Coast and Geodetic Survey.‖

A method of making continuous lines of soundings was developed by the U. S. Lake Survey in 1899-1900, by the use of a heavy weight suspended by a fine wire from a drum, the revolutions of which gave the depth. The weight was raised just clear of the bottom after each sounding. Soundings were made at intervals of 20 sec.¶ A few years afterward the late E. S. Wheeler, M. Am. Soc. C. E., invented an instrument called a bathometer by which a continuous profile of the bottom can be delineated on paper.**

The most important improvement of sounding apparatus is one developed quite lately by the Engineer Department of the U. S. Navy, called the "Sonic depth-finder." With this instrument deep-water depths can be determined at short intervals without stopping the course of a vessel. This instrument has proved of special value in work connected with the placing and repair of submarine cables in ocean depths. With this instrument the

** *Loc. cit.*, 1908, p. 2528.

Hydrographic Office, U. S. Navy, is making bathometric charts of selected ocean areas. In "Bathometric Chart No. 5194, San Francisco to Pt. Descanso", the ocean bed was covered between the 100 and 2 000-fathom contours, with soundings in parallel courses, 10 or 5 miles apart. In 38 days of field work 34 000 sq. miles were contoured by 5 000 soundings made at a ship speed of 12 knots. In working up the data collected by the field parties, a new instrument called the "Pantograver" has proved of value. With attachments eliminating distortion of cloth or paper, it is hoped eventually to be able to engrave plates from photographs; such an attachment is now in use, but it concerns one direction only.*

Many improvements in instruments and methods have been made by the U. S. Coast and Geodetic Survey. Recently, a portable automatic tide gauge has been developed by G. T. Rude, Commander, U. S. Coast and Geodetic Survey, M. Am. Soc. C. E.,† which can be easily carried and installed in the field. A current direction indicator has also been devised with which current directions can be determined simultaneously at three different depths on the same vertical.†

The U. S. Coast and Geodetic Survey has developed a method whereby the position of a survey ship can be accurately determined when it is beyond the range of visibility of shore objects and when closer to shore during low visibility on account of fog and haze. The method also permits surveying during the hours of darkness with the result that offshore hydrography has been materially speeded up by permitting the ship to work continuously throughout the day, and even on those days when formerly field work was impossible. This method and the apparatus have been fully described.‡

The Bureau has conducted extensive tests on various types of echo sounding apparatus, including the Navy sonic depth finder and an apparatus invented by the Submarine Signal Corporation known as the Fathometer. The Fathometer was designed primarily as a navigational sounding machine, and, in its original form, did not possess quite the accuracy required for surveying. However, this defect has been eliminated by the addition of a suitable governor on the timing apparatus so that now results can be obtained with the Fathometer quite as accurately as by any echo sounding apparatus and with almost the precision of direct wire measurements. The Bureau has two ships equipped with this apparatus and expects to so equip all surveying ships. The particular merit in this type of echo sounding apparatus lies in its ability to measure moderate and shallow depths. The Fathometer to date gives very accurate results down to about 15 fathoms, and there is reason to believe that with certain definite improvements the range may be extended to perhaps 4 or 5 fathoms.

Two sounding machines of the reel and wire type have been developed by the Bureau, one for use in great depths and the other for depths of 400 to

500 fathoms. These machines consist of reels driven by electric motors and controlled in such a way that the reels may be stopped instantly and started at any desired speed. While no new principles are involved in this apparatus, it is, nevertheless, a great improvement over the older type, due to its simplicity, sensitiveness, and flexibility, all of which result in greater speed of operation and greatly reduce the danger to the submerged apparatus, detaching rods, water specimen bottles, and thermometers. It has been found that inexperienced personnel can operate these new machines as efficiently as trained operators could handle the older types. As an illustration of this point, it may be mentioned that one survey ship with a new and untrained crew carried a line of soundings from New York to San Diego and, in addition, explored the deep north of Porto Rico without once parting the wire or losing any equipment. That, it is believed, established a new record for oceanographic work.

Pressure tubes for measuring depths as great as 100 fathoms with considerably greater precision than the commercial glass tubes have been developed in this Bureau and are now used extensively on surveys on which heretofore such apparatus could not be tolerated because of its unreliability. These tubes record depths with a probable error not in excess of 5% and are now used extensively for depths greater than 15 fathoms.

Dredging.—Dredges operated by steam power have been used in river regulation for more than a century, but during the past fifty years their efficiency has been vastly increased. In addition to the old type clam-shell, dipper, and ladder dredges (all of which have been greatly improved), hydraulic pump dredges have come into general use.

These dredges are of two general classes: Hopper dredges and pipe-line dredges. The hopper dredge, while under way, excavates material by means of a drag attached to the end of a suction pipe of a pump and discharges into hoppers in the ship. It was invented by a Mr. Lebby, at Charleston, S. C., in 1855, where the first of its type was used in 1857. After the Civil War a similar dredge was built in 1871, by the late Brig.-Gen. William Ludlow, U. S. A., M. Am. Soc. C. E., (then Captain, Corps of Engineers, U. S. A.), for use on the South Atlantic Coast. It is the only type of dredge which can be operated efficiently in a seaway and is now in general use throughout the world for deepening the entrances to harbors and rivers, having been markedly developed in efficiency and power. By its aid, the problem of securing and maintaining entrance channels protected by jetties has been greatly simplified. In the latest dredges of this type, the propelling, steering, and pumping machinery is actuated by electricity generated from power supplied by internal combustion engines.

These electric dredges, due to their ease of handling and close control, are capable of being operated easily in a very limited space, such as in narrow channels, or within a very short distance of piers, which would be both difficult and more dangerous with steam dredges. While cost records for a complete year of operation are not available, it is estimated that operating expenses

will be 20% less than those of the same type of steam dredge. Maintenance expenses thus far can be only estimated.

These dredges have been used largely on experimental work, with a view to determining the type of dredging for which they were best fitted, resulting naturally in an increased cost of operation. On certain classes of dredging the cost has been as low as 3 cents per yd., with approximately 400 000 cu. yd. removed monthly.

Pipe-line hydraulic dredges were first used on the Pacific Coast. These swing in a position which is slowly moved forward, excavate material by means of a revolving cutter at the bow, just in advance of the end of a suction pipe, and discharge through a pipe line supported on floats.

Fig. 1 is a view of the U. S. Pipe-Line Dredge *Wahalak*, showing an old type cutter for soft materials. Fig. 2 shows a new type cutter for soft materials on the U. S. Pipe-Line Dredge *C. B. Harris*.

This type has also received a great development. While the general radius of delivery through the pipe line had averaged about 2 500 ft., with an elevation not exceeding 10 ft., recently, in the Chesapeake and Delaware Canal, a dredge of this type delivered material at a distance of more than 500 ft. and at an elevation of more than 90 ft. In the Panama Canal, another pipe-line dredge, aided by a relay pump on a barge, delivered through a pipe line, 1 500 ft. long, to an elevation of 250 ft., or through a pipe line, 15 840 ft. long, to an elevation of not to exceed 20 ft. This work was done at an average cost of 28 cents per cu. yd.*

It is claimed that a late type of this class of dredge, working in Florida with a 16-in. pump, excavated sand and mud, and delivered at a distance of 3 000 ft. at a cost of 7 cents per cu. yd., and when equipped with a special cutter head excavated and removed the limestone rock found there to a depth of 22 ft. at a cost of 40 cents per cu. yd. Fig. 3 shows the rock cutter on the U. S. Pipe-Line Dredge *Barnard*.

On the Mississippi River, a special class of this type of dredge has been developed for the removal of the bars of fine material found there. In this type, no revolving cutter is used, the material being stirred up by water jets in advance of the suction pipe.

Most of these Mississippi type dredges are self-propelled and resemble in outward appearance a stern-wheel, shallow-draft Mississippi River steamboat. On the hull are mounted power units; a centrifugal dredging pump; a wide structural ladder hinged in a well recess at the bow of the dredge and carrying at its lower end a dustpan-shaped suction head 20 ft. or more wide, which is provided with water-jet nozzles to loosen the material; a hauling winch; hoisting winches; spuds; the necessary auxiliaries and controls for operation; and suction and discharge piping and floating pipe line.

In operation, the dredge steams to a point above the bar, drops two anchors one on each side of the channel to be cut, then drops several hundred feet down stream on the anchor cables, to the lower edge of the bar. The dredge pump, and the pump furnishing water for the jet agitator, are

* J. G. Claybourne, *The Military Engineer*, Vol. XVII (1925), p. 910.

started, the dustpan suction head is lowered to the bottom, and the dredge is hauled up stream by the hauling winches, with the suction head against the bar. The discharge is from the side of the dredge and through a short floating pipe line, 500 to 1 000 ft. long, mounted on pontoons. The pipe line is held in a line abreast of the dredge by the dynamic action of the stream on a baffle-plate located at the end of the line. The dredge material is deposited in the stream, but along the edge of the channel, where it forms a dike which assists in deepening the channel by the scour produced by its action in regulating the direction of the stream.

When the upper edge of the bar is reached the dredge drops back again and makes similar cuts alongside of and parallel to the first cut. Thus, a channel is cut through the bar, and this channel is later widened and deepened by the action of the current through it.

The cost of dredging varies with the relative number of hours of work and of idle time, with efficiency of the plant, the depth of dredging, the character of the materials to be excavated, and the location at which spoil is deposited. For each type of dredge there is a class of excavation for which that type is best fitted, and no judgment can be formed of the relative efficiency of the types without a full knowledge of the conditions found in the work.

In this connection the record of the recent performances of hydraulic dredges used on the waterways engineering works of the United States under the charge of the Engineer Department, U. S. Army, is of value. This record, Tables 1, 2, and 3, includes dredges which worked for the entire year.

Rock Excavation.—As stated previously, soft rock in place can now be excavated by the hydraulic dredge when equipped with a special toothed cutter. Rock in thin strata can be broken by the chisel dredge, first used in the Mississippi River in 1855, but much improved since. The Lobnitz rock cutter is only a development of the old type.

Drill boats, generally equipped with piston and well drills, for drilling and blasting rock under water, also have been markedly improved. Hollow pipe drills have come into use since devised by Col. George McC. Derby, Corps of Engineers, U. S. A. (*Retired*), M. Am. Soc. C. E. (then Lieutenant, Corps of Engineers, U. S. A.), in 1883, in the excavation of Flood Rock, Hell Gate. There, too, the simultaneous explosion of 44 175 charges of rack-a-rock placed in the drill holes in the walls of the galleries cut in Flood Rock, was effected by the method of sympathetic explosions, by the explosion of charges of dynamite laid along the center lines of the galleries. These gallery charges were fitted with fuses which were connected with a firing battery.*

The improvements in drilling machinery, in electric firing batteries and exploders, and in explosives, have greatly facilitated and cheapened this class of work.

River Regulation.—The advances made in the methods of regulation works can be appreciated from a comparison of the methods used by the late Brig.-Gen. O. H. Ernst, U. S. A., M. Am. Soc. C. E. (then Captain, Corps of Engineers, U. S. A.),† in 1879, at Horsetail Bar, Mississippi River, near

† Time lost from work includes all other time.

Prior to 1878, the guiding and cross-dikes were built solidly of stone and brush, placed on the river bottom. When this bottom was soft and erodible, these dikes were quickly undermined and destroyed. Under the direction of Captain Ernst, use was made of brush mattresses (Fig. 4) for holding the bottom, and of permeable screens of brush and of Brownlow weeds for reducing current velocities and inducing fill. Although these proved effective, they were too fragile. Brush mattresses are still used, but of improved construction. The latest advance has been in building brush mattresses of fascines, or of substituting for the brush mattress, an articulated, reinforced concrete mat. Fig. 5 shows a type of woven mattress and Fig. 6 is a view of concrete bank revetment at Gasconade, Mo. The permeable dikes have been made stronger and more permanent in form by the use of pile bents firmly connected. Quite recently, reinforced concrete piles and caps have been used with good results in cost. Fig. 7 shows the results of the use of a retard (permeable dike)

on the Missouri River. The main channel was along the bank at the time of construction.

The system of "retards" made of trees, now extensively used for bank protection, is only a larger "Brownlow weed" firmly anchored by concrete piles sunk deeply into the river bottom by the water-jet process. The channel for the jet is cast in the center of the pile, with exits for the water distributed at intervals along the pile length.

* Time at work includes: Pumping; shifting and waiting on pipe line or scows; shifting dredge; passing vessels; going to and from berth; and miscellaneous.

† Time lost includes all other time.

‡ The higher costs for the 22-in. pump dredge were due to its use in excavating sand and coral rock.

The method of sinking piles by the aid of a water jet* was first used in Matagorda Bay, Texas, at the suggestion of the late Gen. George B. McClellan,

* "The Water Jet as an Aid to Engineering Construction," by the late L. G. Schermerhorn, M. Am. Soc. C. E., U. S. Asst. Engr., Engr. Dept., U. S. Army, 1881.

U. S. A. (then Lieutenant, Corps of Engineers, U. S. A.). It is said that he conceived the idea after watching sand crabs bury themselves. The water jet was used occasionally, thereafter, as an aid in pile-driving and in sinking caisson cylinders, but it was not until 1871 that its true function of relieving the pile from skin friction was established by Captain Brown, Corps of Engineers, U. S. A., in the operation of sinking screw-piles for the pier at Lewes, Del., when he found that the jet had to be applied above, and not below, the screw disk. The patented pile of the "retard" process takes full advantage of this principle. The use of the water jet in pile-driving is now almost universal. Reinforced concrete piles are also of recent origin.

Levees.—In place of the old dump-wagon and horse-drawn scraper process, levees are now constructed more safely, more rapidly, and at less cost by the use of drag-line scrapers and of movable cableways from which scoop buckets are operated.* As a result of experience, the Mississippi River Commission has adopted a standard cross-section for levees, which is proving satisfactory.

Jetties.—Little change has been made in the methods of the construction of jetties at river and harbor entrances, except that brush mattresses are now rarely used, and then only as a foundation on an exceptionally soft bottom. For jetty construction, a trestle built along the jetty axis and carrying a railroad track is now generally preferred.

Canalization.—In canalization work various types of movable dams have been tried out and improvements made. By an improvement in the hurter

* *The Military Engineer*, Vol. XVI, 1924, p. 288.

(the cast-iron shoe against which the end of the prop rests when the wicket is up) of the Chanoine wicket dam, the necessity for the use of the troublesome tripping-bar can be avoided if so desired. A new type of wicket, invented by Mr. Guy B. Bebout about 1913, was placed in service at Dam No. 13, Ohio River, in 1915. The advantages of this wicket are:

1.—It can be raised at any open-river stage to the top of wickets without serious loss of time.

2.—It can be raised against any difference in pool levels, sufficient power being applied at the chains.

3.—It can be lowered under all conditions of river stages and pool levels.

4.—When raising the wicket, drift cannot obstruct or become entangled in the parts to such an extent as to prevent this maneuver, except in very extreme cases, and in such cases the drift should be easily removed.

5.—A boat, barge, or heavy drift striking the top of the wicket will cause the wicket to collapse without damage to the boat or dam.

Bear-trap dams have been greatly improved and dams of this type are now in use with lengths deemed impracticable fifty years ago. Fig. 8 shows Lock and Chanoine Dam No. 24, Ohio River. The fixed wire shows in the foreground, with the bear-trap, partly down, just beyond.

Perhaps the greatest advances made in this branch of engineering art have been in the details of lock construction.

Coffer-Dams.—The invention of interlocking steel sheet-piling has made practicable the construction of coffer-dams of a new and simple type, exemplified in the coffer-dams for the Black Rock Lock, Niagara River, the coffer-dam for the *Maine*, Havana Harbor, the Browns Landing Lock, Cape Fear River, North Carolina, and that for the Forty-Sixth Street Pier, New York, N. Y. In this last,* designed by Charles W. Staniford, M. Am. Soc. C. E., the pressure head of water resisted was 65 ft.

Foundations.—This form of piling has also proved of great value for cut-off walls around and below lock foundations in permeable soils and for cut-off walls in earth dams.

Locks.—In 1892 and 1893, the late W. L. Marshall, Brig.-Gen. U. S. A. (then Captain, Corps of Engineers, U. S. A.), began the construction of the concrete locks of the Illinois and Mississippi Canal. These are believed to have been the first locks constructed entirely of concrete.† To-day, the use of stone masonry for lock walls is exceptional.

Gates.—In the lock of the Davis Island Dam (now removed) single-leaf gates, 118 ft. long, which when operated rolled on a track into or out of a masonry recess in the land wall, were used for the first time (1881-82).

Culverts.—The lock of the Davis Island Dam was filled through culverts in the side-walls, fitted with valves moved by hydraulic power. It was emptied through a culvert below the lower gate recess. In the locks of the St. Mary's Falls Canal of 1881 and, later, as in the Panama Canal locks, the filling and emptying culverts have their orifices in the floors of the locks.

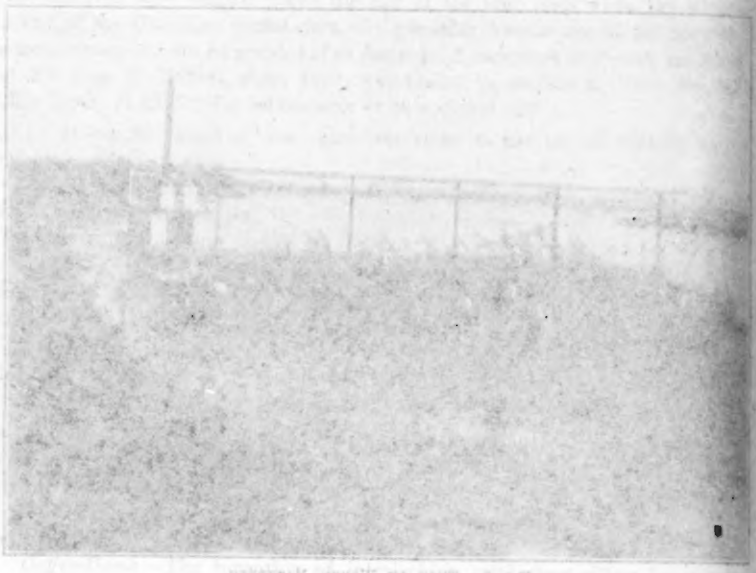

FIG. 7.—BRUSH RETARD (PERMEABLE DIKE), SHOWING FILL RESULTING FROM (LOW-WATER) WINTER SEASON.

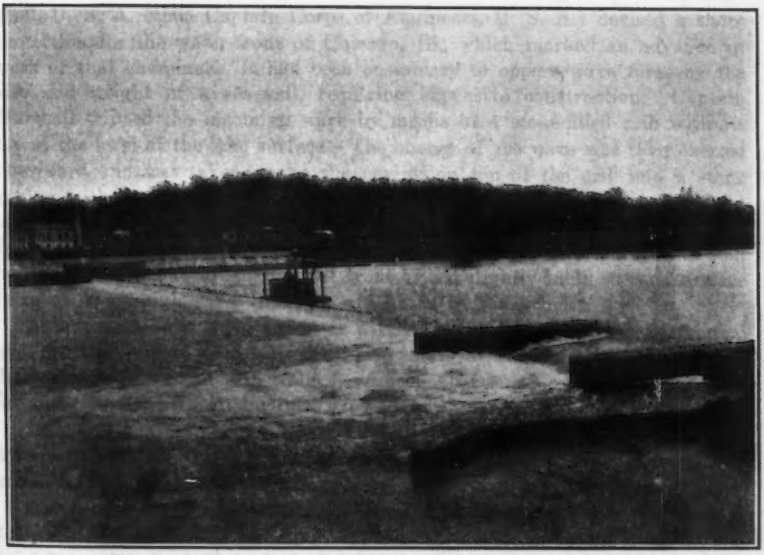

FIG. 8.—VIEW OF LOCK AND CHANOINE DAM NO. 24, OHIO RIVER.

Valves.—The well-known butterfly and cylindrical valves are yet in general use, the cylindrical type having been adopted for the great Panama Canal locks. In 1883, Mr. F. G. M. Stoney, of London, England, invented the sliding valve, known as the "Stoney gate". This type is also widely used, being at times fitted with roller bearings.

The mechanisms for opening and closing lock-gates have been greatly improved, the bull-wheel type (devised by Edward Schildhauer, M. Am. Soc. C. E., for the Panama Canal locks*) operating either chains or spars, being greatly favored for operating heavy gates.

Almost all important locks now have some form of a removable, emergency dam for closing the lock at its upper pool end in case of accident to the gates. The Panama locks are also provided with guard chains to prevent the accidental ramming of the gates.

In addition to these precautionary measures, ships passing into and through the Gatun Locks of the Panama Canal are not permitted to use their own power, but are towed by locomotives operating on tracks laid on the lock-walls.

It has also become customary in the larger locks to operate the gates and valves by power generated from the head between the upper and lower pools.

Fixed Dams.—The major advance in construction methods for fixed dams has been in the development of dams of the single and multiple-arch types. The construction of earth dams by hydraulic pumping methods should also be noted. The Gatun Dam of the Panama Canal is a notable example.

Sea Walls and Breakwaters.—About 1890, the late Brig.-Gen. W. L. Marshall, U. S. A. (then Captain Corps of Engineers, U. S. A.) devised a shore protection for the water-front of Chicago, Ill., which marked an advance in work of that character. It had been customary to oppose wave force by the size and weight of a sea-wall, requiring expensive construction. Captain Marshall tripped the incoming wave by means of a stone-filled crib with its top at the level of the lake surface. The energy of the wave was then exerted downward and was taken up by the paving on top of the crib and a stone paving to the rear laid on a gentle slope. At the crest of the slope only a light wall was needed to stop the final wash of the wave. The same principle was followed by the writer in constructing the Malecon of Havana, the sea-wall being set back about 35 ft. from the front of the slightly inclined rock surface lying at about high-water level, on which the wall was built.

In some sea-walls wave action is partly deflected by building the vertical wall with a concave face. In the breakwaters of the harbors of the Great Lakes, the old vertical crib walls have been abandoned and the breakwaters are made lower, with an inclined exposed face.

Economy has been effected and durability increased in these breakwaters by substituting for the old form of timber cribs, caissons made of reinforced concrete, which after having been placed are filled with concrete in mass.

Reinforced concrete caissons are also being used as subaqueous foundations for walls and for piers. Examples of this use are found in the dock wall at

* Paper No. 20, International Eng. Congress, San Francisco, Calif., 1915; Report, Isthmian Canal Comm., 1910, p. 53.

Petosky, Mich.*, and in the sea-wall for the China Basin, San Francisco, Calif.†

Messrs. Harrison S. Taft and O. D. Jones have written a valuable review of the use of concrete caissons,‡ and Mr. Taft's paper on "Reinforced Concrete Docks",§ presented to the Society, contains much historical data.

The progress of waterways engineering in the United States is reflected in the work accomplished. The work done has been widely spread over the entire country, as must be the case, since the care and improvement of waterways, under the Constitution, is the duty of the Nation. Appropriations for this class of work are made from the National Treasury, and the will of the people at large is that no part of the widespread territory shall be without receipt of some direct benefit from the expenditures for waterways improvements. Under this condition it has been impossible to finish individual projects for improvement as rapidly as would be beneficial were it possible to consider the needs of each improvement separately and allot funds for it irrespective of other demands. Nevertheless, the accomplishments have been great and have materially assisted the economic welfare of the people, as shown by the recorded increases of trade reported in the commercial statistics for each port and waterway published annually by the Government.‖

Space will not permit an enumeration of all work done. A few examples must suffice. Almost all the work mentioned has been done since 1865.

Almost all the harbors of the Great Lakes are at the mouths of rivers. These were obstructed by bars, largely formed by the drift of sand along the coasts under storm action (drift and wave bars). The channels across the bars were shifting, with depths of from 3 to 5 ft. The earliest improvements were to fix and deepen these channels by jetties and to deepen the rivers above the mouths by dredging. Later, a system of breakwaters was built outside the mouths, forming exterior harbors. All of the more important harbors now have a navigable depth of 20 or 21 ft. below the standard lake level. The channels connecting the Upper Lakes have been improved to the same navigable depth. For many years, the navigation between Lakes Erie and Ontario has been through the Welland Canal, lying in Canada. The Canadian Government is now engaged in enlarging the channel and locks so as to permit navigation by ships of 25-ft. draft. The total commerce of the United States ports on the Great Lakes in 1924 amounted to 203 534 234 tons,¶ valued at $3 572 521 000, in addition to a ferry traffic of 926 140 tons, valued at $125 797 000.

The general program for the rivers of the Atlantic Coast is to improve each to the extent justified by present and prospective commercial use and to connect the mouths of all between Boston, Mass., and the Rio Grande, in Texas, by an intra-coastal barge canal. The Mississippi River and its principal tributaries are being improved so as to form a system of barge naviga-

ACKNOWLEDGMENTS

The writer is indebted to Capt. W. S. Crosley, U. S. N., Hydrographer, Navy Department, to Maj. Milo P. Fox, Corps of Engineers, U. S. A., and to R. L. Faris, M. Am. Soc. C. E., Acting Director, U. S. Coast and Geodetic Survey, for valuable assistance in the preparation of this paper.

DISCUSSION

C. L. HALL,* M. AM. SOC. C. E. (by letter).—The author has made what amounts to a survey of standard river and harbor practice. The special type of Mississippi River dredge described is not, and cannot be, used on the Upper Mississippi. The dredge used there is a pipe-line dredge, without cutter, and without propulsion machinery, and was first introduced in 1899.† The dredge is held by spuds, the position of the suction pipe being controlled by a catamaran,‡ moved by a swinging engine. The accordion type of joint, originally used, has been replaced by a ball joint. The normal cut of the dredge is 80 to 100 ft. in width.

The Upper Mississippi type of dredge is used not only for obtaining requisite channel depths, but also for securing material for wing-dams, the two purposes being combined whenever possible. The "sand dams" were first developed during the season of 1911.§ They are built out from shore, and usually are completed only to low-water elevation. They are then capped by the ordinary brush mattress with rock cover. The sand dam is such an economical type of construction that, when dredges are available, it has almost entirely replaced the brush and rock dam along the Upper Mississippi, except in stretches where the slope is abnormally steep.

DE WITT D. BARLOW,‖ ASSOC. M. AM. SOC. C. E. (by letter).—This very interesting paper contains two tables of costs, which the writer thinks are likely to create misunderstanding unless they are further explained.

Table 2 gives the average performance of Government-owned "Hydraulic Pipe-Line Dredges, Cutter Type" during the years 1923, 1924, and 1925, and states the costs as 8.32, 8.48 and 7.44 cents, respectively.

Table 3 ("Performance of Hydraulic Pipe Line Dredges Working Under Contract"), gives the average price per cubic yard for the years 1923, 1924, and 1925, as 20.99, 21.3, and 19.9 cents, respectively. While the casual reader might draw the inference that the cost of hydraulic dredging under contract is vastly greater than that done by Government plant, this is not the case.

In the first place, it will be noted that the total yardage on which the Government figures of approximately 8 cents are based, is about 1 500 000 per year, a very trifling amount; whereas the contract yardages, from which the average prices are obtained, vary between 13 800 000 and 25 000 000 per year. So there is no reason to suppose that there is any similarity between the work done by the Government and by contract plant. Even, however, if the work were identical, the figures would not be susceptible of comparison for the following reason. The contract prices represent the total cost to the United States of performing the amount of useful dredging done. The writer uses the words "useful dredging" advisedly. Contracts are let by the United States for the excavation of channels of fixed widths and depths, and with

* Major, Corps of Engrs., U. S. A., Rock Island, Ill.

§ *The Military Engineer*, September–October, 1924, p. 389.
‖ Pres. and Director, Atlantic, Gulf & Pacific Co., New York, N. Y.

certain fixed side slopes. The contract instrument provides that no payment will be made to the contractor for any work done outside the lines of the desired improvement. The contractor is required, however, to clear those lines, that is, to remove all material from within them. To accomplish that end, it is necessary to remove very large quantities of material from without the prescribed sections. This is called "no pay overdepth." It very often happens that in order to be paid for 1 000 000 yd. of excavation the contractor must remove 1 500 000 yd., or even 2 000 000 yd.

In the computation of costs of operating by Government plant, no account is taken of the amount of useful dredging performed. The amount of yardage set down as excavated is all the material removed by the dredge regardless of what it was. Even this determination is often made with the most trifling regard for accuracy. Sometimes the daily reports of the dredge captains are taken, which are no more than guesses, and are not likely to be too low.

The Government cost figures are obtained by dividing certain expenditures by the yardage thus determined. The expenditures themselves, however, do not include all, or nearly all, the cost to the United States of doing the work. They usually contain merely the operating cost of the plant while it is on the job. They never include plant rental, that is, interest and depreciation on the investment, which is a very considerable item; nor insurance (fire, marine, and liability); nor do they include any of the costs of maintaining idle equipment.

When the United States rents its hydraulic pipe-line dredges to private parties, it charges 0.1% per day of the first cost of the plant for rental, that figure having been determined after a careful study of their actual cost experience. That being the case, it is obvious that a dredge that costs $1 000 000 has fixed charges running against it in the amount of $1 000 per day, no account of which is taken in determining the nominal cost of Government operations. The upshot of the whole matter is, therefore, that the 8-cent costs are only costs in a very special sense. They are quite meaningless, unless one happens to know the formula. In order to compare these nominal Government costs with contract prices, it is necessary to make all the foregoing corrections, and others. Within the writer's experience the effect of these corrections is often to increase the cost to several hundred per cent. of the nominal one. It is astonishing what happens to a fraction when one continues to add to the numerator and to subtract from the denominator.

The writer can see no harm in keeping and publishing such nominal costs as long as the correlative circumstances controlling them are published or generally known. The difficulty is that they are not generally known and these data, which may be useful in the War Department, for purposes of its own comparisons, are likely, as in this case, to come before the public in an unexplained form and to mislead, although there is no intention on the part of any one to do so.

W. M. Black,* M. Am. Soc. C. E. (by letter).—Major Hall brings out two points which were omitted from the paper. The type of dredge described as

* Maj.-Gen., U. S. A. (*Retired*); Engr. (Black, McKenney & Stewart), Washington, D. C.

developed on the Mississippi River is efficient only for handling the very finely divided materials which form the bars in that river below the mouth of the Missouri, as well as in the Missouri, Arkansas, and other of the tributaries of the lower river. In the upper sections of the Mississippi River, above the mouth of the Missouri, the materials forming the bed of the stream are coarser and for their removal require the application of a greater cutting power than that afforded by the water jets of the lower-river type of dredge. The "sand dams" of the upper river mark an advance in the art of river improvement which should have been noted.

The comments of Mr. Barlow are also of value. To avoid misconceptions some further discussion of the costs of dredging seems desirable. Mr. Barlow is in error when he states:

"* * * that the total yardage on which the Government figures of approximately 8 cents are based, is about 1 500 000 per year, a very trifling amount; whereas the contract yardages, from which the average prices are obtained, vary between 13 800 000 and 25 000 000 per year".

A more careful scrutiny of Table 2 will show that the figures for "average performances" give the average of the work of 42 dredges in 1923 and of 43 dredges in 1924 and 1925, operating in approximately 20 different districts and having a total output varying between 61 000 000 and 72 000 000 cu. yd. per year.

With respect to the over-depth dredging, each contract makes provision for payment for the removal of materials from below the contract depth, usually for 1 ft. or 2 ft., in order to make due allowance for the unavoidable irregularity of the bottom of a cut. The statement that 1 500 000 or 2 000 000 cu. yd. "very often" must be removed in order to be paid for 1 000 000 cu. yd. of dredged material, may be true for exceptional cases. However, available records show that, as a rule, the yardage of "unpaid-for" over-depth dredging varies between zero and 30% of the yardage paid for. In certain cases dredging beyond over-depth limits is credited to the output of Government dredges, but the amount of such yardage is very small. Any extensive over-depth dredging by Government plant is done intentionally to avoid the necessity for early maintenance dredging.

The statement as to the method of computing the yardage excavated by dredges is in error. As a rule the yardage is computed from a comparison of surveys made before and after the dredging. These surveys are made by a field party, not connected with the dredging operation and reporting direct to the District Office. The same procedure is followed in measuring yardage in contract dredging.

The cost figures for the Government work include all operating expenses, except plant rental and depreciation, interest on investment, and fire, marine, and employers' liability insurance. The cost of the repairs and of plant maintenance is absorbed in the cost of the work.

The record for eleven years (1916 to 1926, inclusive) shows that the yearly average of losses to Government floating plant by fire, by collisions, and from miscellaneous causes is $164 195.47. The estimated value of the plant in

1925 was $47 654 706.00. The losses thus averaged $0.003446 per year per dollar of the investment.

The cost figures given for contract work in Table 3 do not show the entire cost of the work to the United States as they do not include the costs of surveys, of inspection, or of office overhead.

The charges for the rental of Government plant are made high purposely in order that such plant shall not be used by private individuals in competition with a contractor's plant. The illustration given by Mr. Barlow of the handicap formed by rental charges is misleading in that there is no Government pipe-line dredging unit which has cost $1 000 000. In very few cases is the valuation as high as $500 000.

It is the policy of the Engineer Department to have dredging done by contract unless there is too great a difference between the cost of contract work and the cost of work with Government plant. In order to be able to judge relative costs more clearly, since 1926 the cost accounting system has included rental and depreciation on all items of floating plant. In estimating the costs of dredging with Government plant in comparison with bids by contractors the Department takes into consideration interest on investment (on value of plant used), and fire, marine, and employers' liability insurance. These, however, are not included in the published cost figures as actual charges against the work.

Paper No. 1702

THE DELAWARE RIVER FROM PHILADELPHIA TO THE SEA*

By F. C. Boggs,† M. Am. Soc. C. E.

With Discussion by Messrs. Charles M. Spofford, Henry J. Sherman, Earl I. Brown, Harry Taylor, F. C. Warner, William Gerig, and F. C. Boggs.

The Delaware River has its origin in a small lake in Southeastern New York. It flows in a general southerly direction, emptying into Delaware Bay, an estuary of the Atlantic Ocean, the entrance to which is marked by Cape Henlopen on the west and Cape May, the southern end of the New Jersey promontory, on the east. The upper reaches of the river have the usual characteristics of a mountain stream. Its middle section is less torrential, but is broken by reefs and rock ridges which, with its shallow depths, render it unfit for navigation except for small boats in the quiet pools between the rapids. At Trenton, N. J., the river begins its long meander as a tidal stream through the low coastal plain bordering the ocean. From Philadelphia, Pa., to the sea, the section with which this paper is concerned, it is a stream of varying depths, increasing in width from 5 000 ft. just below the Schuylkill River near Philadelphia, to approximately 4 miles where it enters the Bay.

The total length of the waterway from the Atlantic Ocean to its source is approximately 365 miles, of which the stretch comprising the first 131 miles from the sea to Trenton, is tidal.

Although there are numerous streams flowing into the Delaware River throughout its entire length, there are two only which can be dignified by the term tributary rivers. These are the Lehigh and the Schuylkill, each having its source in the Blue Ridge Mountains in Pennsylvania, the former

* Presented at the meeting of the Waterways Division, Philadelphia, Pa., October 5, 1926.

† Col., Corps of Engrs., U. S. Army; Dist. Engr., Philadelphia, Pa.

entering the main stream at Easton, 50 miles above Trenton, and the latter at the southern boundary of the City of Philadelphia.

The discharge of the Delaware River at its mouth is a combination of tidal and fresh-water flow. No data are available on which to base an exact determination of the fresh-water flow, but that it is a material factor is evidenced by tidal and current records at Liston Point, the section where the waterway designation is changed from river to bay. At this point the duration of ebb is 6.6 hours as against 5.8 hours for flood, while the ebb current at strength in a vertical section in the channel averages approximately 2.4 knots as compared with the flood of only 1.8. The combined discharge at this section during hours of ebb is at the rate of about 800 000 cu. ft. per sec., and a very rough approximation gives the fresh-water discharge during the same period as averaging nearly 250 000 cu. ft. per sec.

Original Condition

In its original condition, the Delaware River below Philadelphia was obstructed by a number of shoals or bars, over which the minimum usable depths at mean low water were between 17 and 22 ft. Fifty years ago, before the systematic improvement of the river was undertaken by the Federal Government, a ship sailing up the channel to Philadelphia required in some cases four days to make the trip, owing to the necessity of waiting for high water to pass over these shoals.

During the winter months the ship was also likely to be delayed a day or more by ice jams blocking the entire channel at the "Horse Shoe", where the river bends sharply to the westward at the lower end of Philadelphia Harbor. The harbor itself was obstructed by Smith and Windmill Islands and their adjacent longitudinal bars, and by shoals in its upper reaches.

River Bottom

Except at a few localities where there are rock outcrops, the bed of the Delaware River below Philadelphia is composed of sand and gravel overlaid in most sections by a light mud. At some places this overlying mud extends to considerable depths, rendering the construction of dikes and bulkheads difficult and costly. This is particularly true where these works are required to sustain the thrust of earth fills behind them.

Omitting the rock sections, dredging can readily be done by the suction type of dredge, although for contract work clam-shell and dipper dredges have been used almost exclusively for the removal of material from the channel.

At times muddy, the Delaware River below Philadelphia can not be classed as a silt-bearing stream, although in time of freshets in the upper river, or in tributary streams, some deposit is undoubtedly due to silt brought into the river by flood waters. Caving banks and the washing of the banks by waves are also unquestionably the sources of additional deposits.

The shoaling in the channel which must be removed to maintain the project depth is caused partly by these deposits, but the large bulk of such shoaling cannot be accounted for from these sources alone. The tendency of cross-currents to wash the material from the sides of the bed into the

channel has been noted by many investigators. The writer believes that the largest part of the dredging for channel maintenance is due to two factors: First, the building up by these cross-currents, and by deposition of suspended material, of a middle ground where, due to islands or to the peculiar bends in the river, the ebb flow and the flood flow do not naturally take the same channel; and, second, the gradual movement of the surface of the mud bottom toward the dredged channel, resulting in a shoaling of the channel and a general lowering of the bed of the stream to some distance on each side of the channel width. This latter condition is shown by a comparison of surveys made in 1909 and 1924.

Tides and Currents

A complete and exhaustive study of tides and currents in the Delaware River has recently been made by the United States Coast and Geodetic Survey.* A copy of this report was loaned to the writer by the courtesy of the late E. Lester Jones, M. Am. Soc. C. E., Director of the Survey, and what follows under this heading is based almost entirely on this report.

The oldest recorded tidal observations in the Delaware River Basin date back to about 1835. These early records are based on unimproved instruments and methods and are probably far from accurate. The introduction of the automatic, self-registering tide gauge in 1854 and the adoption of standard time about 1885 permitted a more nearly accurate record.

The tide from the open ocean enters Delaware Bay between Cape May on the New Jersey shore and Cape Henlopen in the State of Delaware, a width of about 10 nautical miles. The sweep of the tide follows the estuary of Delaware Bay which widens gradually from the Capes to a maximum width of 23 miles, this width decreasing to about 4 miles at the upper end of the Bay where it merges with no definite topographic feature into the Delaware River. Following the river the tidal wave moves over a generally, but in no case an abruptly, decreasing front until at Philadelphia the width of the river is about 2 000 ft., and at Trenton, the head of the tidal flow, is about 1 000 ft.

A study of the tides at Philadelphia was facilitated by the fact that there is available an almost continuous record from 1901 to 1920. These records are of particular value because they cover much of the period of channel improvement by dredging and the introduction of training works, and afford some opportunity to study the tidal regimen as affected thereby.

The mean lunitidal interval, that is, the interval of time between the transit of the moon and the following high or low water, is given for Philadelphia for high water as 1.5 hours for the first ten years and 1.47 for the second. For low water the corresponding figures are 9.01 and 8.94 hours, respectively. The periodic seasonal change is readily grasped from a study of the graph in Fig. 1.

The authors of the study believe the variations in the lunitidal interval from month to month are due to the variation in the frictional resistance

* "Tides and Currents in Delaware River and Bay," by L. M. Zeskind and E. A. Le Lacheur, U. S. Coast and Geodetic Survey *Special Publication No. 123*, 1926.

to the tidal wave caused by differences in river level, and they point out that in the summer months when the river levels are highest, the intervals are the least, while the reverse is true for the winter months.

The duration of the rise and the fall of the tide at Philadelphia is given in Table 1.

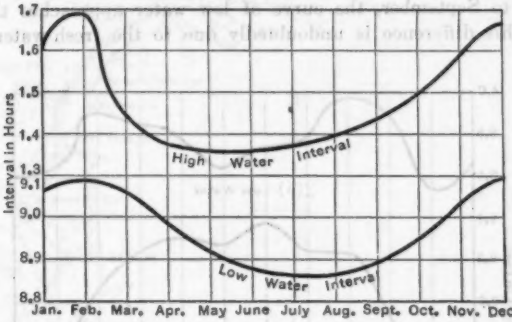

FIG. 1.—ANNUAL VARIATION IN LUNITIDAL INTERVALS, PHILADELPHIA, PA.

Table 1 is typical of river tides where the constant fresh-water flow opposes the flood and runs with the ebb, thus shortening the time of the former and increasing that of the latter. It is interesting to note that while for each full month the sum of the time of rise and fall equals 12.42 hours, a tidal cycle, yet daily records of individual tidal cycles show in some cases considerable variations, the time of an individual rise or fall being, in a few instances, one or two hours greater or less than the monthly mean, due to the effect of the wind advancing or retarding the tidal movement of the water.

TABLE 1.—DURATION OF RISE AND FALL OF TIDE, PHILADELPHIA, PA., ANNUAL VARIATION.

Month.	Duration of rise, in hours.	Duration of fall, in hours.	Month.	Duration of rise, in hours.	Duration of fall, in hours.
January	4.96	7.46	July	4.92	7.50
February	5.01	7.41	August	4.93	7.49
March	4.79	7.63	September	4.98	7.44
April	4.81	7.61	October	4.99	7.43
May	4.89	7.53	November	5.00	7.42
June	4.91	7.51	December	4.98	7.44

To the navigator, the characteristics of the tidal movement in which he is most interested are the low-water and the high-water levels. The annual variations in the plane of low water for Philadelphia for the period, 1901 to 1920, are shown in Fig. 2 (*a*), and corresponding variations in high water are shown in Fig. 2 (*b*). A study of these diagrams is interesting. It is seen that the annual variation in high-water level is more than twice that for the low-water level, and that while the former appears to run through

the year in a single cycle, the latter has two clearly marked cycles. Both are a minimum in February and while the maximum high is in June, yet the April high is very close to the June figure and corresponds with the maximum low which occurs in April. Here, however, the similarity of the curves ceases and while the high remains at nearly a constant maximum from April to September, the curve of low water approaches the minimum in July. This difference is undoubtedly due to the fresh-water flow of the river.

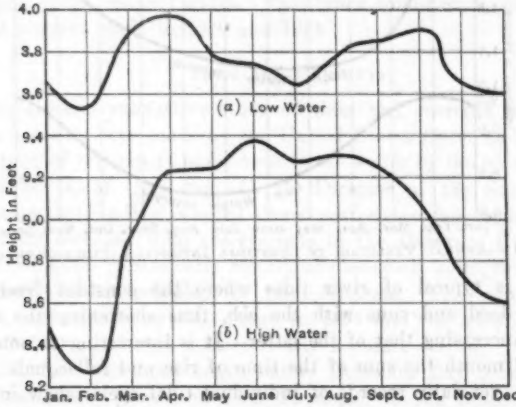

FIG. 2.—ANNUAL VARIATIONS IN LOW, AND IN HIGH WATER, AT PHILADELPHIA, PA.

The highest water recorded on the Philadelphia gauge was on October 11, 1903, when the river rose 4.22 ft. above mean high, or 9.45 ft. above the mean low, for the period, 1901 to 1920. The lowest record for the same period was on March 29, 1919, on which date the water fell 4.05 ft. below the mean low-water plane for that period. The mean range of tide for any year of the period may be obtained by subtracting the mean low for that year from the mean high for the same year. This range varies between 5.03 and 5.34 ft., averaging 5.23 ft. for the 20 years.

From a brief glance at the map of the Delaware River (Fig. 3), it is evident that northwest winds tend to drive the water out of the river, thus producing a tide lower than usual, while an east wind tends to drive the waters up the Bay and river, thus causing a high water higher than usual. Additional tables and discussions in the report from which the data contained herein were extracted, show these phenomena very clearly. An interesting case is cited in that report. During the blizzard in Philadelphia in March, 1914, the wind began blowing from the northwest on March 1 at the rate of 25 miles per hour and at 6:00 A. M., on March 2, it reached a velocity of 40 miles, which was maintained for a considerable time. As a result there was only one high water and one low water between 4:00 P. M., March 1, and 2:00 P. M., March 2, instead of the usual two high and two low, the water falling steadily during the entire 22 hours, dropping almost 4 ft. below normal.

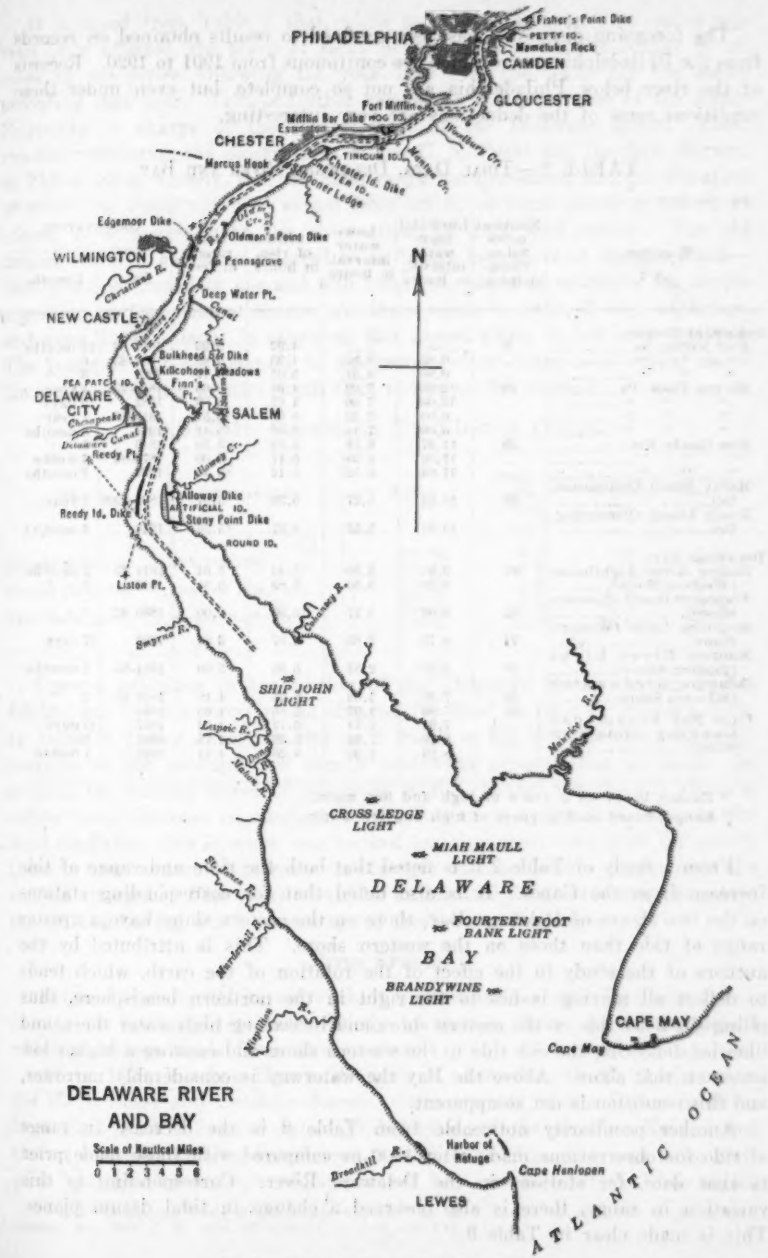

FIG. 3.—MAP OF DELAWARE RIVER AND BAY.

The foregoing discussion has been confined to results obtained on records from the Philadelphia gauge which are continuous from 1901 to 1920. Records of the river below Philadelphia are not so complete, but even under these conditions some of the deductions are very interesting.

* Ranges based on 3 years of high and low water.

† Ranges based on 8½ years of high and low water.

From a study of Table 2 it is noted that both the time and range of tide increase from the Capes. It is also noted that for corresponding stations on the two shores of Delaware Bay, those on the eastern shore have a greater range of tide than those on the western shore. This is attributed by the authors of the study to the effect of the rotation of the earth, which tends to deflect all moving bodies to the right in the northern hemisphere, thus piling the flood tide on the eastern shore and increasing high water there, and likewise deflecting the ebb tide to the western shore and causing a higher low water on that shore. Above the Bay the waterway is considerably narrower, and this condition is not so apparent.

Another peculiarity noticeable from Table 2 is the decrease in range of tide for observations made after 1900 as compared with those made prior to that date, for stations in the Delaware River. Corresponding to this variation in range, there is also observed a change in tidal datum planes. This is made clear in Table 3.

It is noted from Table 3 that, while the plane of mean high water has been little affected, the plane of mean low water is materially higher in all cases in the series following the year 1900 over the plane for the series preceding that year. This is further verified by the experience of the Army Engineers in charge of the improvement of the Delaware River. Their records corroborate the observations of the U. S. Coast and Geodetic Survey, at Philadelphia, namely, that the tidal range has decreased, and the elevation of mean low water has been raised from 0.5 ft. at some points to 0.8 ft. at others, as compared with the observations of 1880 and earlier. The old datum, however, generally referred to as "mean low water at Marcus Hook—1879", has continued in use and still forms the plane of reference for depths appearing on Government charts. As there would be little, if any, advantage and some disadvantages in changing this datum plane, it has been retained. The result is not detrimental to navigators, since there is at actual mean low water a slightly greater depth than shown on the charts.*

TABLE 3.—CHANGES IN TIDAL DATUM PLANES.

Station.	Referred to.	Series.	Mean tide level, in feet.	Mean high water, in feet.	Mean low water, in feet.

		1916-24	13.70	16.42	10.99

Current velocities in the section of the Delaware River between Philadelphia and the sea vary in the channel for flood at time of strength from 1½ knots in Lower Delaware Bay to 2 knots in the river proper. Channel currents at ebb strength are usually somewhat greater than at flood. In general, the vertical curve of velocities in the channel for the ebb shows a rather rapid decrease in strength as the bottom is approached, whereas for flood conditions this is much less marked and at some points near the mouth there is even a decided increase in strength at considerable depths over the surface strength. This is as would be anticipated in a river emptying into the sea and having a fair percentage of fresh-water discharge.

RIVER STUDIES

Before discussing the actual work of improvements on the Delaware River, it may be interesting to refer briefly to certain theoretical investigations which have been made from time to time.

About 1878, the late Henry Mitchell, M. Am. Soc. C. E., Assistant in the U. S. Coast and Geodetic Survey, made a study of the Delaware River from Fort Mifflin, 8 miles below Philadelphia, to the mouth. He followed this at a somewhat later date by other studies based on new and more complete hydrographic surveys which had not been available at the time of his

* See "Tides and Their Engineering Aspects," by G. T. Rude, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 92 (1928), p. 606 and Fig. 21.

original report.* As a result of his first study, Mr. Mitchell laid down the following rules for this section of the river:

First.—The transverse section is directly proportional to the discharge.
Second.—The width is proportional to the discharge.
Third.—The mean depth is the same in all sections.

Mr. Mitchell pointed out as the most interesting feature of these studies the "constancy of mean depth". It is not intended by this statement, nor by Mr. Mitchell's third rule, to imply that mean depths were actually the same in all sections, as at various points there were some variations due chiefly to inequalities of the soil. However, by plotting mean depths along the length of the river, he shows that a horizontal straight line at a depth of 18.64 ft. would be the correct rectification of the irregular curve of actual mean depths.

Starting with this assumption of constancy of mean depth, the width of the river becomes the independent variable. Actual widths at various sections were plotted, and a rectified curve of widths using the plotted points as guides was drawn. Mr. Mitchell found that this curve corresponded to a parabolic formula. The theoretical cross-sections are obtained by multiplying theoretical widths by the mean depth of 18.64 ft.

The practical application of these studies is stated by Mr. Mitchell as follows:

"The persistent tendency to constancy of mean depth throughout the whole length of the estuary would seem to discourage the hope of improvement by dredging. * * * Except for two or three shallow reaches of short extent, there is plenty of water from the ocean to Philadelphia, and at these obstructed reaches, artificial contraction of the waterway may be made without altering the course of the stream or sensibly reducing the tidal volume; so that deepening may be induced where required without changing the conditions elsewhere".

Further studies were made in 1882 by Mr. E. A. Giesler, Assistant Engineer, under the Corps of Engineers, U. S. A. He called attention to the fact that while there was a definite increase in cross-sectional areas going toward the mouth, yet the increase was not a steady one, but was subject to frequent and irregular fluctuations which he very pertinently stated might be due to local causes. He felt that these local fluctuations might confuse the result, and, therefore, in order to eliminate them, he used instead of the actual cross-section at any given point, the mean of ten cross-sectional areas, five above and five below the section under consideration. He also based his theoretical smooth curve of increasing cross-sections on three sections at widely separated intervals of distance on account of their position on the more uniform parts of the curve developed by using mean cross-sections obtained as just described. From his study Mr. Giesler determined that the curve showing the increase in cross-sectional area of the river from Philadelphia to the mouth approached very closely an hyperbola.

* U. S. Coast and Geodetic Survey Report, Appendix No. 8, 1883, and Appendix No. 12, 1885.

Frank C. Warner, M. Am. Soc. C. E., Assistant Engineer in the Engineer Department of the Army, in 1917, modified Mr. Giesler's figures by using the mean of three cross-sections above and three below the section considered. He adopted an hyperbolic formula for increases in sectional areas similar to that used by Mr. Giesler. Mr. Warner states:

"The practical application of the theoretical law thus obtained must be made only in connection with studies of local conditions, or otherwise the results may be erroneous. Applied to a straight tidal river channel with uniform conditions of bed and banks throughout its whole length, definite and reliable results may be expected, but when applied to the Delaware River channel, in which variable conditions exist, such as sharp bends and bed and banks composed of materials varying from soft mud to sand, gravel, boulders, and even ledge rock, it is apparent that such theoretical law can be applied only as a check, but reliable in so far as it will determine limits in regulation beyond which it will not be safe to go with due regard to the regimen of the river as a whole".

H. F. Flynn, M. Am. Soc. C. E., who was Assistant Engineer on the work on the Delaware River, in 1918 called attention to the fact that Mr. Warner's results were based on a survey made in 1916, after a considerable amount of work had been done, including dredging and dike construction. He believed that the natural regimen of the river should be used instead of an artificial state. He noted also that investigators following Mr. Mitchell had used three sections at widely separated points on the river for determining their curves of areas, and he objected to this method for the reason that such sections do not "necessarily indicate that the river has a proper cross-section at those points, but rather that the relation of width to area happens to be such that the river is able or rather forced to maintain them."

In his study, Mr. Flynn went back to the cross-sectional areas and widths used by Mr. Mitchell, based on the survey made about 1880 before the natural state of the river had been materially affected by artificial works. He then, by the method of least squares, developed the following formula for the theoretical curve of increasing cross-sections:

$$X = \frac{a - b\,y}{y + c}$$

in which,

a, b, and c are constants;

X represents the cross-section of the river at any point, in hundreds of square feet; and,

Y represents the distance along the center line of the channel from the place of origin, in nautical miles.

Table 4 gives the results obtained from the formulas developed by these investigators and Fig. 4 shows the relation between the theoretical curves of increasing cross-sections resulting therefrom.

For cross-sections Mr. Flynn adopted the statement by Mitchell that in straight reaches a sine curve coincides very closely with the natural bottom. From this hypothesis the following formula was derived,

$$W = \frac{\pi}{2}\frac{A}{D}$$

in which,

D = maximum depth, in feet.
A = area of cross-section, in square feet.
W = surface width, in feet.

TABLE 4.—THEORETICAL AREAS OF CROSS-SECTION AT HALF TIDE.

Distance below Philadelphia, in nautical miles.	Square Feet.

40	396 000	358 300	387 900
45	476 000	.....	517 400
50	565 000	.....	746 500

Mr. Flynn adds:

"It is recognized that there are many elements affecting the width of the river that have been neglected in the above method of location of training dikes. The effect of curvature has not been taken up, but it is not large. The matter of the location of the deepest part of the channel has been disregarded. It is believed, however, that the method may be used to advantage. It is better adapted to the upper reaches than to the broader portions below. In the narrow, upper portions of the river the dredged portion of the channel forms a considerable fraction of the total width between banks. Here the contraction required to make the channel self-maintaining, that is, to make the distance between the banks such that it will correspond to a natural depth of 38 ft. at half tide, is comparatively small. Proceeding down stream, however, conditions change, until at the lower end we find that the width of the dredged channel is a very small fraction of the total width, and the dredged channel assumes more the form of a ditch or canal dug through the comparatively flat river bed. Any attempt to create a natural depth of 38 ft. at half tide would require so considerable a reduction in width between banks as to be impracticable."

In an interesting paper on the "Relation of Depth to Curvature in Channels", H. C. Ripley, M. Am. Soc. C. E., states, under the heading, "Conclusions":*

"Professor Mitchell has shown,† in his investigations of the estuary of the Delaware River embracing a length of 52 miles from Philadelphia, Pa., down 'that the mean depth is the same in all sections and is equal to 18.64 ft. from all soundings for 46 nautical miles * * *'.

"Now, as the maximum depth in the straight reaches of any stream is equal to the mean depth multiplied by a constant, and the maximum depth in bends is equal to the mean depth multiplied by the same constant plus the effect due to curvature, it follows that the maximum depth in all straight reaches will be the same. Any attempt, therefore, to deepen the channel

* *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927), p. 238.
† U. S. Coast and Geodetic Survey Report, 1883, pp. 239–245.

by dredging will disturb this persistent tendency to uniformity of depth. Hence, it would appear that it is not practicable to secure any permanent improvement in the navigable channel of that river by dredging. It is evident, therefore, that the logical method would be to convert the straight reaches into channels of suitable curvature by means of training walls and to let Nature do the rest. In this way equality of mean depth would be preserved and the increased depth secured would remain permanent forever."

Further reference to these theoretical studies will be made subsequently.

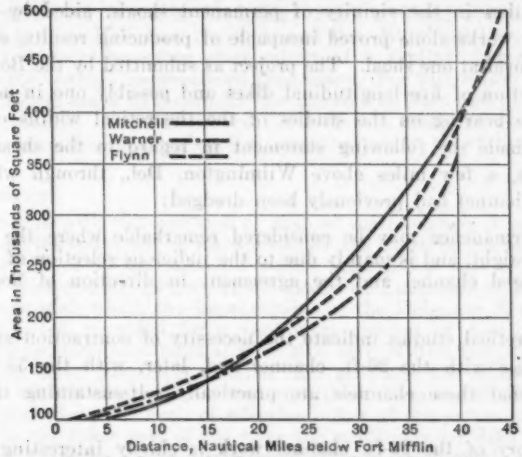

FIG. 4.—CURVES OF THEORETICAL CROSS-SECTION.

PROJECTS

The first project for the systematic improvement of the Delaware River was adopted in 1885. Previous to that year, and commencing as early as 1836, Congress had appropriated funds and work had been done on isolated improvements, such as ice piers and the dredging of channels across the more obstructive shoals.

The River and Harbor Act of July 5, 1885, however, carried an appropriation for the "improvement of Delaware River from Trenton, N. J., to its mouth", and a project was accordingly prepared by a Board of Engineers appointed to consider the subject. This project provided for the construction of a channel having a least depth of 26 ft. at mean low water, and a least width of 600 ft., to extend from the Port Richmond grain piers, in Philadelphia Harbor, to deep water in the Bay, a distance of about 60 miles. This project was prepared a short time after the studies made by Mr. Mitchell and Mr. Giesler, and it is interesting to note the influence that these studies may have had on the proposed work. The late Col. William H. Heuer, U. S. A. (*Retired*), M. Am. Soc. C. E. (then Major, Corps of Engineers, U. S. A.), in his preliminary examination refers to Mr. Mitchell's study, and Mr. Giesler's investigations form a part of Major Heuer's report. Major Heuer states:

"The remedy for improving the channelway is contraction, so as to compel both inflowing and outflowing tides to occupy the same channel".

While the report of the Board of Engineers which reviewed Major Heuer's report, and on which the adopted project was based, made no direct reference to the studies by Mitchell and Giesler, they were undoubtedly in mind and possibly used in the location of some of the dikes recommended.

The improvement was in general to be secured by the construction of low-water dikes in the vicinity of permanent shoals, aided by dredging if the training works alone proved incapable of producing results, supplemented by rock removal at one shoal. The project as submitted by the Board involved the construction of five longitudinal dikes and possibly one in addition. As having some bearing on the studies of the theoretical widths of the river, the Board made the following statement in regard to the shoal at Cherry Island Flats, a few miles above Wilmington, Del., through which a self-sustaining channel had previously been dredged:

"This permanence may be considered remarkable where the river is so wide and straight, and is mainly due to the judicious selection of the location of the dredged channel and the agreement in direction of flood and ebb currents."

The theoretical studies indicate the necessity of contraction at this place, but experience with the 26-ft. channel and, later, with the 35-ft. channel, has shown that these channels are practically self-sustaining through this shoal.

The history of the 26-ft. channel work is chiefly interesting as demonstrating the ineffectiveness of low-water dikes, and the fact that even after raising these works to high water, dredging was necessary to produce the desired depth in any reasonable time. In justice to the original conception it should be added that once the depth was obtained by dredging, the dikes assisted in maintaining it, and it may be that the failure of the contracting works in the first instance was due to character of material.

Before the completion of the 26-ft. project the growth of Philadelphia as a port, and the general change from sailing vessels to steam with increased draft, had awakened a demand for a deeper channel. In 1899, Congress authorized a new project superseding the one of 1885, this new project providing for a channel 30 ft. deep and 600 ft. wide from Philadelphia to deep water in the Bay, at an estimated cost of $5 810 000.

When the 30-ft. project was adopted, about $1 600 000 had been expended on the 26-ft. channel, which depth had been secured over widths varying from 200 to 600 ft. from Philadelphia to the Bay, except for uncompleted lengths aggregating about 4 miles. In addition, the harbor at Philadelphia had been improved by the removal of Smith and Windmill Islands, by the establishment of pierhead and bulkhead lines, and by the partial removal of Mameluke Rock (Fig. 3), an area which interfered with the movement of vessels in the upper harbor. The report on which the 30-ft. project was based was submitted by a Board of Engineers, which had before it a preliminary study

made by the late C. W. Raymond, Brig.-Gen., U. S. A. (*Retired*), M. Am. Soc. C. E. (then Lieutenant Colonel, Corps of Engineers, U. S. A.). In this study Colonel Raymond stated:

"The greatest depth which could probably be maintained at reasonable cost might perhaps be determined by a study of the river itself, if the form and dimensions of the channel were solely the result of the action of flowing water, but this is not the case. Natural obstructions, immovable by water, such as the rock at Schooner Ledge, exist in some parts of the channel; and in other places where bars have persistently formed, old wrecks and other artificial obstructions have been found by dredging. Such artificial obstructions have been removed at Five Mile Bar, Smith Island Bar, Bulkhead Bar, and Reedy Island Bar, and doubtless other obstructions of a similar character will be discovered as the channel improvement progresses. For this reason the various attempts heretofore made to determine the theoretical form and dimensions of an improved channel in the Delaware River from a study of existing cross-sections have been found after careful examination to be of little practical value."

He also states:

"In connection with this question of channel maintenance, it may be asked whether the depths could not be maintained by the construction of dikes properly located to direct the currents and confine their action within the limits of the channel. The original project of the Board of Engineers of 1885, in general accordance with which the improvement of the Delaware River has been thus far conducted, provided for a very large amount of dike construction. Dikes have accordingly been built at Five-Mile Bar, Mifflin Bar, and Bulkhead Bar, and they have admirably fulfilled the purposes for which they were designed. It will be observed, however, that these dikes are all located in the part of the river above the limit of effective inflow of the waters of the marine tide wave. In the lower part of the river the conditions for dike construction are much less favorable. The dikes would have to be of great length. They would be difficult and very expensive to construct, on account of the softness of the bottom, and they would have to be located with the greatest skill and care to avoid obstructing the inflow of the flood tide. Owing to the action of ice and storms these structures would require large expenditures for annual repairs. Moreover, it has been found practically impossible to locate and construct such works on the lower part of the river on account of the real or fancied grievances of riparian owners. Accordingly, the Board of Engineers of 1896 recommended the abandonment of dike construction in this part of the river and the improvement of the channel by dredging. When the Board of Engineers of 1885 submitted its report, the cost of dredging was relatively so great as to amply justify the expense of dike construction. With the improved dredging machinery and low prices of the present time the construction of dikes is no longer generally considered advisable for the improvement of a bar within the mouth of a tidal river."

The Board recommended as a part of the project a longitudinal bulkhead near the Pennsylvania shore, just above the Christiana River, and also one near the New Jersey shore nearly opposite Reedy Island (Fig. 3). These bulkheads were to serve two purposes: First, to act as training dikes; and, second, to form basins into which material dredged from the channel could be deposited. The latter dike finally took the form of an enclosure in the river which has since been raised by those deposits into an island very properly known as Artificial Island (Fig. 3). The bulkhead above the Christiana River was started, but was not completed. The chief matter of interest during the work

on the 30-ft. project was the introduction of the sea-going hopper dredge. This will be described later.

The demands for a channel to accommodate the deeper draft vessels required by the economics of ocean-borne commerce, again became insistent, and an investigation was made with a view to deepening the channel to Philadelphia to 35 ft. The result was the existing project which was adopted in 1910. It provides for the formation of a channel 35 ft. deep from Philadelphia to deep water in Delaware Bay, a distance of about 63 miles, 1 000 ft. wide through Philadelphia Harbor, 1 000 ft. wide at bends, except one quite sharp one at Bulkhead Bar which is to be 1 200 ft., and 800 ft. wide in straight portions. The original estimated cost of the project was $10 920 000, with $300 000 annually for maintenance. It may be noted that General Marshall, the then Chief of Engineers, U. S. Army, was of the opinion that the estimated cost of maintenance was far less than what he considered would be the result of actual work. Experience has demonstrated that General Marshall's opinion was well grounded. In 1922, a re-estimate of the cost of the completed work and that still remaining to be done on the original project was made, and the new figure, $15 300 000, was approved. While this amount is 50% greater than the estimate of 1910, it is noted that the higher cost of labor and materials since that date would more than account for this increase. The cost of maintenance, however, has increased beyond any difference chargeable to higher labor and material costs.

The District Engineer, Major Herbert Deakyne (now Brig.-Gen. Deakyne, Assistant Chief of Engineers, U. S. A., M. Am. Soc. C. E.), who submitted the report reviewed by the Board of Engineers for Rivers and Harbors, stated that past experience indicated that the maintenance of a deep channel by dredging alone would be unduly expensive, unscientific, and border on the impracticable. He added that "systematic contraction and control of the tidal flow are the proper means for the maintenance of the channel." And, further, "it is not expected that these controlling works will obviate the necessity of dredging a channel, but it is expected that they will simplify the problem of maintenance." He recommended construction of certain dikes for the purpose of contraction or controlling the currents.

The Board of Engineers in submitting the report on which the present project is based, agreed with the District Engineer in his recommendations.

The work on the 35-ft. channel necessary to obtain the first deepening from 30 ft. has been carried on practically without interruption since 1910, this original work having been done almost wholly under the contract method. The entire channel from deep water to Philadelphia has been completed with the exception of a 2-mile stretch in the upper end of Philadelphia Harbor, where dredging is now in progress, a few small rock areas in the channel near Chester, Pa., which it is hoped will be removed at an early date, and the removal of Mameluke Rock in the Upper Philadelphia Harbor, which is the chief obstacle to the completion of the work. About 90 000 cu. yd. of this ledge still remain, although it is noted that a 35-ft. channel of reduced width can be dredged to the westward of this area.

On the dikes recommended, the following work has been done (see Fig. 3):

Fisher Point Dike, completed to within 300 ft. of Petty Island. Full completion of this dike was prevented by action of citizens of New Jersey who objected to the cutting off of the channel between Petty Island and the New Jersey shore.

Mifflin Dike, partly completed. Work on this dike was interrupted by the construction of Hog Island Shipyard and objections to the closing of the channel north of Tinicum Island.

Chester Island Dike, from the north end of Chester Island to the New Jersey shore, completed.

Oldman's Point Spur Dike, completed.

Bulkhead Bar Spur Dike, completed.

Edgemoor Dike, small portion finished.

Reedy Island Dike, partly completed. Work stopped due to protests of riparian owners.

Artificial Island, completed.

For maintenance, contracts are let for such work as is necessary in Philadelphia Harbor, and the dredging in the lower river is carried on by Government-owned and operated plant consisting of three sea-going hopper dredges and two pipe-line disposal dredges. At present (October, 1926), a navigable channel 35 ft. deep at mean low water and of widths varying from 200 ft. to the full width of the channel, extends from above the congested portion of Philadelphia Harbor to deep water in the Bay, except at a few isolated spots where the filling in of the channel has kept ahead of the dredging work. On the last examination made in August, 1926, the controlling depth on the center line of the channel was 32.7 ft., this, however, being at one point only.

Each year, however, shows an improvement in maintenance work and there is every reason to believe that with the erection of additional dikes as funds will permit for the combined purpose of disposal basins and control of the current, the maintenance of the channel at project depth can readily be held by dredging.

Methods of Work

As previously stated, the improvement on the Delaware River is a combination of dredging and dike construction. For the latter work the only features of note are that low-water dikes have proven ineffective, and that, due to ice and storm conditions and the nature of the bottom, these dikes must be of a considerably more substantial cross-section than was originally anticipated, this being still further accentuated when the dikes are also required to withstand thrust from back-fill.

Experience in dredging has shown the great advantage of the sea-going hopper dredge, particularly in maintenance work, over the stationary type. The critical feature in the dredging work is the disposal of the dredged material. Several methods have been tried. At first, the material was deposited in available locations in the river outside the channel. This was not found to be economical for the reasons that the bulk of the material quickly found its way back into the channel and had to be re-dredged; the available deposit areas were very limited due to the draft required for the dredges in going to and from the areas; and the filling of these areas frequently interfered with the

use of side channels for tugs, barges, and small freight carriers of shallower draft.

The method of agitation was then tried. This consisted in dredging by the sea-going dredges for long continuous periods, until the hoppers were filled with solid material, the lighter mud and sand being permitted to flow overboard. This was done only on ebb tide, with the expectation that the solids in the overflow would remain in suspension and be carried away by the tidal currents. This also proved uneconomical since these solids did not remain in suspension for any length of time, but came to rest in the channel below the point of operation, thus requiring re-dredging.

The method then adopted is that now in use, and consists in depositing the dredged material on fast land behind embankments or in the river in areas surrounded by dikes. The operation consists in dredging with the sea-going hopper dredges, generally between 30 and 60 min., until the economic load is obtained, this being determined from a consideration of material in hoppers, time of dredging, and time required to move to disposal basins. With bucket dredges the material is loaded into bottom-dump barges which are towed to the place of deposit. At the deposit basin, the dredgings from the sea-going dredges or the dump barges are deposited in basins dug in the bottom of the river and are then pumped into the prepared area by a suction pipe-line dredge. Incidentally, these areas, built up as described to 12 ft. and more above the plane of mean low water, may form valuable sites for industrial and other purposes.

The bucket dredge and the suction pipe-line dredge are familiar to all engineers. The sea-going hopper dredge is not so common. Essentially, it is a sea-going vessel, self-propelled, which contains, in addition to the quarters for the crew and the propelling machinery, suction pumps and bottom-dumping bins of a capacity depending on the size of the vessel. The suction pipe, so arranged as to permit raising and lowering, is fitted at its outer end with a drag head, consisting in general of a heavy casting with grated opening on the bottom. In operation, the suction pipe is lowered below the water level, the pump started, and the pipe then lowered until the drag head touches the bottom. As the dredge proceeds slowly over the area to be dredged, the material from the bottom, combined with a certain quantity of water, is pumped into the hoppers in the dredge. When the economic load has been obtained, the suction line is raised, the pump stopped, and the dredge proceeds under its own steam to the deposit basin, where the load is dumped. In brief, the sea-going hopper dredge is a combined pumping, towing, and dump-scow plant in one hull. Figs. 5 and 6 are views of two of these dredges.

The cost of the work done with the hopper dredge varies with the type of material and the distance from the deposit basins. For sand and gravel combined, with a comparatively long haul, the present cost is approximately 14.4 cents per cu. yd. of material removed. For soft material, with a comparatively short haul, the figure is 2.8 cents. The cost of pumping the material ashore by the pipe-line dredge varies from 2.5 to 10.8 cents per cu. yd., depending on the cost of construction of deposit basins and length of pipe line.

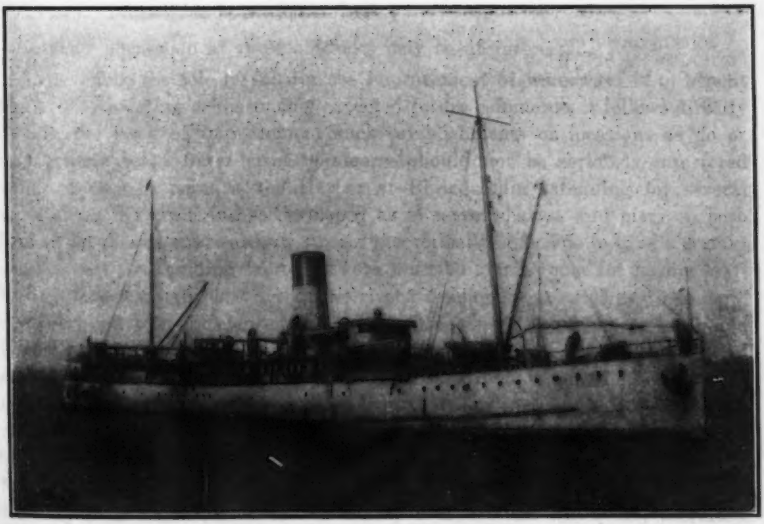

FIG. 6.—VIEW OF DREDGE *Manhattan*.

Depth by Contraction

From a study of the work done under the various projects, and having in mind the studies of theoretical widths which have been discussed, the query naturally arises, why was greater use not made of the contraction system?

As a matter of fact the improvement of the river since the first systematic project for 26-ft. depth was started, has been by dredging supplemented at certain critical sections by longitudinal dikes or by spur-dikes.

Practically, however, the use of dikes has not proven so simple as a theoretical discussion of the problem would indicate, and the number constructed or projected are not in line with those that would be required under any conclusion based on such theoretical discussion, nor such as are desirable for the purpose of economic maintenance.

Some of the obstacles which have seemed and still seem unsurmountable are:

(*a*) Impracticability of placing such structures where they might not interfere with the use of existing or prospective commercial developments on shore, or where shore owners might not object to being cut off from deep water.
(*b*) Uncertainty under the present state of the science as to just where dikes should be located.
(*c*) The time required before any definite improvement throughout the entire length of stream could be obtained.
(*d*) The fixing of the channel at a certain depth.
(*e*) The increased difficulty of navigation of the channel by large vessels if it were developed on a series of curves instead of tangent ranges.
(*f*) Limited funds available.

A brief discussion of these obstacles may be of interest.

(*a*).—Since the sole reason for the improvement of waterways is to benefit and develop existing or reasonably expected future commerce, it follows directly that in the work of improvement such establishments or locations as do or may contribute to water-borne commerce should not be seriously interfered with. A case in point is the Harbor of Philadelphia extending for several miles along the river and so developed as to serve wharves and piers on both banks. In this case, a width of stream theoretically sufficient to give a certain depth is not the deciding factor. There must be ample room for harbor traffic both longitudinally and across the river. Anchorage grounds are necessary, and there must be sufficient width to permit ocean-going vessels to enter and leave their slips without too great interference with other vessels or risk of endangering structures on the other side of the stream. On the other hand, if the necessary width for this consideration is less or greater than the theoretical width for the desired depth, it is inconceivable that owners of existing wharves and bulkheads would re-arrange them to comply with lines based on this theoretical width. Structures in Philadelphia Harbor designed and located solely for reducing the stream to a theoretical width are, therefore, out of the question.

It is admitted that this is an extreme case, and proponents of the training-dike system of improvement may claim that, while true for Philadelphia Harbor, it would not be true on the length of river below Philadelphia. The channels on the two sides of Tinicum Island and the stretch of the river below the Island (Fig. 3) present a waterway of too great a section for the development or maintenance of a channel of the present project depth if dependence is placed on any of the theoretical formulas. In order that the river currents alone might maintain this channel, a longitudinal training wall should be constructed from fast land to Tinicum Island, cutting off the back channel near the Pennsylvania shore, with probably a dike extending below the Island. In fact, the former dike was recommended under one of the original projects of lesser depth than the present one. Incidentally, there would also be required for the theoretical width necessary for maintenance in case the back channel were blocked off, the removal by dredging of a large part of the Island since the material of which it is formed is too heavy and compact to be moved by the river currents.

On this back channel is located one of the large plants of the Westinghouse Electric Company, and, while this industry might consent to the change providing it owns the riparian rights and that portion of the Island within an extension of its property lines, as this would permit it to have access to deep water, yet it is extremely doubtful whether the Town of Essington and the yacht clubs just below would be so complaisant. Likewise, one might imagine the attitude of the Baldwin Locomotive Works, located on the Pennsylvania shore just below Tinicum Island, if it were to find its present wharf, to which it has dredged a channel at its own expense, left several hundred feet landward of a training dike.

This is not an isolated case. The Pennsylvania and Delaware shores are lined for almost the entire distance from Philadelphia to below Wilmington by cities and manufacturing establishments the influence of which would undoubtedly be brought to bear against any system of works that would cut them off by a practically currentless stretch of water from the main channel.

That this objection is real and not fancied is evidenced by past experience. At least two dikes designed for the purpose of contracting the channel were stopped before completion, due to the protests of riparian owners.

(*b*).—In discussing the studies of the river, it has been noted that no two investigators agree as to the theoretical formulas for the contraction required to produce a certain depth of channel. In practice, one must proceed with caution; the cut-and-try method must be adopted. River engineers are familiar with the fact that any artificial work may cause serious changes in the regimen of a stream above and below the structure in question, this effect sometimes extending for long distances. Temporary structures or parts of the proposed work must be built and time must then be permitted to elapse before a knowledge of results sufficiently definite to warrant further progress can be obtained.

(*c*).—Due to the necessity of proceeding slowly and also on account of limitation in available funds, many years would elapse before a complete system of dikes could be built. In the meantime, while certain sections of the

river might be deepened to the desired draft, others would be untouched. The navigability of a channel depends on the governing depth of that channel. There might be a 35-ft. depth throughout 59 of the 60 miles of waterway from Philadelphia to the sea, but a depth of 20 or 25 ft. for the remaining mile or even a small fraction of it, would limit the size of vessels capable of navigating the channel to what could be carried over this governing section. In other words, there would be little real practical improvement until the entire system was completed.

(*d*).—Assuming longitudinal dikes could be placed with full assurance that the pre-desired depth could be obtained, there is the risk of stabilizing that depth, or of being compelled to construct a new series of contracting works to obtain a greater depth. Suppose, for example, the first project depth for the Delaware River had been obtained by the construction of longitudinal dikes. It is problematic whether funds would have been forthcoming for the 30-ft., and then the 35-ft. channel, if dependence had been placed on contraction works alone, for it must be remembered that theoretically the channel would develop close to the dikes along curved sections and the cost of constructing new dikes in the deeper waters would be much greater than the original construction in comparatively shallow water.

(*e*).—It is a fact that a sinuous channel could be navigated, but it is equally true that such a channel would be much more difficult for the handling of large boats than one laid out as a series of straight stretches for which easily distinguishable range signals might be erected, with short turns marked by light buoys or some other distinctive marks. The dangers of collision or of grounding in night running on a 100-mile channel, such as that first mentioned, would almost prohibit its use during hours of darkness, and would tend to diminish its usefulness even during daylight hours. The tendency of the channel to deepen on the outer part of the curve and hence near the contraction works would also increase the danger of navigation.

(*f*).—The revenues of even the Federal Government are limited. These revenues must cover a multitude of necessary governmental expenditures. The result is that the amount available for all the river and harbor work throughout the United States is and always has been comparatively small. Shall these funds be used for works which after a lapse of many years may ultimately be beneficial, but which give little if any relief in the meantime; or shall they be used in such a way as to maintain what is already available and also give a progressively deeper channel, thereby permitting a gradual but steady increase in the size of cargo carriers? It would seem that the answer is obvious.

The writer has attempted to touch very briefly the obstacles to a complete control of a stream like the Delaware River by a system of dikes alone. He does not want to be misunderstood and be set down as opposing all use of dikes for partial control. That these works will not produce the desired deepening of a channel in the Delaware River in any reasonable time has been proven on that river by past experience, for in every case where they have been constructed, it has been necessary to expedite the action of the current by recourse to dredging. Past experience has been equally positive in proving that prop-

erly located dikes will assist materially in maintaining the channel. One principle of location of these dikes has been fully exemplified, that is, that they should be placed so that the ebb and the flood tides shall be forced into the same channel. Wherever this has been done the benefits, as regards maintenance, have been very apparent.

There are many places on the river where work of this kind could be done without injury to commerce or to riparian owners, and with great benefit to the cost of maintenance, and ultimately these works will be constructed. In the meantime, dredging must be carried on continuously to maintain the depth of channel already obtained, and basins must be constructed in which to place the material dredged. In this connection, it is again noted that the dikes and bulkheads constructed for these basins are designed and located not only for this purpose but with a view to their effect on controlling the currents which it is anticipated will result in a material decrease in maintenance dredging.

As is generally true, there is a happy medium between extremes which all things considered gives the best results, and the Government engineers have attempted to strike this medium, between the extremes of "all dikes with no dredging" and "all dredging with no dikes," in so far as funds and the legitimate demands of commerce for early improvement and continuous maintenance of increased depths will permit.

Economics

A paper on the Delaware River would be only partly complete without some reference to the commercial and economic side of the question.

The Port of Philadelphia includes the City of Philadelphia with its wharves on the Delaware and Schuylkill Rivers, Camden, N. J., Gloucester, N. J., and some minor points north and south of Philadelphia. This port serves a large area. For Eastern Pennsylvania, Southern and Central New Jersey, and Delaware, involving a population of about 5 000 000, rail freight rates to Philadelphia are equal to or lower than similar rates to any other first-class seaport. It also has competitive rates with other ports for a large area, including Western Pennsylvania, Ohio, Indiana, Illinois, Michigan, Wisconsin, Iowa, Minnesota, and the Dakotas.

By far the largest percentage of the water-borne tonnage is handled over the wharves of the City of Philadelphia. Practically all these wharves on the Delaware River are served by a belt line which permits shipments or receipts by or from any of the three railroad companies serving the community, the Pennsylvania, the Reading, and the Baltimore and Ohio. The Delaware waterfront is also paralleled by a wide avenue permitting easy trucking between piers and to cross streets leading to all parts of the city. On the Schuylkill River, while there is no belt line, a large majority of the wharves have switch connections with one or more of the railroads mentioned.

These railroad companies have large water terminal developments, including coal and ore piers with mechanical unloaders, general cargo piers, and grain elevators. Of the latter, one has a capacity of 1 250 000 bushels, another of 2 250 000, and a third is now (1926) under construction, the first unit of which, with a capacity of 2 500 000 bushels, will be in operation at an early date.

For many years the City of Philadelphia has followed the policy of development of its water-front. Since 1909, thirteen modern piers have been constructed by the municipality. Figs. 7 and 8 show cross-sections of two of the latest types of pier.

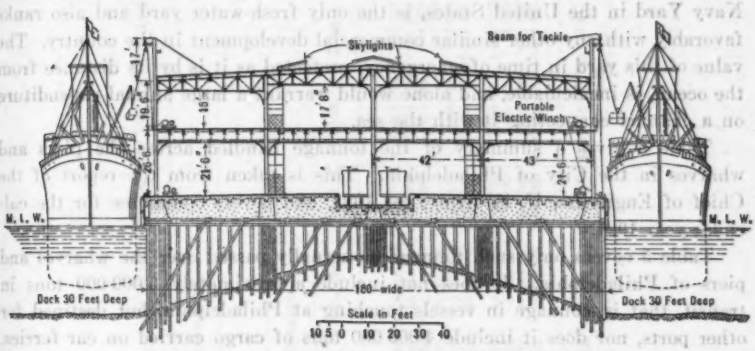

FIG. 7.—TYPICAL CROSS-SECTION, SOUTHWARK PIERS, PHILADELPHIA, PA.

Aside from the rail terminals and the city-built piers, there is little permanent wharf equipment for handling ship's freight, dependence being placed in general on the cargo booms and winches of the vessels themselves.

Under the policy adopted by the City, none of its municipally owned wharves is operated by it, but is leased to shipping lines. The writer regrets that at least a few of these facilities have not been reserved for municipal operation, where all comers could be sure of obtaining berths and reasonable loading, unloading, and storage rates, although it may be added that these rates as charged at privately owned or leased wharves compare favorably with similar rates at other ports.

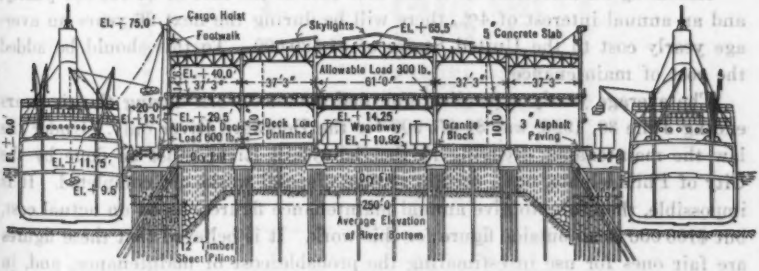

FIG. 8.—SECTIONAL ELEVATION, MCKEAN STREET PIER, PHILADELPHIA, PA.

There are three shipyards on the Delaware River in and near Philadelphia, which can construct or repair any vessel that can navigate the channel.

A large part of the inbound tonnage in the Port of Philadelphia consists of crude oil and oil products. Oil refineries and tank farms are located on the Schuylkill River and on the Delaware River at Marcus Hook, Pa., with one

large plant on the New Jersey side about 10 miles south of Camden and one just north of that city.

In addition to this commercial development, the Delaware River channel serves the League Island Navy Yard, which, in addition to being the largest Navy Yard in the United States, is the only fresh-water yard and also ranks favorably with any other similar commercial development in the country. The value of this yard in time of emergency, protected as it is by its distance from the ocean, is incalculable, and alone would warrant a large annual expenditure on a channel connecting it with the sea.

Table 5 gives a summary of the tonnage handled across the piers and wharves in the City of Philadelphia. This is taken from the report of the Chief of Engineers, U. S. Army, for 1925, and covers commerce for the calendar year 1924.

Table 5 covers only such tonnage as actually passed over the wharves and piers of Philadelphia. It does not include approximately 5 000 000 tons in transit, that is, tonnage in vessels touching at Philadelphia, but destined for other ports, nor does it include 4 000 000 tons of cargo carried on car ferries. The tonnages for Camden, N. J., and Wilmington are also excluded from this summary, although ships for these ports make use of the channel between Philadelphia and the sea throughout its entire length for the former and over approximately two-thirds of its length for the latter.

Every engineering work is subject to scrutiny as to whether or not it is a paying proposition. Examination of the Delaware River, from this point of view, will show that the total cost of all new work on this river between Philadelphia and the sea, including the deep-draft channel for the lower six miles in the Schuylkill River, not only on the present project, but also on all former ones, for work done by the Federal Government, to June 30, 1925, was $26 000 000 in round numbers.

Assuming an amortization of the first cost at the rate of $1 000 000 yearly, and an annual interest of 4%, there will be during the next 26 years an average yearly cost to the United States of $1 520 000. To this should be added the cost of maintenance.

The average yearly expenditure on maintenance work during the six years ending June 30, 1926, was $1 475 000 for the Delaware River only. Under the law the maintenance dredging in the Schuylkill River must be done by the City of Philadelphia, until certain sewage disposal works are completed. It is impossible, therefore, to give annual maintenance figures, based on actual cost, but $100 000 is an outside figure for this work. It is believed that these figures are fair ones for use in estimating the probable cost of maintenance, and, in fact, are somewhat excessive, as they include the cost of disposal basins, which will be available for several years.

These amounts, interest on cost of new work, and yearly maintenance, give $3 095 000 as the amount the United States Government will be required to pay each year for the next 26 years on account of the 35-ft. channel from Philadelphia to the sea.

What is the return on this yearly outlay? From Table 5, the figure of 25 000 000 tons is obtained as the total commerce passing over the wharves and piers in the City of Philadelphia. It would be erroneous, of course, to attribute this entire tonnage to the work done on the channel by the United States Government, since, before any work was started, there was an available depth of possibly 18 ft. at mean low water. The increase of tonnage due to increased depth as obtained by work done by the United States is impossible of exact determination, but it is believed a rough figure can be obtained.

Table 6 gives the number of vessel trips made during the year 1924, together with vessel drafts. The figures in Column (3) give the ratios between tonnage of cargo carried in a vessel of the draft given to that carried by a vessel drawing 18 ft. This is, as must be realized, quite arbitrary and may be far from the actual ratio. However, data were not available to determine the correct figures and the best obtainable were used.

TABLE 6.—Draft of Vessels and Number of Vessel Trips.

Draft of vessel, in feet. (1)	Number. (2)	Ratio of cargo to 18-ft. draft. (3)	Product. (4)	Total. (5)
More than 30	18	5	90	.....
28 to 30	129	4	516	.....
26 to 28	512	3	1 536	.....
24 to 26	363	2.75	998	.....
22 to 24	476	2.33	1 110	.....
20 to 22	664	1.75	1 162	.....
18 to 20	1 336	1.25	1 670	7 082
16 to 18	1 500	1	1 500	.....
Less than 16	5 798	0.75	4 348	5 848

Column (4) gives the product of Column (2) by Column (3). It is noted that, by using the arbitrary ratios adopted, the number of vessels of more than 18 ft. would carry 7 082 18-ft. vessel cargoes, while those under 18 ft. would carry 5 848. These vessels drawing more than 18 ft., therefore, carry about 55% of the yearly tonnage. Fifty-five per cent. of 25 000 000 tons gives 14 000 000 tons per year as the approximate increase of commerce due to the deepening of the channel by the Federal Government.

Using this tonnage and $3 000 000 as the annual cost to the United States, it is found that, for each ton, the United States is expending 21.4 cents or, since the distance from Philadelphia to deep water in Delaware Bay is 60 miles, 3.6 mills per ton-mile.

While there is much controversy in regard to the advisability of improving inland rivers, the writer has yet to hear any arguments against the development of waterways leading to large seaports. The Port of Philadelphia is claimed by some writers to be the second seaport in the United States in the amount and value of its water-borne commerce. Whether or not actually second, it is beyond argument that this port ranks well up in the list of those following the Port of New York.

Foreign imports and exports to and from Philadelphia carry about the same rate as those for New York and Baltimore. Rail freight rates to Philadelphia from these two cities for Class 6 commodities are 18½ and 17½ cents per 100 lb., respectively. Without its waterway the people of Philadelphia and its vicinity would be placed under a tremendous handicap in transferring imports and exports and its coastwise shipments by rail to or from either New York or Baltimore.

DISCUSSION

CHARLES M. SPOFFORD,* M. AM. SOC. C. E.—This paper impresses the speaker as a most enlightening contribution to engineering literature relating to the regulation of rivers. The feature of greatest interest to the speaker is the theory on the "constancy of mean depth" originally suggested by the late Henry Mitchell, M. Am. Soc. C. E., and adopted by various members of the U. S. Engineer Corps who have studied the river.

The author states that no two investigators agree as to the theoretical formulas for the contraction required to produce a certain depth of channel; that there still seem to be insurmountable obstacles in determining where dikes should be located; and that, in practice, it is necessary to adopt the "cut and try" process and to permit considerable time to elapse before sufficient knowledge of results can be obtained to warrant further progress. These conditions make pertinent the inquiry as to why small scale experiments on models of the river have not been made to determine the validity of the theoretical conclusions before spending large sums in construction. The money required for experimental tests would seem to be so insignificant compared with the cost of unsatisfactory construction that such means of investigation should be ignored only for the most potent reasons.

Experimental work of this character has been conducted for many years in German universities. Apparently, it has been well worth while, judging by the fact that in recent years several additional important laboratories, equipped to make such experiments, have been constructed and many experimental investigations made on German rivers.

The speaker inspected two of these European laboratories in May, 1926, the State Laboratory in Vienna, Austria, and the laboratory at the Technische Hochschule at Karlsruhe, Germany, in both of which he found much activity. At Karlsruhe, experimental work was being conducted under Professor Rehbock on the River Maas, in The Netherlands, and on the Quadälquiver, in Spain, and the speaker understood that experimental investigations had also been made in this laboratory on certain South American rivers. In recent years, a large and expensively equipped laboratory has been constructed in Stockholm, Sweden, and complete plans have been prepared for an extensive laboratory for this purpose at the Technische Hochschule at Zurich. Evidently, other countries than Germany are alive to the wisdom of such experimental investigations. Complete accounts of the experiments that have been performed in the various European laboratories have been published.† In this country, no such laboratory as yet exists, but the Massachusetts Institute of Technology is seriously considering the construction of one.

The figures given for the cost of dredging seem exceptionally low and it would be interesting to know whether these figures include all charges, such as overhead, interest on investment, salaries of engineers and officers con-

* Hayward Prof. of Civ. Eng., Mass. Inst. Tech., Cambridge; Cons. Engr. (Fay, Spofford & Thorndike), Boston, Mass.

† "Die Wasserbaulaboratorien Europas."

nected with the work, depreciation, insurance, and other factors. The question arises, if dredging by Government plant is done along the lower reaches of the river, why is it not also economical in Philadelphia Harbor where dredging is now done by contract? Possibly this is due to the fact that, while constant dredging is required in the lower reaches of the river, the dredging in Philadelphia Harbor is only intermittent.

In the paper, the construction of dikes, both as a means for controlling the channel and also for holding the dredged material within given areas, is mentioned. It would be of added value if information was presented as to the method of constructing these dikes; particularly as to whether wooden bulkheads have been used. It would seem, because of the comparatively soft material of the bottom at some locations, that the construction of dikes would be decidedly expensive.

Considerable attention is given to the commercial advantages resulting from the improvement of the Delaware River, thus establishing Philadelphia as a first-class port. The Port of Philadelphia is one of a notable group situated on rivers and canals, including such important ones as London, Hamburg, Antwerp, Montreal, New Orleans, Baltimore, Manchester, and Houston. These ports, all of which are some distance from the sea, and many of which have required large expenditures for improvements, are among the busiest in the world. Apparently, inland ports are in favor with shippers, but just how far the Government should go in the development of river ports in a country where natural harbors of deep draft, requiring but moderate expenditures for maintenance and improvements, already exist, is difficult to determine. Why should the Government spend large sums in improving the Port of Philadelphia when considerable freight passing through this port could equally well be shipped from Boston, for example, which is at least one day nearer Europe and which possesses an admirable natural harbor and excellent shipping facilities?

It is true that, in time of war, interior ports are safer against destruction by enemy battleships, although they are not much better protected against airplanes. On the other hand, they are more easily obstructed by sunken vessels and are sometimes greatly hampered by ice. Even a port as far south as Baltimore was seriously hampered by ice in 1918. If private capital is to be used in developing a port, no one can justly protest. By the expenditure of large sums of private capital a self-sustaining port has been developed at Manchester, England, all ships entering it proceeding directly past the Liverpool docks. Even in this case, one naturally questions whether, if the same sum had been expended in Liverpool and upon the railways connecting Liverpool and Manchester, it would not have been for the economic advantage of the country.

HENRY J. SHERMAN,* M. AM. SOC. C. E.—A cross-current passing over a shoal area and thence across a channel deposits its burden of material, carried in suspension, into the latter. No doubt in the Delaware River, as else-

* Cons. Engr., New Jersey Board of Commerce and Nav.; Cons. Engr. (Sherman & Sleeper), Camden, N. J.

where, this is one of the principal causes of shoaling. Movement of a soft bottom in shallow waters, caused by passing vessels in narrow channels, is a constant source of shoaling. It is fortunate that there is now available complete and exhaustive studies of the tides and currents from a high source like the U. S. Coast and Geodetic Survey, on which to base future operations.

In Table 1, showing monthly duration of rise and fall of tides, it is observed that the greatest variation is 0.22 hour for rise, or 4.50%, while it is only 0.12 hour for fall, or 1.60%, the monthly average being decidedly constant, despite the great variation in single cycles noted by the author.

A further study of Fig. 2, showing annual variations in high and low water, reveals the maximum difference of 0.4 ft. for low water and 1.10 ft. for high water, the latter being nearly three times the former.

In Table 2, the differences in the tidal ranges on the two sides of Delaware Bay are so great as to be worthy of mention, being no less than 1.76 ft. at Maurice River, a large percentage of the total range.

In Table 3, it is shown that high water in New Castle, Del., has been raised 0.38 ft. as compared with only 0.05 ft. and 0.07 ft. at Philadelphia, Pa., and Marcus Hook, Pa., respectively, and that the low-water plane at Philadelphia and Marcus Hook has been raised exactly the same amount, namely, 0.53 ft. Opinions will probably differ as to the causes of raising the low-water plane, a number believing that the contraction of the river is the answer. The figures given for cost of dredging seem very low in comparison with contract work, even after allowing for contractor's profit, and marine and liability insurance, items which, it is understood, are not included in these figures.

The fact that the 26 and 35-ft. channels have been self-sustaining near Cherry Island, without reduction in the width of the river, as theoretical studies had indicated would be necessary, is a vindication of a conservative policy in dike construction. The summary of the obstacles preventing dike construction is excellent. Specific mention might also be made of the high cost of installation and maintenance of such structures.

The author speaks of the strong opposition of shore interests cut off by a dike, and particular reference was made to citizens of New Jersey stopping the completion of Fisher's Point Dike. In this connection it may be said, there is now a demand for the removal of the outer portions of that dike and the re-opening of the channel back of Petty Island. In September, 1926, the War Department held a hearing to obtain views on proposed harbor lines at this point. This channel would accommodate prospective commerce in the upper part of the City of Camden. When the dike was proposed many years ago, the riparian lands were of little value; the navigation interests cut off were small; not much interest was shown in the project; and no public body was charged with the duty of studying the effect of the jetty on State or local interests. To-day, however, with the great increase in the value of riparian lands, and State and municipal bodies watchful of all water-front changes, such strong opposition would develop against the building of any dike that the project would probably be abandoned. Opposition is so strong

to another dike that is partly completed that a provision was actually inserted in the River and Harbor Bill prohibiting the use of any of the funds for the continuance of that dike.

Under Obstacle (*c*), the author states: "The navigability of a channel depends on the governing depth of that channel". This is now 32.7 ft., so near the project depth, that further dike construction might appropriately be undertaken if this were the only obstacle.

Under Obstacles (*d*) and (*e*), it is observed that where longitudinal dikes have been constructed, the channel in every case is maintained in straight ranges and, in some cases, is a considerable distance from the dikes.

The author makes timely reference to the control of some piers by the municipality. Manufacturing and small shippers who cannot afford to locate on an expensive water-front should, nevertheless, have those facilities and be assured access to a pier at all times at reasonable rates.

Under "Economics" the interest rate has been taken at 4.50%, which appears somewhat high. A rate of 4% or even 3.5% as an average of Government borrowing over a long term of years might be fairer.

The author has ingeniously worked out a cost of 21.4 cents per ton to the United States for the increased tonnage due to the deepening of the channel beyond the actual depth of 18 ft. While, undoubtedly, this figure is high compared with Northern rivers, it probably would compare favorably with the alluvial streams of the South.

While the paper is directed specifically to the part of the Delaware River from Philadelphia to the sea, reference might be made to the proposed ship canal across New Jersey from Bordentown to Raritan Bay, as the estimated tonnage from this source will utilize a large portion of the river under discussion. The State of New Jersey, believing the United States is almost ready to undertake construction, has made an appropriation to begin purchase of the right of way.

The author has compiled the important data and engineering opinions of the best minds in the U. S. Engineer Corps and Staff bearing on the problem of regulating the Delaware River. Supplementing this are his own observations and conclusions on certain features of the work. His presentation of the arguments for and against dike construction is eminently fair and unbiased. Out of the controversy which has been waged on this question, a middle course has been adopted utilizing each method to some extent. Careful thought and study have been given to the expenditure of the funds committed to the War Department, and the results achieved justify the confidence reposed in those charged with the work.

In his plain and comprehensive review of the work accomplished and analysis of the problems involved, he has made a splendid contribution to the literature of river and harbor improvement.

EARL I. BROWN,* M. AM. SOC. C. E.—The author is to be congratulated upon the very complete justification he has given of the policy of placing more

* Col., Corps of Engrs., U. S. A.; Engr., Eighth Corps Area, Fort Sam Houston, Tex.

dependence upon dredging to secure immediate and positive increases in depth of channel than upon regulation by training walls and dikes. Not that walls and dikes should be neglected, but they should be constructed only as a supplement to dredging, after an exhaustive study of commercial requirements as to channel depths, and of the susceptibility of the river to improvement by regulation. Some rivers lend themselves to it more readily than others, the character of the bottom, the shape of the bed, and the amplitude of the tide being factors.

Many engineers, not themselves engaged in active practice of river improvement, but reading in current engineering literature of the extensive and expensive regulating works constructed in the tidal rivers and harbors of the Old World, and comparing them with the scarcity of such works in practice in the United States and the greater reliance here placed on dredging for these improvements, are tempted occasionally to protest that river engineers in this country are not utilizing regulating works as they should.

The tide and its resultant phenomena are the means whereby the regulating work in a tidal stream achieves its ends. Compare the usual ranges of 15 to 20 ft. in European seaports with the average range of 4 to 5 ft. in ports of the United States, and it will be appreciated that this country could not expect to accomplish the same result with the same structure. A study of tidal conditions and manifestations is not a matter of such vital importance to America.

It is not to be understood, however, that it is the speaker's purpose to minimize the importance of tidal studies in connection with the improvement of rivers. He believes, on the contrary, that it could and should be carried out to a greater extent than it usually is. If the results of a full and complete tidal study are available, the engineer can prepare his project and execute his work with a greater degree of confidence in the ensuance of benefit to navigation.

That part of the paper relating to studies made upon physics and hydraulics of the river does not indicate that much attention has been paid to these very important questions. However, it must be conceded that any improvement project must be based on a study of them if the work is to be accomplished in the most successful manner. Failure to plan the improvement so as to take full advantage of the knowledge derived from those studies is a step in the dark, which may be injurious.

Previous investigators only went so far as to endeavor to find a law of variation in the width and cross-section of the river, based on an assumption that the mean depth is the same in all sections. These investigators proceeded on empirical rather than theoretical lines, and found equations of either the parabolic or the hyperbolic type. It is now generally conceded by river engineers that the law of variation of width of a tidal river is best expressed by a logarithmic equation. Recent investigations show that there is a definite relation between the variation of the energy of the tidal wave and the width of a tidal river. If the bottom be horizontal, as reported by Mitchell and assumed by the other investigators, the equation is of the simple exponential

form as a function of the distance from the mouth of the river. If the bottom has a horizontal slope, the law of variation is more complicated, and is in the form of a compound exponential equation.

In most estuaries and tidal rivers, the amplitude, the speed of the wave, that is, its rate of propagation, and the velocity of the currents diminish more or less rapidly going up stream, because of the expenditure of the energy of the wave as a pure loss in overcoming the friction that results from the insufficiency of the mean depths and from the excess width of the bed, as well as from obstacles which it meets. By lessening these obstacles, it is possible not only to provide for the utilization of that energy for the conservation of the amplitude, the speed, and the velocity of the wave, but also to measure them to some extent by suitable means. All these factors have a bearing on the cost and probable degree of success of any project, and they cannot be neglected without paying the penalty in increased improvement and maintenance costs.

The Artificial Island mentioned by the author is an example. The curves showing the range of tides in the Delaware River as given in Fig. 4 emphasize a marked falling off of range of tide in the period 1890-1900 on that part of the river between Woodland Beach and near the upper tidal limit. Colonel Boggs indicates this falling off, but gives no explanation of it. However, by reference to the same source quoted by the author,* a statement is found that this change is to be attributed to the improvements effected in the river under the projects in force.

This explanation is not satisfactory, and cannot be accepted. The dredging of shoal areas beneath the plane of low water would have no effect on the height of tides, and the volume of material excavated from above that plane would not be sufficient, quantitatively, to account for the decreased volume of tidal flow above Woodland Beach. Some other explanation must be found.

The drop in range occurs in the reach between Woodland Beach and Delaware City, Del. Some of the most extensive contraction works on the Delaware River have been constructed in this reach. These include Artificial Island and the dikes connecting it with the mainland, and a dike running down stream from Reedy Island.

In his study of the law of variation of widths, H. F. Flynn, M. Am. Soc. C. E., gives the data shown in Table 7.

It will be noted that the greatest contraction of area is at Mile 35, near the lower end of Artificial Island, where, expressed in percentages, the original channel was about 5% in excess of theoretical requirements. It has been contracted to 75% of its original width, and has only 80% of its theoretically required width.

A contraction of this magnitude in the bed of a tidal river, the bottom of which is mobile, would cause scouring to the extent that the cross-section might be thereby restored approximately to its original size, and no material damage would be done in the long run to the tidal propagation. However, the bed of the Delaware River at this point cannot be classed as mobile. It is a very hard stiff mud which, when dug out by a bucket dredge, retains its

* *Special Publication No. 123*, U. S. Coast and Geodetic Survey, 1926, pp. 43 and 47.

shape and consistency. The river, therefore, has not been able to erode its bed and restore the magnitude of its cross-section. Consequently, the loss of energy due to this contraction is still felt in a decreased tidal range above the point of contraction. The injurious effects of this great contraction could be largely obviated, and the cross-section restored to a great degree by the removal of the two dikes which connect the island with the mainland.

TABLE 7.—CROSS-SECTION AREAS, DELAWARE RIVER.

Mile.	Mean area of section in 1881–82, in square feet.	Measured area in 1916, in square feet.	Theoretical area, as computed by formula, in square feet.	Decrease in area, 1881 to 1916, in square feet.	Present deficiency in area, in square feet.
31	248 700	241 100	256 000	7 600	14 900
32	263 200	248 000	267 000	15 200	19 000
33	301 400	236 000	279 200	65 400	43 200
34	324 500	249 000	291 500	75 500	42 500
35	321 700	241 000	304 700	80 700	63 700
36	317 300	261 000	318 900	53 300	57 900
37	331 600	323 800	334 100	7 800	10 300

It may be contended that this reduction in tidal range manifests itself, as it usually does, in a raising of the plane of mean low water in the upper section of the river, thus rendering increased depths available at that stage for navigation. This is a pertinent reply, and the resultant benefit must be balanced against those that would follow the increased tidal range, with its greater current velocity, and hence greater facility for self-maintenance.

It has been predicted by some engineers that a permanent improvement of the Delaware River by dredging could not be successfully accomplished, as there was a tendency to constancy of mean depth throughout the estuary. The author quotes the late Henry Mitchell, M. Am. Soc. C. E., to that effect, and also refers to the recommendation of H. C. Ripley, M. Am. Soc. C. E., that instead of dredging the straight reaches be changed into channels of suitable curvature by means of training walls to secure depths suitable to navigation needs.

The very satisfactory results that have been obtained by dredging are sufficient refutation of adverse predictions on that score, and Colonel Boggs indicates the many serious practical objections to a sinuous channel. From a theoretical point of view the increase in constant mean depth thereby obtained, will result in increased amplitude, speed, and velocity of the tidal wave, thus enabling the river to maintain the increased depth, when once obtained, by reason of the improved tidal conditions. There is, however, a limit beyond which tidal conditions can not be improved, and artificial maintenance will have to suffice. That limit, however, is not known.

As between straight and sinuous tidal channels, theoretical as well as practical considerations lead to a preference for the former. There is less friction and, consequently, less loss of energy in a straight than in a sinuous channel, and it is the preservation of the tidal energy to the farthest limit up stream that is to be sought. The principles enunciated by M. Fargue relating to

curvature and depth of channel, apply to streams flowing in one direction, but not at all satisfactorily to tidal streams. One of the greatest bends on the Delaware River, that just below New Castle, Del., is not accompanied by any perceptible deepening, and the channel lies on the convex point, not in the concave bend.

The author has touched upon shoaling as a result of lack of coincidence in certain places of the thread of the flood and ebb currents. It would have been very interesting and instructive if he had given a statement or tabulation showing the points where there is such a lack of coincidence, and had indicated the comparative amount and cost of maintenance dredging per mile at such places as compared with the same amounts in channels more suitably conditioned. It is the general impression that the larger part of the annual maintenance dredging is now done on a few bad places, perhaps not to exceed six. If that is a fact, it indicates the necessity of such a tidal study as herein referred to with a view to finding means of eliminating those conditions.

Summing up, the speaker's views are, that the general policy under which the improvement of the Delaware River is being done, is correct, and is based on sound principles, although some errors of judgment have been made in the locations of channels and of regulating works (including disposal grounds when in the bed of the river). A detailed study of the conditions of tidal propagation in the river might have prevented some of these errors, and might now enable them to be corrected, with a strong probability that maintenance costs could thereby be lessened, and future errors largely avoided.

HARRY TAYLOR,* M. AM. SOC. C. E.—The question of the relative cost of Government and contract dredging has been raised. The difference in cost of the two methods is explained at least partly by the fact that the Government owns comparatively few dredges and these are busy all the year. If work could be let in large contracts, which would keep all dredging contractors' plant busy for long periods and the contractors could be sure that when one job was finished another job would be available, so that all their plant would be always busy, the work should cost less; but whether the price to the Government would be less is another question, for experience has shown that low prices are obtained when there is little work and strong competition. However, such a happy condition for the contractor can never exist, for no contractor would be satisfied with the amount of work he had, and every one would be building more plant in the hope of getting more work and making a little more money.

Another item that favors the Government plant is that the Government does not have to go out and look for work, and is, therefore, not under the expense of bidding for it. Every contractor must bid for every job he obtains, and every bid costs money whether or not a job is secured. Not every contractor obtains work every time he bids, but he must charge up as part of his overhead expense the cost of preparing his bids, and some job must pay for it, otherwise the contractor will soon go out of business. Still another item is the expense of moving plant from one point to another. These

* Maj.-Gen., U. S. A. (*Retired*), Washington, D. C.

items explain, in part at least, why the Government should be able to do work at a lower price than the contractor. Other items which add to the contractor's cost are depreciation and insurance. Depreciation is fully covered by the present cost-keeping methods of the U. S. Engineer Department, but owing to the very excellent care taken of all Government dredges, they last for many years and in some cases are still at work after their entire cost has been charged off. Therefore, the item of depreciation, when such plant is used, is a book charge only, and does not represent actual outlay of Government money. An example may be shown by the dredge, *Manhattan* (Fig. 6), which was built in 1908 for use in digging the Ambrose Channel. The whole cost of that dredge was charged against the Ambrose Channel improvement, but it was sold to the Philadelphia District and now, after about twenty years, it is in fair condition and still doing good work. Insurance is charged in the cost-keeping accounts for the purpose of making comparative estimates of cost, but that item is a very small one.

The U. S. Engineer Department has adopted the policy of retiring its old, out-of-date dredges. The first sea-going hopper dredges were built with wooden hulls and some of them were used for as long as thirty-five years, but they have finally all been retired from service and most of them have been sold for very small prices, practically junk. All the dredges in use at present have steel hulls, and there is no reason why they should not last longer than those with wooden hulls.

The sea-going hopper dredge does work in certain places, such, for example, as the ocean bars of many harbors, at a much less cost than such work can be done by any other type. The type of sea-going hopper dredge in use in the United States has been developed entirely by the U. S. Engineer Department. Dredges somewhat similar to the American sea-going hopper dredges are in use in Europe, but the type apparently most favored there is one which was tried in the early days of the Ambrose Channel improvement and proved not to be a success. The newer sea-going hopper dredges in use by the Engineer Department are very expensive, costing $600 000 and more. The great cost of these dredges is probably the reason why contractors do not use them, because they cannot afford to tie up so much money in a single piece of plant that may not be kept busy at all times. The extremely small cost at which these dredges can do work fully justifies the ownership and operation of a limited number of them by the Government. Their great flexibility in being able to work in crowded channels, such as those in New York Harbor, and the facility with which they may be transferred from one locality to another, also give added reasons for their use by the Government. The element of portability is shown by the fact that one of these dredges, which was built on the Delaware River, was sent to Alaska under its own power. There it worked under conditions that would have been very difficult for any other type of dredge on account of the heavy tide, the distance from base of operations, and other unfavorable conditions. The District Engineer, basing his estimates on the best data that he had been able to obtain from contractors as to prices they would probably charge for this work, considered that the use of the hopper dredge saved more than $100 000 to the Govern-

ment in the cost of this one operation alone. Considering the difficulties of doing the work with any other type of dredge, it is believed that this estimate of saving is not too high.

F. C. WARNER,* M. AM. SOC. C. E.—The Mitchell and Giesler studies, mentioned by the author, were made when the Delaware River was in its natural condition, no work of improvement having been done beyond a small amount of dredging. There is no record so far as known to the speaker that the results of these studies had been used in any way in connection with the improvement of the Delaware River until they were taken up by him in his study in 1917. The natural regimen of the river has been materially changed by dredging and the construction of dikes and jetties in connection with the projects for the 30 and 35-ft. channels, particularly in changes in currents, depths, and tidal conditions. It has been found that the mean tidal range has decreased about 0.7 ft. and the elevation of mean low water has been raised about 0.8 ft., compared with the range and elevation of the tides in the river in its natural condition. This is due largely, it is believed, to the improvement work. The existing condition of the river in 1916 rather than its natural condition, therefore, was taken as the basis for this study.

In the author's reference to the study by H. F. Flynn, M. Am. Soc. C. E., in 1918, it is noted that Mr. Flynn takes exception to this, as he believed that the natural regimen of the river should have been used instead of an artificial state. For the reasons stated, the speaker does not agree. For this study, cross-sections of the river channel were taken, in the fall of 1916, at each nautical mile, beginning at Fort Mifflin Light and extending a distance of 40 nautical miles down the river, the locations being the same as for those used in the Mitchell study. Fig. 9 shows the results of this study.

The survey could not be extended the full 46 nautical miles covered by the Mitchell study, nor could intermediate cross-sections be taken, as the field work was stopped by cold weather and ice in the river. To cover the full 46 nautical miles, cross-sections were taken from a recent survey. Examination of many charts and surveys of the river showed that at certain stretches, from 1 mile to 3 miles long, natural depths of 35 ft. or more at mean low water and a bottom width of about 800 ft. existed in both its natural and improved condition. Other stretches were found to be 35 ft. or more deep, but less than 800 ft. wide. These natural depths of 35 ft. or more that existed in the original condition of the river, and still exist at the same places in its improved condition, must be maintained according to some definite law, and it was assumed, therefore, that cross-sections could be accepted as "standard" for the volume of tidal flow at these points, from which theoretical cross-sections for natural maintenance at intermediate points could be determined. With this in view three typical, or "standard", cross-sections were selected, 3, 20, and 44.6 nautical miles from Fort Mifflin Light, respectively, the last being at the head of the Delaware Bay channel where there was a depth of 35 ft. at mean low water and a bottom width of 800 ft. For a better average cross-section at these points the arithmetical mean of three cross-sections, one above

* U. S. Senior Engr., Office of Div. Engr., Northeast Div., New York, N. Y.

and one below, was used. Applying the Giesler equation, the hyperbolic curves for cross-sectional areas at mean low-water and half-tide stages were determined, from which intermediate cross-sectional areas at each nautical mile were computed.

The author's Table 4 gives the half-tide cross-sectional areas for each 5 miles from 5 to 40 nautical miles, inclusive, below Fort Mifflin Light. These curves, thus determined, platted on the low-water and half-tide profiles of cross-sectional areas obtained from the survey, are shown on Fig. 9. The low-water curve passes through five cross-sectional areas having natural depths of 35 ft. or more at mean low water, all of them being 800 ft. wide, including two "standard" cross-sectional areas used in determining the curve. They have a length of 7 nautical miles out of the total of 44.6 nautical miles under consideration. The curve also passes through, or close to, other intermediate points having a natural depth of 35 ft. at mean low water, which serves to verify the correctness of the equation. It appears safe to assume, therefore, that as this curve passed through five "standard" cross-sectional areas with an aggregate length of 7 nautical miles and the "standard" cross-sectional area at the head of the Delaware Bay channel at Nautical Mile 44.6, it should give correct theoretical cross-sectional areas for the natural maintenance of a 35-ft. channel, 800 ft. wide at all points of the remaining 37.6 nautical miles of channel of less than 35 ft. depth.

From these theoretical cross-sectional areas, widths at mean low water may be determined at each point where a reduction in the present cross-section and width is required. It is believed that this theory is entirely rational and can be applied, in connection with the location of regulation works for natural maintenance, at sections of the river channel that now require continuous maintenance dredging. The author has quoted the speaker, as to the practical application of this theoretical law.

The speaker intended to continue this study progressively by taking cross-sections annually at the same points and also study the tides, currents, river slopes, etc. With this in view automatic tide gauges were installed in the spring of 1917 at five places below Fort Mifflin Light to the head of Delaware Bay. Precise level bench-marks of the U. S. Coast and Geodetic Survey and the U. S. Engineer Office at Philadelphia, Pa., are located along the west shore of the river, to which the planes of mean low water, as determined by these gauges, may be referred. This program was interrupted, however, by his transfer to another district.

The Delaware River carries a large percentage of material in suspension, brought down from its head-waters and from its many tributaries, particularly during periods of freshets, much of which is deposited in the dredged channel. It is believed that this sediment is precipitated largely when the fresh water, with its suspended burden of silt, meets the salt water and this great mass of mud and water moves along the bottom up and down with the tides until a condition favorable to its deposit is reached, which is usually at the broad sections of the river where the currents slow down. These are the sections that require continuous dredging for maintenance. It is believed

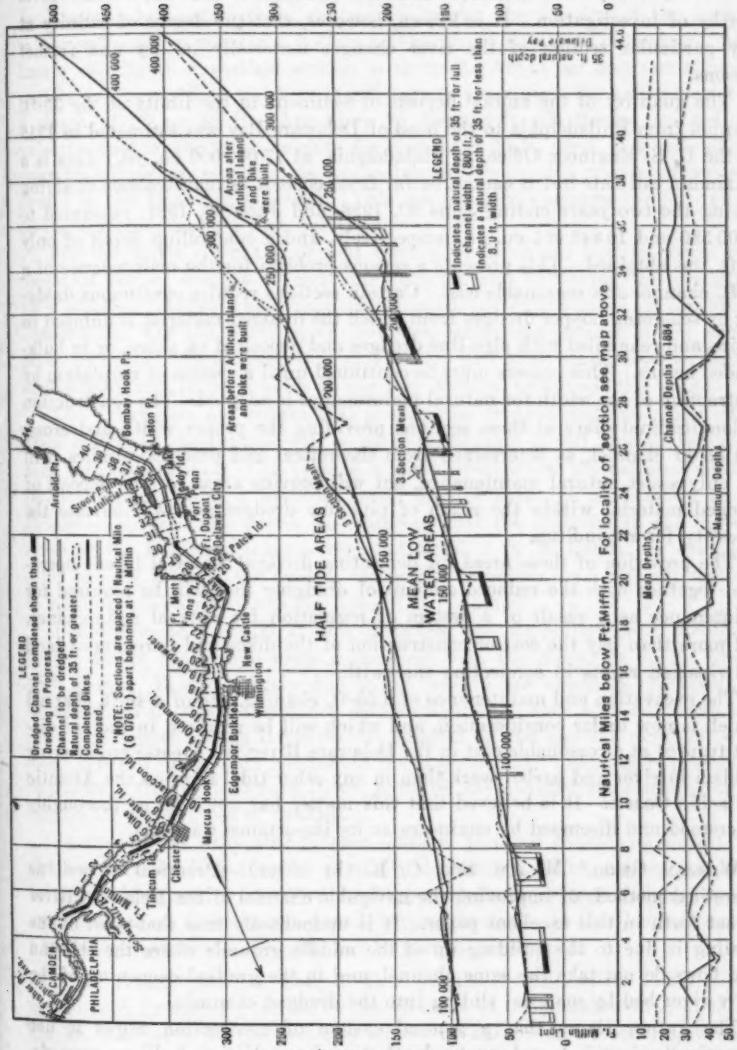

FIG. 9.—CURVES OF CROSS-SECTIONAL AREAS AND DEPTHS, 35-FOOT CHANNEL, DELAWARE RIVER.

that the degree of salinity of the water has much to do with the precipitation and deposit of sediment, but as no study of this feature has been made, so far as known, the particular sections where this occurs are uncertain. It is worthy of investigation. It is known, however, that the degree of salinity at any particular section of the river changes materially in dry and freshet seasons.

The quantity of the annual deposit of sediment in the limits of the 35-ft. channel from Philadelphia to the head of Delaware Bay was estimated in 1915 by the U. S. Engineer Office, at Philadelphia, at 17 000 000 cu. yd. This is a maximum estimate but it cannot be far from correct as maintenance dredging during the two years ending June 30, 1926, and June 30, 1927, amounted to 9 200 586 and 10 845 001 cu. yd., respectively, and a controlling depth of only 34 ft. was obtained. This presents a serious problem for the maintenance of a 35-ft. channel at a reasonable cost. Certain sections require continuous dredging by sea-going hopper dredges from which the dredged material is dumped in basins and rehandled with pipe-line dredges and deposited on shore, or in bulkheaded basins. This process must be continued until a system of regulation by contraction of the width for natural maintenance is adopted. The construction of longitudinal dikes at these sections providing the proper width and cross-section of channel, as determined from theoretical and practical studies, will not only assist natural maintenance, but will provide areas for the deposit of dredged material within the reach of pipe-line dredges and will obviate the necessity for rehandling.

The provision of these areas for depositing dredged material in one operation, together with the reduced amount of dredging that will be required for maintenance as a result of a system of regulation for natural maintenance, will more than pay the cost of construction of the dikes and purchase of land and riparian rights in connection therewith.

The excavation and maintenance of a 35-ft. channel, and of a 40-ft. channel (which is now under consideration, and which will be required in the not distant future) at a reasonable cost in the Delaware River is a greater engineering problem in river and harbor work than in any other tidal river on the Atlantic or Pacific Coasts. It is believed that this matter has not been as thoroughly understood and discussed by engineers as its importance warrants.

William Gerig,* M. Am. Soc. C. E. (by letter).—Practical as well as theoretical methods of improving the navigable channel of the Delaware River are set forth in this excellent paper. It is undoubtedly true that most of the shoaling is due to the building up of the middle grounds where the ebb and flood flows do not take the same channel, and to the gradual deepening of the entire river bed by material sliding into the dredged channel.

The author shows that a general system of contraction works is not economically justified and contends that a few additional dikes, properly placed for guiding the ebb and flow into one channel, will considerably reduce the maintenance. The writer believes that such dikes, although expensive to

* Senior Engr., Office of Chf. of Engrs., U. S. A., Washington, D. C.

build, are justified, and can be placed so as to do a minimum amount of damage to adjoining property.

The material coming into the channel from the sides must be removed by dredging because, without contraction works, the velocity of the current is not sufficient to scour the bottom at this great depth. The average maximum velocity in a vertical section is about 2.4 knots per hour, or approximately 4.0 ft. per sec., which is insufficient to scour even the soft material at a depth of 30 or 35 ft. According to Kennedy's silt theory, the critical velocity, that is, the mean velocity for a channel 35 ft. deep, just sufficient to prevent silting or scouring, is approximately twice the maximum velocity found in the Delaware Channel. This low velocity accounts for the failure of the agitation method that was tried.

For the upper river, the present method of dredging, that is, using self-propelled hopper dredges to clear the channel, and delivering the dredgings to a pipe-line dredge where they are pumped out of the river, is considered economical. On the lower river, however, where the haul does not exceed 30 to 50 miles, it is believed that it will be found more economical to dispose of the dredgings in deep water in the Bay Section, or outside the Capes.

The writer does not believe that placing the dredged material along either or both sides of the channel will be effective, because it will immediately come back into the channel. This is done in some rivers where the material encountered is usually sand, a material much heavier than the mud found in the Delaware River. The writer has observed that the material in the disposal areas of the Delaware takes a very flat slope, 1 ft. in 100 ft., or even less, after passing through the dredge. It would, therefore, be a difficult material to retain on the already moving sides of the channel.

For delivering material at long distances, the sea-going hopper dredge of proper design has proved more economical than the dipper or bucket dredge with scows. This is largely due to its facility for handling, its speed, its capacity and its non-interference with navigation. Also, each cut made by a sea-going hopper dredge improves the channel by the amount removed, while other types of dredges do not benefit the channel until dredging is practically completed. On the Delaware River, however, the channel deteriorates rapidly behind the latter types of dredges.

In economical work with hopper dredges, it is, of course, important that the economic loading time be carefully determined. The method for ascertaining this is well understood by hopper-dredge operators and has become standardized on Government-owned hopper dredges. If this loading time is not carefully obtained, the cost may be greatly increased.

F. C. Boggs,* M. Am. Soc. C. E. (by letter).—The writer is heartily in accord with Professor Spofford in his views as to the possible value of models for an indication of the probable effects of harbor and river improvement works. He trusts that one or more laboratories will be established in the near future, where these and other problems of hydraulics may be studied. In this connection attention is invited to the recommendations along these lines,

* Col., Corps of Engrs., U. S. Army; Dist. Engr., Philadelphia, Pa.

made by Maj. Gen. Edgar Jadwin, Chief of Engineers, U. S. Army, M. Am. Soc. C. E., in his report on flood protection works for the Mississippi River.

Professor Spofford and Mr. Sherman raised the question as to cost-keeping methods. General Taylor has quite fully covered this phase of the subject. Professor Spofford also pertinently suggests that if costs for work done by the Government plant are so low, it might be advisable to use this plant in Philadelphia Harbor instead of having dredging work there done by contract. The self-propelled hopper dredge, used by the Government on the Delaware River, would not be satisfactory for work in the restricted limits of the harbor. The numerous passenger and car ferries, small boats, and towed barges, together with larger boats at anchor or entering or leaving their slips, would make the operation of a self-propelled dredge unsatisfactory and dangerous. The width of the harbor, about 1 800 ft., does not offer the opportunity of alternate routes as does the much wider Hudson River at New York. Moreover, the many under-water cable lines which can be readily handled by clam-shell or dipper dredges, would be subject to serious damage from the suction drag-head of a self-propelled dredge. While these difficulties are not insurmountable, they would add materially to the cost, which would be still further increased on account of the long run necessary to reach a disposal area. These dredges, when loaded, draw from 18 to 20 ft.

Mr. Sherman comments on the statements made by the writer in regard to the municipally owned piers. In justice to those who have control of the policy of handling these piers, it should be stated that the Pennsylvania Courts have decided that, except by Special Act of Legislature, private piers as well as piers leased from the City of Philadelphia, must be open to all comers. As one jurist expressed it, "the owner of a wharf is under the same obligation as an inn-keeper to receive those who call, provided he has room, and they tender a reasonable compensation." Despite the legal aspects, the writer is still of the opinion that one or more municipally owned and operated piers would be advantageous.

Professor Spofford asks why inland ports, such as Philadelphia, should be developed by the Federal Government. This presents a matter which cannot be fully covered in a brief paper. The writer believes that a consideration of the comparative costs of transportation by rail from Boston, New York, or Baltimore, to the 5 000 000 or more people in the Philadelphia area, with costs of water deliveries through the Port of Philadelphia, will give a convincing answer to this inquiry.

Several of the discussors mention the increased height of the mean low-water plane in recent years, in the river above Artificial Island. The writer agrees that this is undoubtedly due to the constriction of the river between Artificial Island and Reedy Island Dike. Whether this constriction, with the resultant raising of the low-water plane, has been harmful, is open to question.

The writer cannot agree with Mr. Warner in the theory that all the maintenance dredging required is due to silt originating in the upper river and its tributaries and deposited from suspension in the lower river. While undoubtedly some of the material removed in maintenance work is of this

origin, the writer believes that the main cause of the formation of shoals in the channel is the gradual movement of the soft material forming the river bed. Under natural conditions he believes that the bed of the stream at any cross-section would maintain, with little change, a semi-permanent profile. If this is modified by dredging a channel or by placing over-burden on any part of the profile, the equilibrium of forces is disturbed. Cross-currents produced by the ebb and flood tides, which it may be noted attain approximately the same maximum strengths, facilitate this movement down the sloping bed of the river into the channel.

The writer again desires to state that he is not opposed to dikes constructed for the purpose of regulating flow. He is opposed to dikes in the tidal section of the Delaware River, constructed for the purpose of inducing strong currents, since such structures, due to practical equality of ebb and flood currents, would tend to induce scour during both these stages of the tide. The result would be that about the same amount of material would be carried up stream on the flood as would be carried down stream on the ebb. In his opinion, dikes to eliminate undue widths of the stream, or to guide currents in lines parallel to the channel, would be advantageous. Such dikes should be constructed only after careful and extensive current studies at each locality where shoaling occurs.

Paper No. 1703

THE HEAD-WORKS OF THE IMPERIAL CANAL*

By C. E. Grunsky,† Past-President, Am. Soc. C. E.

With Discussion by Messrs. E. S. Lindley and C. E. Grunsky

Synopsis

The diversion of water from the Colorado River for the irrigation of lands in the Imperial Valley, California, has been fully described in papers previously submitted to the Society.‡

In 1916, mainly on account of difficulty with the silt carried by the Imperial Canal, it became necessary to make considerable improvements which included an up-stream extension of the canal for about 1 mile and the building of an intake structure which is known as the Rockwood Gate. This gate was designed for erection on a sand foundation. It is a structure with seventy-five openings between piers and extends for more than 600 ft. along the bank of the river. For about 400 ft. of this distance, the foundation is fine sand which has been prevented from being piped out from under the gate by placing upon it, without pile support, the floor of the structure, heavily weighted by a box of sand carried by the piers which sub-divide the gate into sluice-like openings. There has been no trouble with settling since its completion.

The Imperial Canal and Its Intake Structure

The Imperial Canal, so called because it was built for the irrigation of lands in that part of the Salton or Coahuila Basin now known as Imperial Valley, is also known as the Alamo Canal. Its head is in California on the right bank of the Colorado River just up stream from the International

* Published in November, 1927, *Proceedings*.

E., Vol. LIX (1907), p. 1; also, "Irrigation and River Control in the Colorado River Delta," by H. T. Cory, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXVI (1913), p. 1204.

Boundary line between California and Mexico. Its course is first southerly into Mexico, thence westerly and northwesterly back into California. About 40 miles of the main canal are in Mexico. This canal supplies water to about 450 000 acres of cultivated lands in California and to about 200 000 acres in Mexico. Not an acre of the cultivated land could produce crops without irrigation, normal rainfall being only 2 to 3 in. per year.

Within a few hundred yards of the International Boundary line, at the base of Pilot Knob which rises toward the west, is a regulating gate that was built in 1905 on good rock foundation. This was originally provided with eleven openings or sluices through which the flow was controlled by Taintor gates. Drift and silt were troublesome and interfered seriously with the manipulation of the gates, wherefore, in the course of time, several of the original gates were replaced with Stoney gates. There was an open cut, a little more than ¼ mile long, from this gate to the river, in which a dredge had to be maintained to stir up silt deposits and prevent reduction of capacity, which were always likely to occur there on a falling river. The importance of maintaining capacity will be appreciated when the fact is taken into account that about 2 000 sec-ft. of water in winter and more than 5 000 sec-ft., at the height of the irrigation season (in 1927 already in excess of 7 000 ft.) had to be sent down the canal, practically without interruption.

The water entering the canal carried from about 0.3% to 4.0%, averaging probably about 0.8%, of very fine silicious silt in suspension and, besides, had an appreciable bed or bottom load of fine sand. At the time the modification of this intake arrangement was recognized as essential, all the silt which entered the canal was carried by the water down the main canal, into the laterals, into the small irrigation ditches, and, in large part, out on the fields, lodging in the canals, ditches, and on fields, frequently at points where its accumulation became increasingly embarrassing. The quantity of this silt transported down the main canal, estimated at a weight of 100 lb. per cu. ft., was computed, from the data available, to be about 12 000 acre-ft. per year. It has been reported by M. J. Dowd, Assoc. M. Am. Soc. C. E., Chief Engineer of the Imperial Irrigation District, to have reached a peak of 24 900 acre-ft. in 1923 and to have averaged more than 14 000 acre-ft. during the period, 1915-1927.

There was a twofold purpose in the up-stream extension of the canal and the building of a gate in the bank of the river:* First, the structure was to be of such a type that it would reduce the incoming silt to a minimum, mainly by holding back the bottom load of the water; and, second, in the mile stretch of canal between the new intake gate and the original regulating gate, there would be ample space in which to operate dredges with which it was proposed to maintain extra depth, thereby providing opportunity for the settling of some of the heaviest of the silt in suspension.

The quantity of solid material in suspension in the water of the Colorado River, at Yuma, Ariz., 8 miles up stream from the head of the Imperial Canal, had been determined by the U. S. Reclamation Service which commenced

* The project was recommended, designs were approved, and general supervision was exercised by the late George G. Anderson, M. Am. Soc. C. E., and the writer, Consulting Engineers to Imperial Irrigation District. The preliminary design was prepared by the writer.

its sampling in 1909. The records thus obtained established the fact that there is somewhat less material in suspension at the water surface than at mid-depth, or near the bottom of the river. These silt determinations indicate that there is about 12% more silt in the water of the Colorado near the bottom than at the surface. It appeared, therefore, worth while to arrange the intake so that mainly surface water would enter the canal. Consequently, the gates of the Rockwood Intake were planned to be of the over-fall type, thereby not only checking the movement of silt on the bottom in the head of the canal, but also, in some measure, reducing the average quantity of silt in suspension.

Two dredges were provided for the inter-gate section of the canal and, for a time, in the period from 1918 to 1920, these removed upward of 500 000 cu. yd. per month of fine sand from this section without making any permanent impression on the depth. These facts relating to the magnitude of the silt problem are noted merely to emphasize the urgent need which had long been recognized for the Rockwood Gate. It is not proposed, however, to enter on a full discussion of the canal's silt problem at this time.

The preliminary design of the new intake structure which is built into and replaces more than 600 ft. of river bank, was made on the assumption that it would have to be constructed on a foundation of fine sand. As built, its location is at the base of a low gravel-topped hill somewhat farther up stream than had at first been planned, with the resulting advantage of securing for its up-stream one-third, or for about 200 ft., a foundation of slightly cemented sand, a material which, although quite soft, can be cut to, and will stand with, a vertical face. A similar formation, exposed at a number of places in the hills along the river at and below Yuma, is soft enough to be carved readily with a knife. Except for the large excavation required, the gate would have been shifted entirely into this cemented sand formation.

The floor of the structure is at two levels. The up-stream gates, 27 in all, have their sills 4 ft. lower than the remaining 48 down-stream gates. The gates with the lower sills are on the better foundation. The structure consists in the main of a heavy concrete floor with cut-off walls at the up-stream and down-stream edges (Fig. 1). Piers rise from the floor and are spaced so as to leave openings about 6½ ft. in the clear between their sides. The piers carry a sand-box, 22 ft. wide by 10 ft. deep, which serves the purpose of loading the floor. The weight of the fill in the sand-box, transferred by the piers to the floor, is relied on to hold in place the sand on which the structure rests.

At the up-stream edge of the structure, sheet-piling has been driven. Its purpose was not only to reduce the movement of water through the underlying sand, but also to serve as a form for the concrete cut-off walls. It will be noted that this piling gives no support to the structure, being placed in front of, and not under, the concrete so that it does not interfere with the transmission of the full weight of the intake to its sand support. It was proposed to drive this sheeting to a depth of 30 ft. below the floor level. A jet was used in driving the sheet-piles which were of the built-up Wakefield type, but so much difficulty was experienced that, in the finished work, few are more than 20 to 25 ft. in the sand. The proposition to drive them to the greater

depth originated with C. R. Rockwood, Chief Engineer of the District, and his assistants, who based their conclusion as to the possibility of doing this on long experience with similar work, although of less magnitude, in the Lower Colorado River region. In the very fine sand, at the site of the intake, the piles would drive readily about 10 or 12 ft. It was difficult to control them

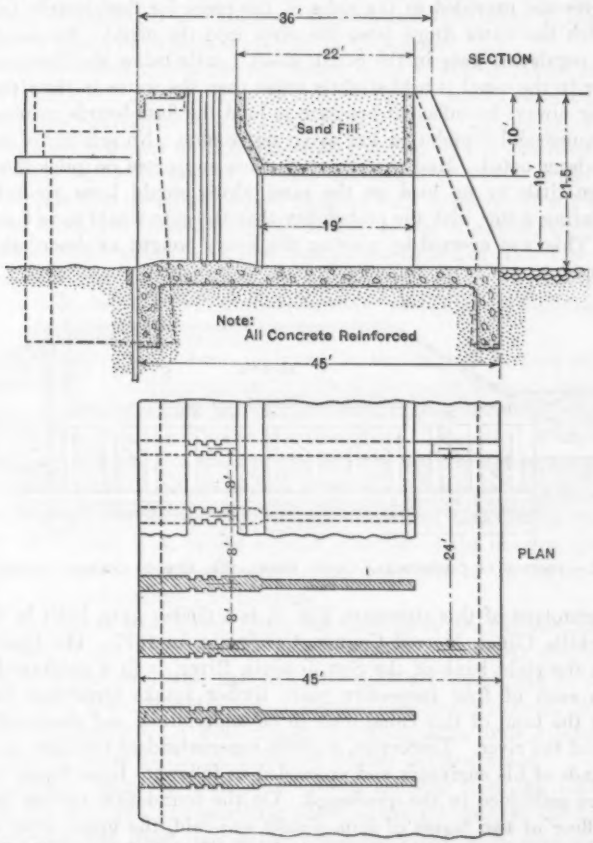

FIG. 1.—PLAN AND SECTION, ROCKWOOD GATE AT HEAD OF THE IMPERIAL CANAL, CALIFORNIA, BUILT 1918.

during further driving. They could not always be held snug against the preceding pile and despite the liberal use of water from a jet, soon required such hard blows that many of them went to pieces and had to be pulled. The sand in which this difficulty was experienced is very fine and has little, if any, admixture of clay. It appears very compact and firm under water, but partakes of the nature of quicksand when jarred or caused to vibrate.

Along the down-stream edge of the structure, at both abutments and across the canal, is a heavy rock-fill. Except for a small portion this was, according

to the original program, to be placed from time to time after the gate went into use, all settlement of the fill to be made good as it developed.

Up stream from the sand-box the piers rise several feet above the extreme high-water stage of the river and are united at the river face of the structure by a slightly ornamented cornice which gives a pleasing aspect.

Grooves are provided in the sides of the piers for flash-boards (stop-logs) over which the water drops from the river into the canal. By means of the original regulating gate in the canal, about 1 mile below the Rockwood Gate, the water in the canal is held slightly lower than the water in the river so that there may always be sufficient pressure to hold the flash-boards in place.

The quicksand foundation has given no trouble. No settling of the structure has been noted. Had the structure been supported on piles there would have been little or no load on the sand which would have yielded readily to percolating water with the probability that the gate would have been undermined. This was averted by placing the heavy weight as described directly on the sand.

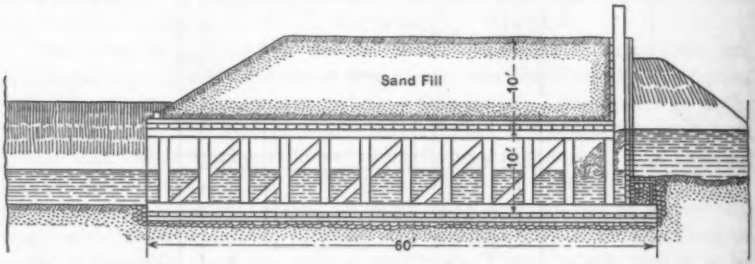

FIG. 2.—SECTION OF CHOWCHILLA CANAL REGULATOR, MERCED COUNTY, CALIFORNIA, BUILT 1877.

The prototype of this structure, Fig. 2, is a timber gate, built in the head of Chowchilla Canal, Merced County, California, in 1877. The head of this canal, on the right bank of the San Joaquin River, is in a quicksand formation. In each of four successive years timber intake structures had been placed in the head of this canal only to be undermined and destroyed by the next rise of the river. Thereupon, a ranch superintendent took the matter out of the hands of his engineers and proceeded as follows: Loose blocks of sandstone were embedded in the quicksand. On the foundation surface thus prepared, a floor of two layers of 2-in. planks was laid, the upper layer at right angles to the lower one. This floor was about 6 ft. below the bed of the river. On this floor a framework of 10 by 10-in. timber was placed which, in turn, supported a 10-ft. deep box, 10 ft. above the floor, filled with sand. Along the up-stream margin of the floor a box-like structure, 5 ft. high, filled with rock was provided, thereby creating a drop of 5 ft. from river to gate floor. The regulating gates moved between timbers which rose from the down-stream edge of this box and gave support to the head-wall of the main sand-box. The over-all length of this structure was 60 ft. The width between its side walls was 23 ft. When last seen by the writer, after it had been in service more than 20 years, it was still in good condition.

DISCUSSION

E. S. LINDLEY,* M. AM. SOC. C. E. (by letter).—The account of the work given in this paper shows practice that differs in several respects from that followed in India. It seems worth while to describe the latter for comparison; but there is no intention of implying, without any knowledge of local conditions, that it would have been applicable in California.

The writer wishes to discuss two points namely, silt exclusion and building on a foundation of sand. The 500 000 cu. yd. per month reported removed by dredges are equivalent to 3 620 acre-ft. per year. Comparing that figure with the earlier estimate of 12 000 acre-ft. per year of silt admitted, and the later estimate of 14 000 acre-ft., with a maximum of 24 900 acre-ft. in one year, it is clear that dredging cannot compete with measures of silt exclusion. Even if as much silt were dredged in a year as was admitted, trouble would still be experienced at times. Under Panjab conditions of river flow, probably about three-quarters of the total silt of the year passes in the four worst months (a flood season when Himalayan snows melt and are supplemented by monsoon rainfall).

The new Rockwood Gate was designed "so that mainly surface water would enter the canal". The design seems to have followed the common tacit assumption that provision of a high sill excludes from the regulator any water which flows in the parent channel lower than the plane of the sill. If the matter is regarded from the point of view of the draw or suck exercised by the offtake at different points in the cross-section of the parent channel, it will be realized that the cleavage between the water taken in and that passed on, is vertical and not horizontal; and that, except for the behavior of the heaviest particles in a vertical current, a high sill admits the same silt as an under-shot gate, because it does not change this cleavage.

Investigation is now showing that the cleavage is sensibly vertical over the greater part of the depth in the parent channel; but near the bed, where forward velocities are lowest and silt conditions are worst, flow to the offtake comes from a greater width, to a degree considerably more than would ordinarily be expected. A side offtake, therefore, must draw a large share of the more silty water to the exclusion of cleaner surface water.

The author refers to local observations showing that the bottom water contains the most silt. If sampling could be carried close to the bed without disturbing the bed itself, the water would be found to be even dirtier than stated.

Observations at other places have shown, not only that the average silt charge is greater at the bottom than near the surface, but that this concentration is greater in the coarser grades of the silt carried. Heavy silt is absent from the surface water, and the heaviest is confined to the bottom water, unless the current is turbulent. Viewed in the light of these considerations, it can be understood that a side offtake is a selector of silt, or the opposite of a

* Superintending Engr., Indian Public Works Dept., Panjab Irrig. Branch; Wotton-under-Edge, Gloucester, England.

filter. In developing the design of offtakes intended for silt exclusion from this point of view, the object is to secure the utmost concentration of silt in parts of the approaching current which are then excluded. The first step involves conducting the flow of the parent channel for a sufficient distance in a smooth channel, at a velocity that just avoids depositing silt on the bed, and also avoids eddies and boils as much as possible.

For the second step, a device that is applicable in some cases, consists of smoothly curved vanes on the bed, which guide the dirty water away from the offtake, give the whole current a twist, and thus also bring it clean water on the surface. This device first suggested by Mr. H. W. King, of the Panjab Irrigation Department,* is thus the opposite to that used by Benjamin F. Groat, M. Am. Soc. C. E., to exclude ice.†

Another suggestion, applicable on a large scale, is due to the late Mr. F. V. Elsden, of the Panjab Irrigation Department. For a new work he would build a regulator in two stories across the parent channel, in the position of the under-sluices of a Panjab head-works. The gates of the lower story would escape dirty bottom water down the river, while those of the upper story would take the cleaner upper flow to be conducted away in the canal.‡

A plain high and long sill also has some effect in excluding the coarsest silt, without affecting the plane of cleavage of the parent channel. Any given grade of silt could approximately be excluded if the flow had nowhere an upward vertical velocity exceeding its rate of settlement in still water. This presupposes prevention of eddies to stir up the bottom silt or cause local upward currents, and a slight current along the face of the sill to prevent the excluded silt from banking up there until it all enters again.

Referring to the second point for discussion, when a work is built on a pervious foundation to head up water, and without a cut-off to an impervious stratum, the difference of head causes flow through all the pervious medium, and there is a regular drop of head along any stream line. *Prima facie,* it might be expected that the easiest path (along which the greatest flow occurs) would be the shortest; that is, the envelope embracing the work and cutting off any re-entrant angles. However, observation of static pressures under such works has shown that distances in which equal falls of pressure occur should be measured along the "line of creep", or junction between the work and foundation, along both vertical and horizontal lines. The weight of the work must exceed the total upward pressures indicated by the line of hydraulic gradient thus drawn. According as to whether or not the work is tied together by reinforcement, the weight must be suitably distributed for stability, or must be sufficient from point to point.

The shorter the line of creep the steeper the gradient and the greater the velocity of flow. For any given material there is a limiting velocity which must not be exceeded to avoid sand being blown at the toe of the work, with consequent piping. In that material such a velocity will be caused by a certain gradient, which is the (maximum) limiting gradient for that material. There-

† *Transactions,* Am. Soc. C. E., Vol. LXXXII (1918), p. 1138.

‡ Panjab Irrig. Branch, *Paper No. 25.*

fore, with a given heading up, this gradient gives the minimum length of line of creep for the work. To exceed that length would add unnecessarily to the dimensions of the work and the weight required to balance upward pressures.

The limiting gradient for the sandy beds of Panjab rivers about 50 miles from their emergence from the foot-hills is generally taken as 1 in 15. In the finer loam of the plains between rivers, a gradient of 1 in 4 is used, but for finer pure sand it is flatter than 1 in 15. The length of the line of creep under the Rockwood Gate is about 80 ft. With the canal empty, the maximum head would be nearly 11½ ft., which would give a gradient of 1 in 7. The gradient for the Chowchilla regulator would seem to be about 1 in 6. As the sand is described as very fine and free of clay, these works seem very short, on these data and judged by this criterion. With a given length of line of creep, if the gates are moved down stream a greater part of the work has water at full depth standing on it, leaving a smaller part of the upward pressures to be balanced by the weight of the work. Therefore, it is economical to provide an impervious up-stream apron, especially as it is generally desirable to protect the bed against scour, and to have a smooth floor, thereby causing less eddying and less raising of silt in the stream.

C. E. GRUNSKY,* PAST-PRESIDENT, AM. SOC. C. E. (by letter).—Several points of importance in connection with the planning of offtake structures from silt-laden streams are brought out by Mr. Lindley. He states that it is not only water from the top of the stream that will go out over the top of flash-board gates, but water from all depths. In this he is quite right, but when the over-falling sheet of water is generally less than a foot in depth and the approaching water, or rather the water flowing along the face of the offtake structure, has various depths up to 20 ft. or more, it is only reasonable to assume that some advantage will result from the over-fall system. Furthermore, the sand or silt moving by saltation close to the bottom, which should be classed as bed-load, and the sand which actually rolls along the bottom, are excluded by the system.

As stated by Mr. Lindley, there is, undoubtedly, some flow of water through the sands under the Rockwood Gate, but the gradient from the water surface in the river to that in the canal is not as steep as he has assumed. There is a regulator in the canal about 1½ miles below the Rockwood Gate and the drop from the river to the canal is controlled by this regulator. There is no definite information at hand as to the allowable maximum, but ordinarily the drop is only a fraction of 11½ ft., which is the amount introduced into the calculation by Mr. Lindley. This value (11½ ft.) should be regarded as a possibility only when the canal is out of commission during fairly high water —a condition which it is thought will never obtain.

Paper No. 1704

THE SCIENCE OF FOUNDATIONS—ITS PRESENT AND FUTURE*

By Charles Terzaghi,† M. Am. Soc. C. E.

With Discussion by Messrs. Charles R. Gow, E. P. Goodrich, Victor A. Endersby, George Paaswell, C. C. Williams, Herbert Chatley, J. Albert Holmes, Jacob Feld, W. S. Housel, Frank S. Bailey, T. L. Condron, Lazarus White, R. D. N. Simham, Frank A. Marston, Arthur M. Shaw, D. P. Krynine, S. P. Wing, M. L. Enger, Albert Jorgensen, and Charles Terzaghi.

Synopsis

The paper reviews the present state of the science of foundations, its principal shortcomings, and the possibilities for its improvement.

The principal shortcomings were found to be: First, the practice of selecting the admissible soil pressure regardless of the area covered by the individual foundations and irrespective of the maximum differential settlement that the superstructure can stand without injury; second, the practice of computing the bearing capacity of the piles by the *Engineering News* formula regardless of the character of the soil; and, third, the practice of considering the bearing power of the individual piles as a sufficient guaranty that the bearing capacity of the entire foundation will be adequate.

In his discussion of these topics the writer tries to explain the reasons for the inconsistencies that are often experienced in attempts to interpret the results of loading tests for designing purposes. Concerning the pile-driving formulas the writer presents physical arguments why, for certain soils, no pile-driving formula can possibly furnish reliable information concerning the bearing capacity of the tested pile. For those soils for which the

* Presented at the meeting of the Structural Division, New York, N. Y., January 20, 1927.

† Prof., Foundation Eng., Mass. Inst. Tech. Cambridge, Mass.

pile-driving formulas can be used to advantage, the *Engineering News* formula is found to furnish values which are by far too small, provided a drop-hammer is used and the penetration per blow amounts to less than ½ in.

Progress in the field of foundation engineering is handicapped essentially by the absence of reliable information concerning previous construction experience. Again, the lack of reliable information is due to inadequate description of the soils and to an interpretation of the observed facts which, in many cases, is inconsistent with the laws of physics and mechanics. The first step toward improving conditions should consist in establishing an adequate soil classification.

Thus far, related efforts have failed, because they represented attempts to classify the soils according to properties that have no bearing at all, or no well-defined bearing, on the behavior of the soil under load.

The writer presents a list of those soil properties that determine the character, the amount, and the speed of the settlements. He shows how the knowledge of these properties can be utilized for establishing a soil classification suited for its purpose and briefly discusses the difficulties associated with such an attempt.

The problems of foundation engineering are as inseparably associated with the problems of structural engineering, as is the shadow with the light, because one cannot conceive of a structure without a foundation. Therefore, they are among the most vital.

Effect of Type of Building on Admissible Settlement

Suppose it is desired to construct a reinforced concrete building on a lot selected and bought by the future owner. After inspecting the ground in the light of previous experience, it is decided to dispense with piles and put the building on individual spread footings. The mental operation leading to this decision is experienced almost daily, and is familiar to every engineer. This apparently simple decision may be analyzed by common sense. By spreading the weight of the building over the base of sufficiently large footings, the pressure can be reduced to a certain value, q, per unit of area. Under the influence of the pressure, q, the footings will settle through a distance, S. Perfectly uniform settlement will not hurt the building. However, because of the variations in the distribution of the live load, the pressure may vary between q and $0.8\ q$ (to name an arbitrary figure) which corresponds to a difference in settlement between S and $0.8\ S$. In addition, it may be that the compressibility of the ground varies to such an extent, that the settlement produced by a load, q, may range between S and $0.5\ S$ (which, again, is an arbitrarily selected figure, the actual value depending on circumstances). Hence, a difference, amounting to as much as $S - 0.5 \times 0.8\ S = 0.6\ S = H$, may be expected between the settlement of the individual footings. In the formula,

$$H = S - 0.5 \times 0.8\ S = 0.6\ S = n\ S \ldots\ldots\ldots\ldots\ldots (1)$$

the factor, n, represents the numerical effect of both the variations in live load and the variations in the compressibility of the soil. The value, H, will rule

all further considerations. If the building is statically determinate a value of several inches for H would be permissible. On the other hand, if it is statically indeterminate, the allowable intensity of the secondary stresses must be selected first. Consider, for example, that an increase of 15% in certain maximum bending moments would be admissible. Then, the maximum value, H, for the difference in settlements is at once determined. It may range between 0.1 in. and 1.0 or 2.0 in., according to the character of the building, the distance between the columns, and the cross-section of the beams. Hence, the decision to admit an increase of 15% in the dangerous stresses, would require selecting the soil pressure, q, anywhere between limits as far apart as 1 and 10 or 20, according to the character of the building. Selecting the value, q, on the other hand, irrespective of the structural characteristics of the building, would mean either ultra-conservative wastefulness or danger, according to the circumstances. Since this is done in most of the cases dealt with in actual practice, one cannot help feeling the necessity of a thorough reform. Every foundation design ought to be started by roughly computing the maximum admissible value of H.

Relation Between Settlement, Size of Loaded Area, and Depth of Foundation

The second inconsistency that confronts the foundation engineer daily, concerns the relation between the settlement, S, and the diameter of the loaded area. In selecting the admissible unit soil pressure, should the width and the length of the loaded area be taken into consideration? Consider, as an example, that some one makes a bending test on a 10-in. by 10-ft. I-beam, freely supported at both ends, and finds that the beam breaks under the influence of a concentrated load of P-tons. He publishes the results of his test, and as a consequence, in future practice, the designers would consider a load of $\frac{1}{4}$ P as a safe load for the beam, irrespective of the span and mode of support. In the light of present knowledge, such procedure would be considered simply absurd. However, in the field of foundation engineering it corresponds precisely to what is actually done. The safety of the building depends on H ($= 0.6\ S$) not exceeding a definite value. The value of S depends as essentially on the diameter of the loaded area and on the depth of the foundation as the load causing the rupture of the I-beam depends on the span. Nevertheless, all tables of admissible soil pressures, given in textbooks and building codes, contain the values without any indication as to what areas and to what depths of foundation they apply. They can well be compared with tables containing the loads under which I-beams of different cross-sections broke down, without mentioning the distance between supports.

The rather indifferent attitude of practising foundation engineers toward the important influence of these two items—the dimensions of the loaded area and the depth of foundation—is essentially due to the apparent inconsistencies of related experiences which seem to contradict each other, to such an extent that an attempt to digest them appears to be hopeless. However, by analyzing them and correlating them with present theoretical knowledge, one finds that they already represent a fund of most useful information, and

that the apparent contradictions do not exist. The following facts may serve to illustrate these statements.

In 1916, the Foundation Committee of the Austrian Society of Engineers and Architects, in Vienna, made a series of loading tests for the purpose of investigating the influence of the shape and size of the loaded area on the amount of settlement in a typical cohesive Vienna soil (a variety of loess).* The tests were performed on the bottom of a trench, 10 ft. deep and 5.75 ft. wide, protected by a roof. The loaded soil consisted, according to a statement issued by the investigators, of 27% of sand with grains larger than 0.2 mm., 31% of sand with grains less than 0.2 mm., and 42% of very fine-grained constituents. The water content was said to range between 11.2 and 13.2 per cent. When moulded into cubes and dried, the soil developed a cube strength of about 35 tons per sq. ft. The tests included load settlement, time settlement, and rebound observations on square and on round plates with areas of 0.053, 0.110, 0.672, 2.700, and 6.100 sq. ft. Fig. 1 shows some of the results obtained. They include the settlements of plates with different diameters under loads of 2 and of 4 tons per sq. ft., and the rebound of the soil

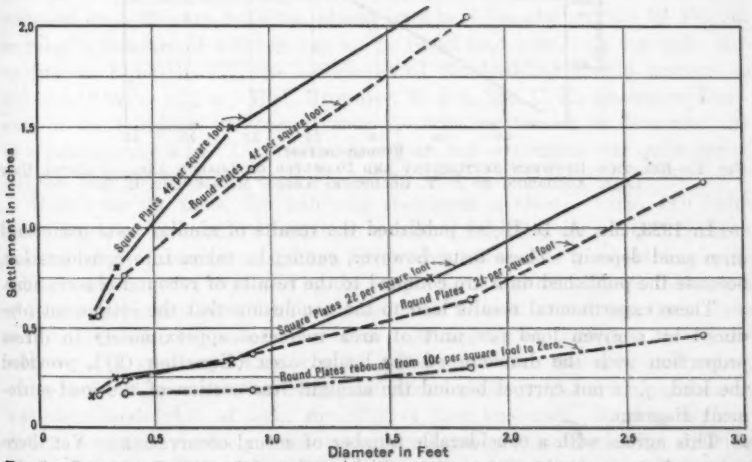

FIG. 1.—RELATION BETWEEN SETTLEMENT AND DIAMETER OF LOADED AREA FOR VIENNA LOESS AT EQUAL UNIT LOAD ACCORDING TO DR. FRITZ EMPERGER.

produced by removing a load of 10 tons per sq. ft. (Computed from the rebound, corresponding to the removal of smaller loads.) Fig. 1 plainly demonstrates that the settlement produced by a given load per unit of area increases almost in direct proportion with the diameter of the loaded area, or, in algebraic terms,

$$S = c \times d \times q \text{ (more or less)} \ldots\ldots\ldots\ldots (2)$$

* According to a manuscript, "Der Wiener Löss und seine zulässige Belastung," by Dr. Fritz Emperger, received in May, 1926. According to Dr. Emperger's letter of March 16, 1926, an extract of this paper has been published in *Die Bautechnik*, Berlin, *Le Genie Civil*, Paris, and *Gewappend Beton*, Amsterdam.

wherein, c is a constant of the soil. The shape of the upper set of curves is obviously due to the fact that the load-settlement curve for each one of the individual plates is, in itself, more or less parabolic.

A few years ago, A. T. Goldbeck, Assoc. M. Am. Soc. C. E., carried on some research work for the U. S. Bureau of Public Roads, on artificial mixtures of sand and clay for the purpose of investigating the relation between the area of a bearing block and the settlement produced by a given unit load.* The area of the bearing blocks ranged from a few square inches to 9 sq. ft. The results of the tests made on plastic mixtures were of the type shown in Fig. 2. They indicate, as do the Austrian tests, that for cohesive soils the penetration produced by a given unit load increases in direct proportion with the diameter of the loaded area.

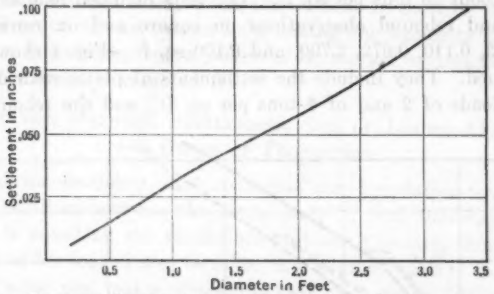

FIG. 2.—RELATION BETWEEN SETTLEMENT AND DIAMETER OF LOADED AREA AT EQUAL UNIT LOAD, ACCORDING TO A. T. GOLDBECK, ASSOC. M. AM. SOC. C. E.

In 1923, Mr. A. B. Bijls† published the results of similar tests performed on a sand deposit. These tests, however, cannot be taken into consideration, because the published data are confined to the results of rebound observations.

These experimental results lead to the conclusion that the settlement produced by a given load per unit of area increases approximately in direct proportion with the diameter of the loaded area (Equation (2)), provided the load, q, is not carried beyond the straight line section of the load-settlement diagram.

This agrees with a considerable number of actual observations. Yet there seem to be quite striking exceptions to this rule. A loading test was made by the Chicago Union Terminal Company, in Chicago, Ill., on two full-sized caissons, resting on the surface of a layer of hardpan, approximately 60 ft. below the surface of the ground.‡ The diameters of the bearing area were 4.3 ft. and 8.5 ft., respectively, and the settlements produced by a load of 10 tons per sq. ft. amounted to $\frac{1}{8}$ in. and $\frac{5}{8}$ in., respectively. Hence, although the larger diameter was equal to only twice the smaller, the settlement of the larger pier was five times greater than that of the smaller one. According to Equa-

† *Le Génie Civil*, May 26, 1923, p. 490. Abstract of a report by M. Wolterbeck to the Ministère des Travaux Publics des Pays Bas, 1922.

‡ *Journal*, Western Soc. of Engrs., February, 1924.

tion (2), it should not have been more than twice as large. This fact seems to indicate that the formula represents an optimistic statement.

On the other hand, experience shows that, under certain circumstances, the settlement of the larger area may be very much smaller than the value obtained by the formula. Numerous loading tests made on the plane surface of a natural bed of well-compacted sand, have shown that the settlement of a single bearing plate, with an area of 1 sq. ft., loaded with 3 tons, is never less than about ⅛ in. Hence, according to Equation (2), a foundation 20 ft. square, resting on a firm sand deposit, should settle 2½ in. under a load of 3 tons per sq. ft. Every engineer who has had experience with foundations on firm sand can testify that the settlement will be very much less, certainly not exceeding ½ in. In 1922, the Society's Special Committee on Bearing Value of Soils for Foundations, etc., published the results of loading tests performed on a building lot in San Francisco, Calif.* A stratum of soft, clean, or sticky sand, with occasional layers of sand clay and yellow clay was encountered. It was tested at eight different points. Under a load of 4 800 lb. per sq. ft., the settlement of the bearing plate ranged between 0.04 and 0.17 in., averaging 0.10 in. For the past few years the lot has been occupied by a 22-story building, placed on a raft foundation, 218 by 152 ft., exerting a pressure of 4 800 lb. per sq. ft. (dead load only)† on the soil. According to Equation (2), the settlement of the building should amount to 152×0.10 in. = 15.2 in. H. J. Brunnier, M. Am. Soc. C. E., Designing Engineer of the building, has found‡ that the total settlement to date amounts to approximately 2 in. During the first year, the settlement was quite rapid, but the rate has been less each succeeding year.

Reviewing the facts, the following statement is clear: First, two independent sets of experiments have been quoted concerning the relation between the size of the loaded area and the settlement. Both sets have led to practically the same result, expressed by the simple Equation (2). Then, the results of these experiments have been compared with those of two observations made on a large scale. In one of these cases (Chicago Union Terminal tests), the settlement of the larger area was 2.5 times more than the computed value; while in the other case (San Francisco office building), the actual settlement was about one-eighth of what should have been expected. Suppose a foundation company sincerely tries to obtain some reliable basis for drawing conclusions from the results of its loading tests. The engineers of the firm make their observations year by year, accumulate the data in their files, and, finally, when they try to correlate the data, they face grotesque contradictions of the type quoted. They cannot be blamed if they give it up in disgust, loading tests, observations, and all. However, if they would examine the data in the light of applied mechanics, they would first realize the following facts, which the writer published§ in 1925:

* *Proceedings*, Am. Soc. C. E., March, 1922, Papers and Discussions, p. 529, Plate VII.

† "Continuous Mat Foundation for 22-Story Building," *Engineering News-Record*, July, 1922, pp. 73 *et seq.*

‡ By letter of December 4, 1925, to Maj. W. A. Danielson.

§ "Erdbaumechanik," by Charles Terzaghi, M. Am. Soc. C. E., Franz Deuticke, Wien, 1925.

(*a*) The relation between the diameter of the loaded area and the settlement produced by a given unit load depends essentially on the cohesion (actual shearing strength) of the soil. For soils with great cohesion the settlement produced by a given unit load increases in direct proportion with the diameter of the loaded area. On the other hand, for perfectly cohesionless soils, the size of the area has very little effect.

(*b*) With increasing depth of foundation, the settlement produced by a given unit load decreases. However, the ratio between the settlement, S_0, for a foundation depth of 0, and the corresponding settlement, S, for a depth, t, does not depend on the value of t alone, but on the ratio, $\frac{t}{d}$, between the depth of foundation and the diameter of the loaded area. Thus, if a foundation 5 ft. deep was found to reduce the settlement of a footing, 5 ft. square, by 50% of S_0, the effect of a footing 10 ft. square, and 5 ft. deep, in reducing settlement, will be very much less. In order that the potential settlement, S_0, of a footing 10 ft. square, and 0 ft. deep, may be reduced 50%, the depth would have to be increased to 10 ft., thus making the ratio, $\frac{t}{d}$, for both cases equal.

(*c*) The effect of the ratio, $\frac{t}{d}$, on the settlement is the less, the greater the cohesion. For perfectly cohesionless materials, a ratio of $\frac{t}{d} = 1$ (depth of foundation = diameter of loaded area) almost triples the bearing capacity and reduces the settlements to one-third of what they would be if the footing rested on the surface of the ground.

Knowing nothing more about soil mechanics than these three simple rules, the foundation engineer would at once discover that there are no contradictions in the data hereinbefore quoted. The experiments of the Austrian Committee and of Mr. Goldbeck were made on very cohesive soils. Hence, in strict agreement with theory, they showed that the settlement increases in direct proportion with the diameter of the loaded area. The Chicago tests were made on a cohesive soil, but the ratio between the depth of foundation and the diameter of the loaded area was twice as great for the larger area as for the smaller one. That fully accounts for the difference between the computed and the actual value of the settlement of the larger area. On the other hand, the soil of San Francisco belongs to the class of very slightly cohesive soils and, according to Rule (*a*), which is supported by experience, the size of the area should have comparatively little effect on the settlement.

Thus, if it combines actual observation with proper soil investigation and with a thorough consideration of the mechanical aspects of its problems, the same firm that gave up the attempt of systematic study in disgust, could gradually build up an experience covering the whole range of its activities and acquire a fairly reliable basis for the interpretation of the results of loading tests. However, under the present system of interpretation, loading tests are practically good for nothing.

Distribution of Soil Reactions Over Rigid, Loaded Slabs

The preceding discussion deals exclusively with the potential settlement of structures without questioning the stresses that may develop within the foundation. As a matter of fact, when referred to individual spread footings, these questions are of minor importance. However, the situation changes when it becomes necessary to connect the footings with each other, replacing the group of footings by a continuous mat. In order to keep the costs of such a mat within reasonable limits, the stresses must be computed as closely as possible. It is first necessary, however, to know the forces acting on the mat, and this is where difficulties arise. Suppose the mat is rectangular, and the dead load of the structure is distributed in such a manner that the resultant force passes through the center of gravity of the mat. Under such conditions, it is generally assumed, that the soil pressures are uniformly distributed over the entire area. However, according to the measurements carried out by M. L. Enger, M. Am. Soc. C. E., the distribution of the soil reactions over the base of a rigid slab is by no means uniform.* The pressures are equal to zero at the edge of the slab and greatest at the center, the pressure curve having a parabolic shape. In order to show the effect of the difference between uniform and parabolic stress distribution, the diagram, Fig. 3, has been plotted, showing the bending moments in a mat, loaded by four walls,

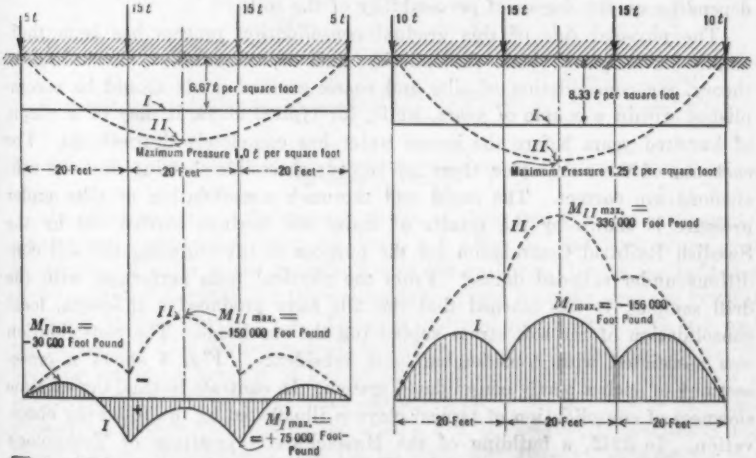

Fig. 3.—Bending Moments in Rectangular, Perfectly Rigid Slab for (I) Uniform and (II) Parabolic Distribution of the Soil Reaction.

and supported by a homogeneous soil. For a parabolic stress distribution the maximum bending moments will be about 100% greater than they are for a uniform reaction. Thus far, all attempts to deal theoretically with the problem of stress distribution have failed, and there is little hope for success within the near future. The data obtained by Professor Enger are confined

* "The Distribution of Pressure by Granular Material," *Engineering*, Vol. 101, 1916, p. 170.

strictly to perfectly cohesionless materials; hence, the information they furnish is not yet conclusive. Considering the importance of the possible error involved in assuming uniform stress distribution, the need of a more exhaustive experimental investigation of this phase of the foundation problem becomes obvious.

Effect of Degree of Permeability and of Time on Settlements

Another interesting aspect of the foundation problem concerns the changes that will take place in the soil under pressure. Since every soil, without exception, is compressible, the pressure tends to produce a decrease in volume. If the voids of the soil are filled with air, the volume change can take place at once, because the excess air can readily escape toward the surface. On the other hand, if the voids are completely filled with water, which is usually the case with very fine-grained and very compressible soils (silts, mud, clay), a decrease in volume obviously involves a considerable decrease in the water content, and the compression cannot possibly proceed with a greater speed than the corresponding speed of squeezing out the excess water. The less permeable the soil, the more slowly the water escapes, and, as a consequence, the more slowly the volume of the compressed soil decreases. Hence, the settlement of the foundation will not occur at once. There will be a lag, depending on the degree of permeability of the soil.

The physical side of this gradual consolidation process has been thoroughly investigated, both theoretically and experimentally. According to theory, the consolidation of silts and coarse-grained muds should be accomplished within a couple of years, while, for typical clays, it may be a couple of hundred years before the excess water has completely drained out. For each one of these examples, there are records accessible showing that the conclusions are correct. The rapid and thorough consolidation of silts under pressure is shown by the results of many test borings carried out by the Swedish Railroad Commission for the purpose of investigating the soil conditions under railroad dams.* From the physical tests performed with the drill samples, it was learned that the fills have produced a thorough, local consolidation of the soft strata supporting the surcharge. The consolidation was associated with considerable local subsidence. Fig. 4 shows a cross-section† of such a partly consolidated system. In contrast to this, the extreme slowness of consolidation of typical clays is illustrated by the following observation. In 1915, a building of the Massachusetts Institute of Technology was erected on a 30-ft. layer of sand, silt, and fill, resting on a soft clay deposit. The pressure exerted by the building on the clay amounts to approximately 1 500 lb. per sq. ft. In 1926, a test boring was made next to the heaviest section of the building. Physical examination of the drill samples disclosed the fact that the consolidation of the clay deposit had hardly started. A similar observation was published in 1923 by Thaddeus Merriman, M. Am. Soc. C. E., concerning the behavior of a mass of puddled clay forming part

* Statens Järnvägars Geotekniska Kommission, 1914–22, Stockholm, May, 1922.
† Copied from Statens Järnvägars Geotekniska Kommission, 1914-22.

of an embankment on the Ashokan Reservoir, Catskill Water Supply.* The surface of the puddled clay deposit, confined between the core-wall and the up-stream slope of the core ditch, carries the weight of an embankment 85 ft. high. Nevertheless, nine years after the construction of the embankment, a test boring disclosed the fact that the clay core was practically in its original condition.

The study of these and similar facts has led to the recognition of two essentially different types of settlements:

(*a*) Those due mostly to lateral flow, with very little, or no, consolidation; and,

(*b*) Those due to consolidation and lateral flow combined.

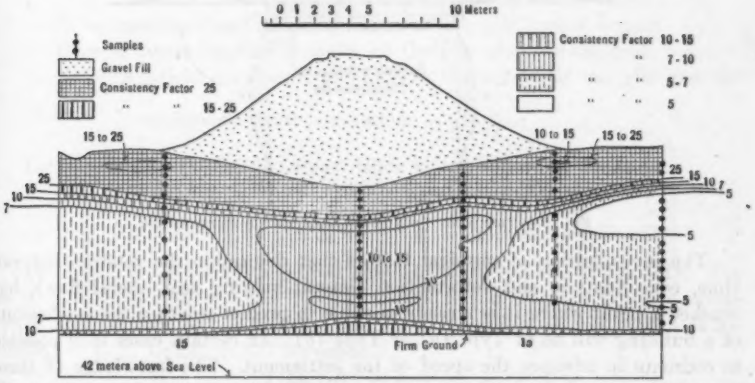

FIG. 4.—CONSISTENCY FACTORS OF SOIL DIRECTLY UNDER AND ON THE SIDE OF THE BANK AT SMEDSERÖD, SWEDEN.

In order to explain the characteristics of these two types of settlements, assume that two vertical reference lines, *a b* (Fig. 5), had been established in the ground, prior to the construction of the building. Under the influence of the weight of the building the soil tends to spread laterally, and the vertical lines, *a b*, become Curves *a c b*. The area included between the lines, *a b*, and the curves, *a b c*, is obviously equal to the area, $a\ a\ a_1\ a_1$, through which the building settles on account of lateral soil displacement. If, on account of a low permeability of the ground, the consolidation of the soil due to increased pressures, proceeds very slowly, the area, $a\ a\ a_1\ a_1$, represents practically the entire vertical displacement that the building will undergo, at least for one generation. The speed of the settlement will be governed exclusively by the laws of viscous flow in plastic materials, and if the flow is successfully stopped by driving deep sheet-piling, or by similar measures, the settlement of the building will be practically stopped. Those are the characteristics of Type (*a*) settlements.

On the other hand, if the material is permeable enough to release its excess water within a couple of years, the settlement of the building will consist of

* Discussion of the paper entitled "Design of Earth Dams," by Joel D. Justin, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1924), p. 109.

two different parts, namely, the settlement through a space, $a\ a\ a_1\ a_1$, due to lateral bulging; and a settlement through an additional space, $a_1\ a_1\ a_2\ a_2$, due to compression of the soil beneath the loaded area. In this case the speed of the settlement will be governed by two essentially different laws: (1) Viscous flow in plastic materials; and (2) hydrodynamic stress compensation; which the writer formulated several years ago.* By artificially preventing the lateral flow of the material, one could somewhat reduce the settlements of the building, but one could not possibly prevent them. Those are the characteristics of Type (*b*) settlements.

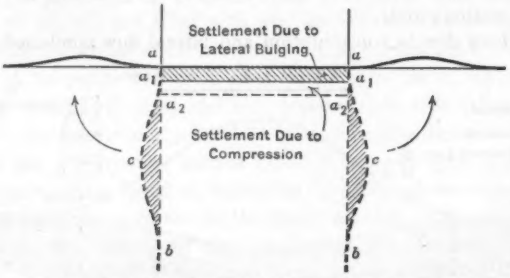

FIG. 5.—THE TWO PRINCIPAL SOURCES OF SETTLEMENT.

The investigation of physical factors that determine the relation between time, consolidation, and deformation (lateral bulging and lateral flow), has reached a point where it is already possible to predict whether the settlements of a building will be of Type (*a*) or Type (*b*). In certain cases it is possible to estimate in advance the speed of the settlement. The knowledge of these factors is particularly useful in all cases where the engineer faces the problem of reducing or stopping the settlement of an existing building.

BEARING CAPACITY OF INDIVIDUAL PILES

At the beginning of this paper it was assumed, that the engineer trusted with the design of a building, decided to erect it on spread footings. Let it now be assumed that his decision was premature. Suppose that test borings made after the first inspection of the building lot revealed the fact that the solid top layer of soil rested on a deposit of soft silt of such a thickness that there was no chance to carry the foundations down to solid ground. Then the engineer decided to put the foundations on piles. In order to find out how many piles he needed, he was obliged to drive a couple of test piles and determine the amount of load one individual pile could stand (unless he had previously tested some piles driven into similar deposits). To follow the traditional procedure, one must observe the average penetration of the pile under the last ten blows; compute the bearing capacity of the pile by the *Engineering News* formula; and divide the total weight of the building by the bearing capacity of the individual pile. This practice rests on two assumptions: (1) That the bearing capacity of a pile can be computed from

*"Die Theorie der Hydrodynamischen Spannungserscheinungen und ihr erdbautechnisches Anwendungsgebiet," *Proceedings*, International Congress for Applied Mechanics, Delft, Holland, 1924.

the effect of the blow; and (2) that the bearing capacity of the complete foundation is equal to the sum of the bearing capacities of the individual piles. To examine Assumption (1), let,

R = weight of the hammer.
G = weight of the pile.
L = length of the pile.
F = area of the cross-section of the pile.
E = modulus of elasticity of the pile material.
h = distance the hammer drops.
s = penetration produced by one blow.
m = coefficient of elasticity of the impact; $m = 0$ for perfectly non-elastic impact; and $m = 1$ for perfectly elastic impact.
Q_d = resistance against penetration of the pile, under impact.
Q = ultimate bearing capacity of the pile under static load.
C = empirical constant depending on the nature of the pile and the

$$\text{resistance against penetration} = \frac{Q_d L}{2 F E}$$

The theory of semi-elastic impact leads to the following equation:

$$Q_d = \frac{F}{L} E \left[-s \pm \sqrt{s^2 + \frac{2 R h}{E} \frac{R + m^2 G}{R + G} \frac{L}{F}} \right] \quad \ldots\ldots\ldots\ldots (3)$$

The value, m, is usually assumed equal to 0.5 (semi-elastic impact). For $m = 0$, the equation becomes Redtenbacher's formula, which is quite extensively used in Europe.* On the other hand, if perfect elastic impact is assumed, $m = 1$, Equation (3) becomes,

$$R h = Q_d s + \frac{1}{2} \frac{Q_d^2}{F} \frac{L}{E} = Q_d \left(s + \frac{1}{2} \frac{Q_d}{F} \frac{L}{E} \right) \quad \ldots\ldots\ldots\ldots (4)$$

or,

$$Q_d = \frac{R h}{s + \frac{1}{2} \frac{Q_d}{F} \frac{L}{E}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

If the fact that the term, $\frac{1}{2} \frac{Q_d}{F} \frac{L}{E}$, depending on both the nature of the pile and the resistance against penetration, is disregarded, and if this variable term is replaced by an empirical constant, C, independent of all these factors,

$$Q_d = \frac{R h}{s + C} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

which is none other than the well-known *Engineering News* formula.

From a mechanical point of view, the assumptions on which these formulas are based, are sound, and there is not much doubt about their giving a fairly accurate conception of the resistance one has to overcome while driving the pile by a succession of impacts. Therefore, if experience shows that in certain cases the values furnished by the pile-driving formulas have practically

* "Formeln und Versuche über die Tragfähigkeit eingerammter Pfähle," by Ph. Krapf, Leipzig, 1906.

nothing in common with those determined by loading tests, being either far too small or far too large, the cause cannot be a defect in the formulas, but must be due to the fact that in these particular instances the forces, Q_d, resisting the penetration of the pile under impact, are fundamentally different from the forces, Q, which resist the penetration of the pile under static load.

This is precisely the situation a theoretical study of the pile-driving phenomenon has disclosed. It is known that the bearing capacity of piles depends on two different factors, namely, the frictional resistance acting along the sides of the piles, and the point resistance, or the resistance of the soil against being compressed and displaced by the pile. If these two resistances were dependent only on the character of the ground and on nothing else there could be no question about the resistance, Q_d, against driving the pile, and the bearing capacity, Q, of the pile, being identical. However, it is easy to prove that either one of them may be very different according to whether the pile is slowly forced down or driven by impact.

If a friction test is made on a layer of sand, by loading it and then measuring its resistance against shear, it is found that the shearing resistance of the loaded layer, immediately after the application of the load, is practically the same as it is three days later. If, however, precisely the same test is performed with a layer of clay immersed in water, it is found that immediately after application of the load the frictional resistance is very small, so small indeed that one has the impression that the material is lubricated. The full frictional resistance does not develop for a couple of days. If a laterally confined mass of sand is compressed, the speed with which the compression is performed has very little influence on the amount of work required to compress the material. On the other hand, the amount of work required for rapidly reducing the volume of 1 cu. ft. of laterally confined clay by 2 cu. in. may be 100 times as great as the amount of work required for producing the same volume change slowly. The physical causes of these phenomena are clearly understood. The writer has called them the hydrodynamic stress phenomena. They inevitably develop as a result of rapid application of loads or pressures on water-soaked materials with a low degree of permeability.* The theory has been repeatedly checked by experiment.

Applied to the mechanics of pile-driving, knowledge of the hydrodynamic stress phenomena has led to classifying soils in two main types. In certain materials (particularly in sand, gravel, and permeable artificial fills), the resistances acting while the pile is being driven, are practically identical with those acting on the pile under static load. Under such conditions the pile-driving formulas can be expected to furnish results of sufficient accuracy.

In other materials (very fine-grained silts, soft clays, etc.), the friction acting on the pile during the driving (hydrodynamic pile friction) is very much less than that which develops after a couple of days' rest (static pile friction), while the resistance of the point of the pile under impact (dynamic point resistance) is very much greater than its resistance under static load (static point resistance). Due to these facts the total resistance against penetration of the pile into such materials is:

* "Erdbaumechanik," by Charles Terzaghi, Wien, 1925.

(1) Dynamic resistance (resistance, Q_d, against penetration under impact), which is the sum of a very small frictional resistance (dynamic pile friction) and a very considerable point resistance (dynamic point resistance).

(2) Static resistance (ultimate bearing capacity, Q, under static load), which is the sum of a full frictional resistance (static pile friction) and a very small point resistance (static point resistance).

Since the pile-driving formulas furnish the value, Q_d, there is no assurance whatsoever that for this class of materials the value, Q, may be of the same order of magnitude. The value, Q_d, may, by chance, be equal to Q, the deficiency in static friction being compensated by an excess in point resistance; but this condition is by no means necessary. It could as well be very much greater or very much less, depending on the material. The following analogy demonstrates the error committed when applying the pile-driving formulas to resistance against the penetration of piles in this second class of materials. Suppose that a body slides on a rail under water. In order to produce a slow forward movement of this body, the only resistance there is to overcome is the static friction between the body and the rail, the resistance of the water being negligible. On the other hand, in order to keep the body sliding rapidly along the rail, the only resistance that counts is the resistance of the water, which, in this case, may be very considerable, while the frictional resistance along the rail will practically be eliminated because of a film of water trapped between the rail and the sliding body. Application of a pile-driving formula to materials of the second class is no more logical than an attempt to identify the static resistance of the sliding body against being set in motion with its dynamic resistance acting while moving rapidly through a viscous medium.

The best way to distinguish whether a material belongs to the first or to the second class is that of comparing the penetration per blow immediately before and after a period of rest of at least 24 hours. If these two penetrations are identical, one can be quite sure that the material belongs in the first class, and that the pile-driving formulas can be expected to furnish fairly reliable results. However, for this case, experience seems to show that the formulas based on the theory of impact (Equation (3)), furnish far better results than the *Engineering News* formula.

In 1925, the writer investigated the bearing capacity of an artificial fill, consisting of residual soil (stones, sand, and earth mixed), at Pasha Liman, on the Asiatic shore of the Bosphorus. When an attempt to make test borings with a normal outfit failed, several test piles were driven, one of which was loaded to the limit of its bearing capacity. The pile-driver was of the drop-hammer type with a weight of 0.575 metric tons. Fig. 6 (*a*) shows the results of the loading test; Fig. 6(*b*) shows the resistance against penetration under impact computed by the *Engineering News* formula (dotted lines) (Equation (6)) and by the theory of semi-elastic impact (thin full drawn line) (Equation (3)). The two sets of values are not very different, because the penetrations were rather important (ranging between 1.0 and 1.4 in.), although the values obtained by the impact theory are nearer the ultimate bearing capacity determined by the loading tests.

However, with decreasing values of the penetration produced by the last blows, the error involved in the *Engineering News* formula rapidly increases. A rather striking example can be quoted from pile-driving in Germany. As a result of many years of experience, the foundation engineers of Berlin, Germany, have developed the following empirical rule for the sandy soil of that city: For a pile that penetrates less than 0.4 in. under the impact of a 1-ton hammer, dropping from an elevation of 3.3 ft., the safe bearing capacity ranges between 20 and 25 tons. If the *Engineering News* formula is applied to this case, the ultimate bearing capacity is found to be 28.2 tons, corresponding to an allowable load of $\frac{1}{6} \times 28.2$ tons $= 4.7$ tons! For the ultimate bearing capacity of the same pile, Redtenbacher's formula* furnishes a value ranging between 52.8 to 63.6 tons, which is very close to the actual ultimate bearing capacity of these piles. On the other hand, by driving a 90-ft. wooden pile to refusal with a 5 000-lb. steam hammer (2.8-ft. drop), the safe bearing value of the pile, according to the *Engineering News* formula, should be equal to 127 tons. This is even more than the ultimate bearing capacity

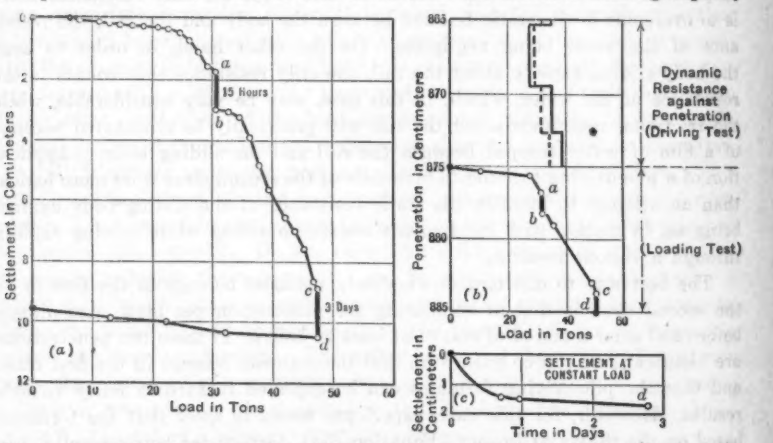

FIG. 6.—LOADING TEST PERFORMED ON TEST PILE IV ON APRIL 20–24, 1925, AT PASHA LIMAN, ASIA MINOR.

(92 tons) computed by Redtenbacher's formula. Thus, within the range of small penetrations, the defects of the *Engineering News* formula become strikingly apparent.

In connection with the pile tests performed in Pasha Liman, penetrations under the influence of a series of blows were observed, the hammer dropping from an elevation of 6.57 ft. (2 blows), 1.64 ft. (2 blows), 3.30 ft. (2 blows), 6.57 ft. (4 blows), and 9.83 ft. (4 blows). Fig. 7 shows the results of the observations. The points that correspond to a drop of the hammer of 6.57 ft. (200 cm.), 1.64 ft. (50 cm.), and 3.30 ft. (100 cm.), are located on a straight line. According to the theory of pile-driving by impact, this fact indicates that the resistance of the ground remained unchanged during the driving period.

* "Formeln und Versuche über die Tragfähigkeit eingerammter Pfähle," by Ph. Krapf. Leipzig, 1906.

Hence, for this period, a correct pile-driving formula ought to furnish identical values, irrespective of the height from which the hammer was dropped. Table 1 shows the values obtained by the *Engineering News* formula and the theory of semi-elastic impact, respectively. It demonstrates that for penetrations of less than 1 in., the *Engineering News* formula furnishes values that are by far too small, the error rapidly increasing with decreasing depth of penetration.

The obvious reason for this deficiency of the *Engineering News* formula is that the variable item, $\frac{1}{2}\frac{Q_d}{F}\frac{L}{E}$, (Equation (5)), forthcoming as a result of the theory of impact, has been replaced by a constant, C.

All these facts and data refer to typical materials of the first class, that is, to materials for which the pile-driving formula can be expected to furnish fairly reliable values. This conclusion was reached by observing, among other things, that the penetration produced by impact of a given intensity was practically the same before and after a period of rest.

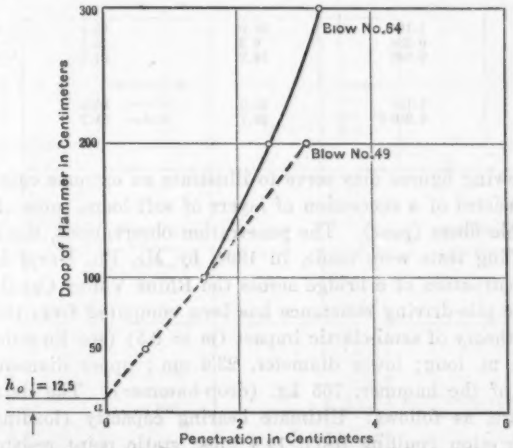

FIG. 7.—RELATION BETWEEN THE DROP, h, OF THE HAMMER AND THE CORRESPONDING PENETRATION, s, PRODUCED BY THE BLOW.

On the other hand, if the penetrations produced by a given impact before and after a period of rest are very different, the material belongs in the second class, and the values furnished by any pile-driving formula may be either equal to, very much larger than, or very much smaller than, the static bearing capacity of the pile.

Notice the physical processes associated with driving a pile into a material of the second class. Every blow of the hammer squeezes a certain quantity of water out of the soil beneath the point of the pile. The water escapes toward the surface through the space between the pile and the ground, and forms a film acting as a lubricant, just as any liquid does if trapped between two surfaces. Due to the presence of this film, the friction acting along the surface of the pile is very much less, whereas the force required to squeeze

the water rapidly out of the soil beneath the point of the pile is greater than that required to compress the same soil slowly. During a period of rest, the film of water is gradually absorbed by the soil and the full static pile friction develops. When pile-driving is resumed, one has to overcome both the static friction and the dynamic point resistance. However, during the same period of rest the annular space, serving as an outlet for the water squeezed out of the soil by impact, has closed. Hence, in certain kinds of soils, the dynamic point resistance acting after a period of rest may be much more than such resistance acting before the rest.

TABLE 1.—COMPARISON OF THE BEARING VALUE OF PILES.

Drop of hammer, in feet.	Penetration, in inches.	ULTIMATE BEARING CAPACITY, IN TONS, BY:		Remarks.
		Engineering News formula.	Semi-elastic impact theory.	
6.57	1.160	21.0	25.4	Should be equal
1.64	0.236	9.2	26.5	
3.30	0.590	14.2	24.6	
6.57	1.160	23.0	30.3	.....
9.83	1.280	29.7	35.2	.....

The following figures may serve to illustrate an extreme case of this type. The soil consisted of a succession of layers of soft loam, some of them mixed with vegetable fibers (peat). The penetration observations, the loading tests, and the pulling tests were made, in 1904, by Mr. Ph. Krapf in connection with the construction of a bridge across the Rhine Valley Canal in Austria.* The dynamic pile-driving resistance has been computed from the penetration data by the theory of semi-elastic impact ($m = 0.5$) (see Equation (3)). The pile was 8.4 m. long; lower diameter, 23.6 cm.; upper diameter, 33.3 cm.; and weight of the hammer, 765 kg. (drop-hammer). The data concerning this pile were, as follows: Ultimate bearing capacity (loading test), 17.2 tons; skin friction (pulling test), 14.4 tons; static point resistance, 17.2 — 14.4 tons = 2.8 tons; dynamic pile-driving resistance, computed from penetration after continuous driving, 20.0 tons; and dynamic pile-driving resistance, computed from penetration after a period of rest of 30 days, 80.0 tons.

In this case, by mere chance, the pile-driving formula applied to the effect of the hammer for continuous driving furnished a value close to the actual bearing capacity; while the value derived from the penetration after a period of rest was by far too great. In other cases, the second value is found to be closer to the actual bearing capacity. This may be learned from the customary practice of introducing into the *Engineering News* formula the values obtained after a period of rest.

Based on what is known about the physics of the penetration of a pile in the second class of material, the aforementioned data can be interpreted.

* "Formeln und Versuche über die Tragfähigkeit eingerammter Pfähle," by Ph. Krapf, Leipzig, 1906.

While continuously driving the pile into the ground, the skin friction is practically eliminated. Hence, the dynamic pile-driving resistance is practically equal to the dynamic point resistance; or, before the period of rest, the dynamic point resistance is 20.0 tons, as compared with 2.8 tons static point resistance.

After a 30-day period of rest, the hammer had to overcome the full static friction (17.2 tons) plus the dynamic point resistance (62.8 tons); or a total of 80 tons.

Fig. 8 represents this interpretation graphically. The shaded areas correspond to the pile friction acting during the pile-driving process (*a*); under impact after a period of rest (*b*); and under static load (*c*).

This and similar examples show that the application of any pile-driving formula to the bearing capacity of piles driven into the second class of materials is a gamble, trusting that the deficiency in skin friction associated with the driving of the pile may, by chance, be compensated by the corresponding excess in point resistance.

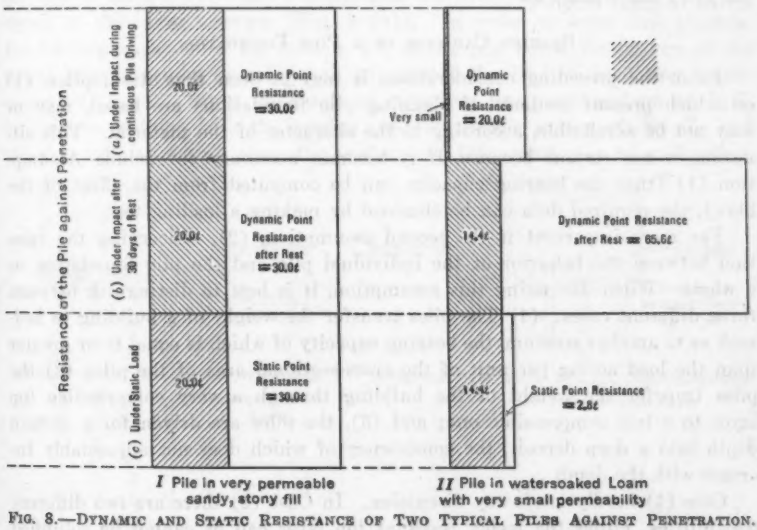

FIG. 8.—DYNAMIC AND STATIC RESISTANCE OF TWO TYPICAL PILES AGAINST PENETRATION.

Considering these facts it seems to be futile to attempt any further improvements in the field of pile-driving formulas. For materials of the first class, the pile-driving formulas were good enough even fifty years ago; while for materials of the second class, no reliable pile-driving formulas are possible at all, because the resistance against penetration of the piles under impact into such materials has physically nothing more in common with the static bearing capacity than has the static friction between solids (following the law of Coulomb) with the viscous resistance of liquids against rapid deformation (following the law of Newton). In the future, the penetration curve of piles, and particularly the difference between the rate of penetration before and

after a period of rest, may give more reliable information about the character of a ground of the second class than a test boring, but it never will give any reliable information about the bearing capacity of the piles.

Therefore, future investigations in the field of bearing capacity of piles should be directed toward studying the effect of the shape, thickness, and length on the bearing capacity of piles driven into different kinds of soils. In this connection attention should be called to the exhaustive investigations by the engineers of the Whangpoo Conservancy Board, in Shanghai, China. The tests included more than forty complete driving, loading, and pulling tests in soils the nature of which was previously investigated by test borings. The soil consisted principally of clay and silt, apparently belonging to the second class of materials. The tests furnished valuable information concerning the effect of the shape and length of the piles on the ultimate bearing capacity. Characteristically enough, the published reports do not contain any information on the penetration observations, for the reason that "the application of general pile-driving formulas to the local conditions has resulted in great errors".*

Bearing Capacity of a Pile Foundation

From the preceding considerations it may be seen that Assumption (1) on which present methods of planning pile foundations are based, may or may not be admissible, according to the character of the material. This situation is not serious because, if it becomes necessary to exclude Assumption (1) (that the bearing capacity can be computed from the effect of the blow), the required data can be obtained by making a loading test.

Far more important is the second assumption, (2), concerning the relation between the behavior of the individual pile and the pile foundation as a whole. When discussing this assumption, it is best to distinguish between three different cases: (1) The piles transfer the weight of a building to bedrock or to another stratum, the bearing capacity of which is equal to or greater than the load acting per unit of the cross-sectional area of the pile; (2) the piles transfer the weight of the building through a very compressible top layer to a less compressible one; and (3), the piles are driven for a certain depth into a deep deposit, the consistency of which does not appreciably increase with the depth.

Case (1) hardly needs any discussion. In Case (2) there are two different possibilities; either the feebly resistant top layer can or cannot be solidified by pile-driving. For instance, the average water content of the soft clay deposits in Boston, Mass., ranges between 30 and 40%, corresponding to a volume of voids ranging between 45 and 52%, filled with water. If piles are driven into a deposit of this kind, the surface of the clay rises between them through a height of several inches, which indicates that the volume of voids of the material remains practically unchanged. Pile-driving produces not only no consolidation of the deposit, but it even seems to cause the material to become softer. This last conclusion has been drawn from the observation

* Whangpoo Conservancy Board, S. H. T. Series 1, No. 7. Various reports to the Engineer-in-Chief on special investigation, Shanghai, 1921; report to the Engineer-in-Chief on pile tests.

that the compressive strength of an undisturbed sample of clay is always considerably greater than that of the same sample, with the same water content, after the sample has been moulded by external pressure. In striking contrast to this behavior of the deposits of blue clay stands the behavior of other very fine-grained deposits. Quite recently, when piles were driven into a deposit of exceedingly fine-grained saturated quicksand, the surface of the deposit subsided between the piles through a distance of almost 1 ft. Judging from previous experience, the original volume of voids of the material was certainly not greater than 45%, corresponding to the volume of voids of a clay with a water content of 30 per cent. Nevertheless, based upon the subsidence of the surface of the deposit, the pile-driving must have reduced the volume of voids by several per cent., which, in turn, involves a considerable increase in the bearing power and a decrease of the compressibility of the deposit.

In these two cases, the piles must serve two very different purposes if they are to be utilized to full advantage. In the first case, they should transfer the load to the more resistant sub-stratum, thus diverting the pressure from the upper to the lower stratum (Fig. 9 (*a*)). In order to serve this purpose, the bearing capacity of the section, *b c*, of the pile below the bottom of the upper layer must be great enough to support the load without any appreciable settlement. Since the result of a loading test performed on an individual pile includes both the bearing capacity of this section of the pile and the skin friction acting along the section, *a b*, this result may be misleading.

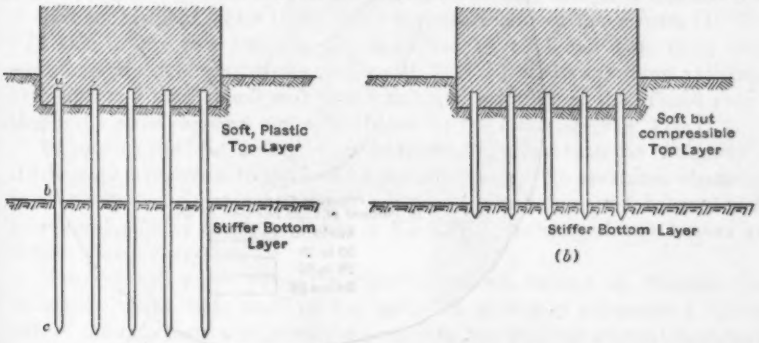

FIG. 9.—PILE FOUNDATION ON A TWO-LAYER SYSTEM.

Fig. 9 (*b*) represents the same combination of strata as Fig. 9 (*a*), with the only difference that the top layer is apt to be solidified (artificial fill, quicksand, etc.). In this case it may be more economical to use the piles merely for the purpose of increasing the bearing capacity of the top layer by pile-driving, letting the piles extend to the bottom of the top layer only. Here, again, the result of a loading test performed on an individual pile, prior to driving the others, would fail, by far, to furnish any reliable information concerning the number of piles required. What is needed is to learn about the effect of driving on the density of the surrounding soil. Deposits that can be consolidated by pile-driving belong almost exclusively to those

classes of material for which the pile-driving formulas are valid. The proper procedure would be to start with piles far apart and to drive intermediate piles until the bearing capacity, computed from the penetration, indicates the resistance of a well-consolidated ground.

In the third case (piles driven into the upper part of a very deep deposit with a fairly uniform consistency), the value of the piles may or may not be problematical, depending on the ratio between the width of the foundation and the length of the piles. Suppose that the pressure diagrams, Fig. 10 (*a*) and Fig. 10 (*b*), have been plotted. The left-hand sections of these diagrams show the distribution of soil pressures beneath two raft foundations with different widths, computed approximately by Boussinesq's theory. The right-hand sections of the same diagrams show the change in the stress distribution due to the presence of 20-ft. piles in the ground, computed by the same theory.

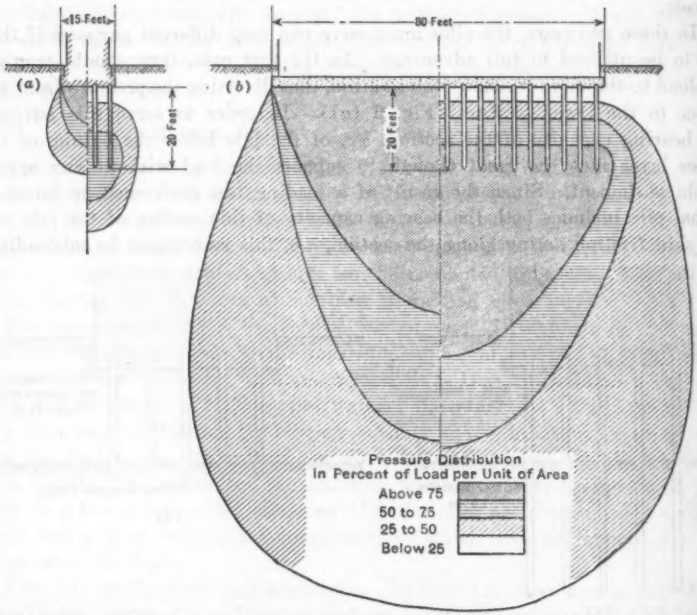

FIG. 10.—STRESS DISTRIBUTION BENEATH A NARROW (*a*) AND A WIDE (*b*) PILE FOUNDATION.

If the length of the piles is at least equal to the width of the base, their effect is obviously very beneficial (Fig. 10 (*a*)). The piles reduce the intensity of the maximum pressure acting on the ground, and, in addition, they shift the zone of maximum stress from the surface to the level where their lower ends are located. Since the effect of the depth of foundation on the bearing capacity of the ground depends, as previously noted, not on the depth, *t*, but on the ratio between the depth of foundation and its width, the effect of transferring the pressure to a deeper level, in the case of Fig. 10 (*a*), may be quite important. On the other hand, if the width of the foundation is considerably greater than the length of the piles (Fig. 10 (*b*)),

the pressure-reducing effect of the piles is very small and the ratio between the depth of foundation and the width of the structure is also very much smaller than in the case of Fig. 10 (*a*). Hence, the beneficial effect of the piles may be negligible and the money invested in them may represent an unwarranted expenditure. The reason piles are so generously used beneath raft foundations, in spite of the facts represented in Fig. 10, is that many engineers confound the bearing capacity of the individual piles with the bearing capacity of a score of them. Yet one can hardly conceive of a more obvious fallacy. The individual pile spreads the load over a wide area, thus reducing the specific soil pressure to a negligible item, while beneath a wide pile foundation, the soil pressure is just as great as it is under a simple raft foundation of equal width. In structural engineering such a procedure would correspond to considering that, since a bridge has stood the load of a single car without measurable deflection, it will stand the load of 200 cars, acting simultaneously.

Some years ago a company intended to construct a power house with a raft foundation supported by 500 reinforced concrete piles, 25 ft. long, because a similar building resting without piles on the same mud deposit had suffered a subsidence of more than 12 in. A loading test performed on an individual pile showed that a weight of 4 tons did not produce a measurable sinking of the pile. As a consequence, it was believed that, if a load of not more than 2 tons were assigned to each pile, no settlements would occur. After the mud deposit was investigated, the company was advised to sell the piles and construct a simple raft foundation, because conditions were similar to those shown in Fig. 10(*b*). However, as some of the piles were already driven, it was decided to drive all of them. Fig. 11(*a*) shows the settlements of the corners (I, IV, VII, X), of the new building (*a*) supported by piles and Fig. 11(*b*) the simultaneous settlements of the corners (*A, B, E, F*) of the adjoining building (*b*), supported by a simple raft foundation and exerting on the ground practically the same pressure per unit of area as the building (Fig. 11(*a*)).

By keeping the load, acting on the individual pile, less than the "safe load", it is merely transferred to the level of the pile points. No assurance whatever is obtained as to how the ground below the pile points will behave, and in cases of piles of the type shown in Fig. 10(*b*), the ground may behave as if they were non-existent.

Hence, in all cases where the piles do not act strictly as columns, the knowledge of the "safe load" of the individual piles only represents a minor part of the information required for predicting the behavior of the foundation as a whole. The essential part of the problem consists of studying the effect of the load on the ground located around the piles and beneath the points. Yet building codes are satisfied with specifying the load per pile, disregarding the true cause of future complications.

Effect of Freezing on Foundations

During recent years valuable contributions have been made to current knowledge of the effect of frost in the soil and on the structures supported by it. Most important among them are the investigations of Professor Stephen Taber,* of the University of South Carolina, concerning the capacity of

* "The Growth of Crystals Under External Pressure," *American Journal of Science*, 4th Series, Vol. 41, pp. 532–556; "Pressure Phenomena Accompanying the Growth of Crystals," *Proceedings*, National Academy of Sciences, Vol. 3, No. 4, pp. 297–302.

freezing veins of water to absorb additional water out of the surrounding clay soil, or through the clay soil from the ground-water, and to develop from thin seams into layers with a considerable thickness. The space required for the growth is produced by the pressure of crystallization, forcing the soil out of the way.

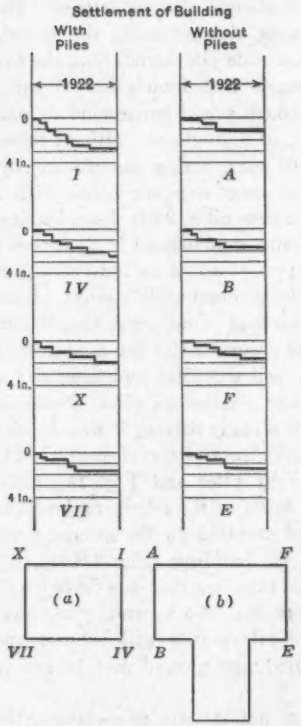

FIG. 11.—SETTLEMENT OF TWO ADJOINING BUILDINGS.

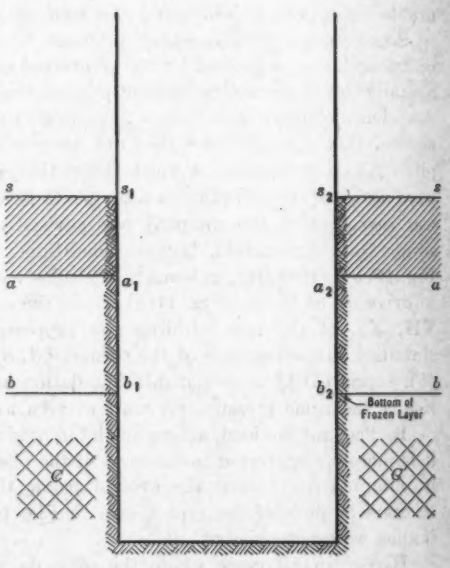

FIG. 12.—EFFECT OF SOIL FREEZING ON A FOUNDATION PIER.

In connection with foundation engineering, the importance of frost action essentially resides in the capacity of the freezing ground to lift foundations bodily several inches above their original position. This is apt to cause differential heaving associated with secondary stresses in the superstructure. Quite a number of such cases have been brought to the attention of the profession and many more have been undoubtedly observed.*

* "Freezing Ground Acts Like Hydraulic Jack: Heaving and Settling Back of Piers of Railroad Bridge Over City Street, Lead to Interesting Deduction," by H. J. Gilkey, *Engineering News-Record*, Vol. 79 (1917), pp. 360–361; "Some Observations on Effect of Frost in Raising Weight," by L. B. Wyckoff. *Engineering News-Record*, Vol. 80 (March 28, 1918), pp. 627–628; "Water Expansion in Ground Cause of Heaving in Winter," by C. D. Norton, *Engineering News-Record*, Vol. 80 (May 30, 1918), p. 1058; "Action of Frost in Heaving Concrete Piers," by L. DeB. McCready, *Engineering News-Record*, Vol. 91 (August 30, 1923), p. 360.

However, thus far, apparently no attempt has been made to go beyond the observed phenomena and to analyze the conditions required for producing the lifting effect. The following conclusions represent the results of a preliminary survey of these conditions.

The freezing starts at the surface of the ground and gradually proceeds toward the interior. At the same time the soil freezes to the pier, the adhesion being practically equal to the shearing strength of the frozen soil. Suppose that at some intermediate state, freezing has proceeded from the surface, *S-S* (Fig. 12), to the level, *aa*, the frozen soil being cemented to the pier along the faces, a_1 s_1 and a_2 s_2. If the freezing process continues still farther, causing the freezing and the expansion of the soil located within the space, *a a b b*, there are then three possibilities:

(*a*) The ground beneath the freezing layer is feebly compressible, and the adhesion between the faces, $a_1 s_1$, $a_2 s_2$, and the soil may be greater than the weight of the pier. In this case the pier should be lifted bodily, as freezing proceeds, leaving an empty space beneath it.

(*b*) The ground is compressible, but the adhesion along the faces, a_1 s_1 and a_2 s_2, is greater than the weight of the pier. In this case, with the pier as a reaction, the freezing soil will exert a downward pressure causing a small, but permanent, consolidation of the ground within the spaces, *C-C*.

Every frost season will add some additional consolidation, until, after several seasons, the soil located within *C-C* will be so compact, that finally a frost will succeed in lifting the pier, the consolidated material, *C-C*, acting as a reaction.

(*c*) The ground is feebly compressible, but the weight of the pier is greater than the adhesion. In this case the expansion of the soil, *a a b b*, will cause a slow upward creep of the soil, *s s a a*, along the outside of the pier, associated with an upward lift equal to the adhesion. The result should be a fatigue effect, similar to repeated application and removal of a live load, causing slight additional settlements of the pier.

From these remarks it may be learned that the lifting action of the expanding ground should depend on several factors, namely, the compressibility of the unfrozen foundation soil, the compressive strength of the frozen soil, the depth of freezing, and, finally, on the ratio between the weight of the pier and the total adhesion between the pier and the frozen ground. As experiences increase, other factors may have to be added to this list. Considering the scarcity of available information, any observations made in this field may increase the engineer's capacity for predicting the effect of freezing on proposed foundations.

Soil Classification Based on Elastic Constants of Soils

The preceding parts of this paper have brought out the following facts: (1) The settlement produced by a given unit load may increase either in direct proportion with the diameter of the loaded area, or at a very much smaller rate, depending on the character of the soil; (2) the settlement of a building may be due to volume change combined with lateral flow, or to lateral flow alone, depending on the character of the soil; (3) the pile-driving

formulas may furnish fairly reliable or utterly inconsistent results, depending on the character of the soil; and (4) the driving of piles into a soft top layer may cause a softening of the soil associated with a rise of the surface, or consolidation associated with subsidence, depending on the character of the soil.

The fundamental requirement for bringing the manifold foundation experience into a rational working system consists of establishing a system for the classification of soils based essentially on those characteristics that are of engineering importance.

Thus far, attempts to classify soils (including the revised soil classification* scheme of the Special Committee on the Bearing Value of Soils for Foundations, etc., of the Society) have been based essentially on such properties of soils as: (*a*) mineral composition; (*b*) volume of voids; (*c*) grain composition (result of mechanical analysis); (*d*) water content; and (*e*) percentage of colloidal material present in the soil. A study of these factors, covering a period of several years, has disclosed that:

(*a*) The mineral composition of very fine-grained soils cannot be determined except by elaborate optical or chemical methods, the cost of which is forbidding. Even if it were possible to make such a determination, the benefit would be doubtful.

(*b*) The volume of voids is so complicated a function of the shape and uniformity of the grains that it is impossible to correlate it with any definite properties of the soil, even if both the uniformity and the effective size of the material are known.

In 1926, the writer investigated the permeability of two sets of samples; one coming from a deposit of modified glacial drift near Westfield, Mass., and the other from a glacial lake deposit near Springfield, Mass. The effective size of both materials ranged between 0.01 mm. and more than 1 mm. In order to simplify the laboratory work, an effort was made to determine for each set the relation that exists between the uniformity coefficient (according to the well known definition of Allen Hazen, M. Am. Soc. C. E.) and the volume of voids. Fig. 13 shows the results of this investigation. Although there was a slight difference only between the shape of the grains and the mica content of the various samples, the relation between the volume of voids and the uniformity coefficient was found to be very erratic. To quote an example: At a voids' ratio of 0.8 (volume of voids of 45%), Soil No. 7, from Westfield, is as compact as it could possibly be and, if loaded, it would have a considerable bearing capacity. At the same voids ratio of 0.8 (volume of voids of 45%), Soil No. 34, from the same locality, would be very compressible, although its uniformity coefficient is practically equal to that of Soil No. 7.

(*c*) A mechanical analysis, according to the revised size grades of the Society's Special Committee on the Bearing Value of Soils for Foundations, etc., involves more than two weeks of work per sample, and the costs are forbidding. Nevertheless, the writer performed more than one hundred complete

* *Proceedings*, Am. Soc. C. E., February, 1921, Papers and Discussions, p. 17.

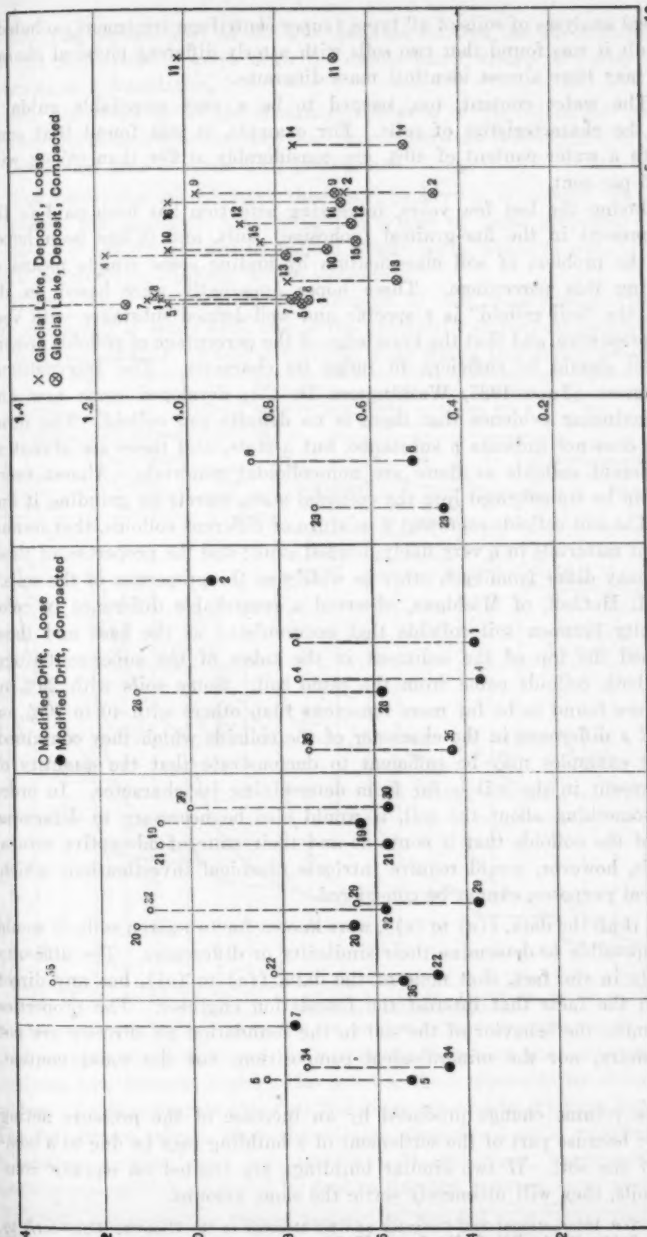

FIG. 13.—RELATION BETWEEN VOIDS RATIO AND UNIFORMITY.

mechanical analyses of soils of all types (super-centrifuge treatment excluded). As a result it was found that two soils with utterly different physical characteristics may have almost identical mass diagrams.

(*d*) The water content, too, seemed to be a very unreliable guide in judging the characteristics of soils. For example, it was found that some clays with a water content of 40% are considerably stiffer than others with one of 25 per cent.

(*e*) During the last few years, increasing attention has been paid to the colloids present in the fine-grained (cohesive) soils, and it has been hoped to solve the problem of soil classification by finding some simple means of determining this percentage. These hopes apparently were based on the idea that the "soil colloid" is a specific and well-defined substance with very unusual properties, and that the knowledge of the percentage of colloids present in the soil should be sufficient to judge its character. The International Soil Congress (June 1927, Washington, D. C.), developed some new and rather convincing evidence that there is no definite soil colloid. The term, "colloid", does not indicate a substance, but a state, and there are almost as many different colloids as there are non-colloidal materials. Almost every mineral can be transformed into the colloidal state, merely by grinding it fine enough. The soil colloids represent a mixture of different colloids, that means, of different materials in a very finely divided state; and the properties of these mixtures may differ from each other as widely as the properties of the soils.* Mr. M. M. McCool, of Michigan, observed a remarkable difference in color and tenacity between soil colloids that accumulated at the base and those that formed the top of the sediment in the tubes of the super-centrifuge, although both colloids came from the same soil. Some soils with 20% of colloids were found to be far more tenacious than others with 40 to 70%, on account of a difference in the character of the colloids which they contained. These few examples may be sufficient to demonstrate that the quantity of colloids present in the soil is far from determining its character. In order to learn something about the soil, it would also be necessary to determine the type of the colloids that it contains and their state of adsorptive saturation. This, however, would require intricate chemical investigations which, for practical purposes, cannot be considered.

Hence, if all the data, ((*a*) to (*e*)), were known for two given soils, it would still be impossible to determine their similarity or differences. The difficulty is obviously in the fact, that none of the data, ((*a*) to (*e*)), has any direct bearing on the facts that interest the foundation engineer. The properties that determine the behavior of the soil in the foundation pit directly are not the uniformity, nor the mineralogical composition, nor the water content. They are:

(1) The volume change produced by an increase of the pressure acting on the soil; because part of the settlement of a building may be due to a compression of the soil. If two similar buildings are erected on equally compressible soils, they will ultimately settle the same amount.

* "The First International Soil Congress and Its Message to the Highway Engineer," by C. Terzaghi, *Public Roads*, Vol. 8, No. 5, pp. 89–94.

(2) The permeability of the soil; because the less the permeability of the soil the more time it takes until the excess water drains out after the construction of a foundation.

(3) The cohesion or the shearing resistance of the soil under zero load; because the cohesion determines the relation between settlement and diameter of the loaded area at equal unit pressures.*

The determination of these three soil properties is enough for practical purposes. The question concerning the causes of these properties—whether or not they are determined by colloid constituents, effective size, or mineralogical composition—belong in the laboratory.

Hence, when approaching the problem of soil classification, the writer first attempted to study each one of the practically important properties, ((1) to (3)), individually, to find out within what limits they could possibly vary.

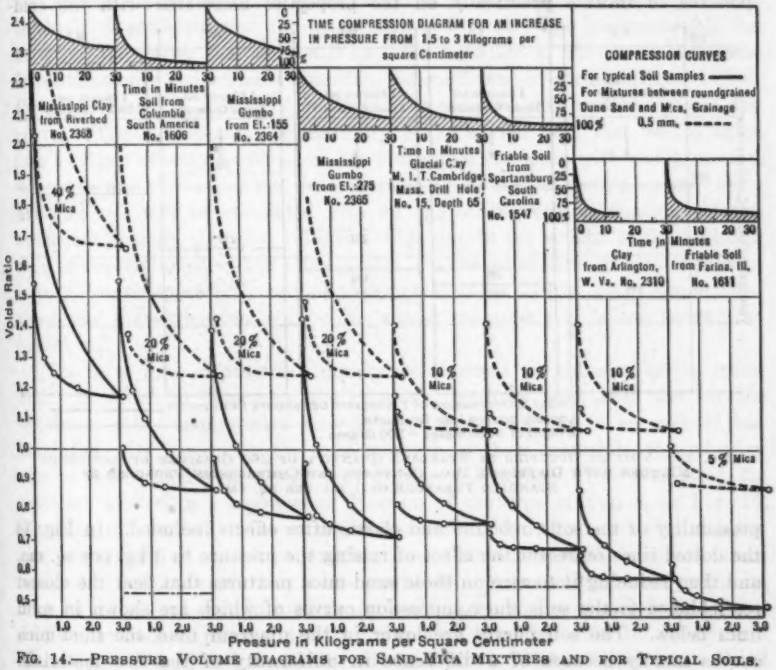

FIG. 14.—PRESSURE VOLUME DIAGRAMS FOR SAND-MICA MIXTURES AND FOR TYPICAL SOILS.

A careful study disclosed the surprising fact that the compressibility of soils may vary between limits as far apart as the compressibility of concrete and rubber. To demonstrate this fact the diagrams of Fig. 14 have been plotted. The full drawn curves show the volume changes of soils, ranging between Mississippi gumbo (most compressible soil) and clean, round-grained sand (least compressible), produced by first raising the pressure from zero to 3 tons

* "Erdbaumechanik," by Charles Terzaghi, M. Am. Soc. C. E., Franz Deuticke, Wien, 1925.

per sq. ft. (3 kg. per sq. cm.), and then gradually reducing the pressure to zero. At the outset the water content of each one of the samples was equal to the water content of the material after slow sedimentation in quiet water (Atterberg's lower liquid limit). From Fig. 14 it may be learned that the compressibility of the sand amounts to only a small fraction of the compressibility of the Mississippi gumbo. Even a year ago (1925) the cause of the tremendous difference in the compressibility of different soils was not yet quite clear to the writer. Suspecting that it might be due to the greater or smaller abundance of scale-like particles in the soil, he induced Glennon Gilboy, Jun. Am. Soc. C. E., of the Massachusetts Institute of Technology, to investigate the elastic properties of differently proportioned mixtures of sand and mica, both with a grain size of 0.5 mm.* The results of these investigations certainly were striking. By properly selecting the mica content of the sand, it was possible to imitate practically all the properties associated with the com-

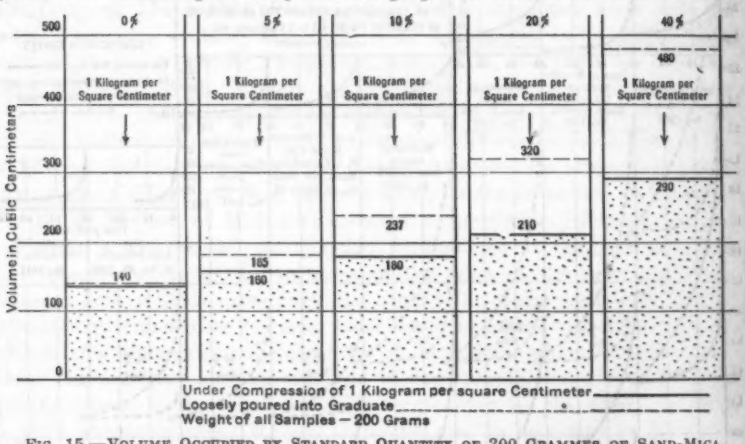

FIG. 15.—VOLUME OCCUPIED BY STANDARD QUANTITY OF 200 GRAMMES OF SAND-MICA MIXTURE WITH DIFFERENT MICA CONTENTS AND COMPRESSION PRODUCED BY STANDARD PRESSURE OF 1 KG. PER SQ. CM.

pressibility of the soils, rebound and elastic after effects included. In Fig. 14 the dotted lines represent the effect of raising the pressure to 3 kg. per sq. cm. and then reducing it to zero on those sand-mica mixtures that bear the closest resemblance to the soils the compression curves of which are shown in solid lines below. The soil curves are lower in the diagram than the sand-mica curves merely because of a difference in uniformity of the two materials. In order to make these facts clearer, the diagrams, Fig. 15, have been prepared. The upper row of numbers shows the space occupied by a standard quantity of 200 grammes of sand-mica mixtures with a mica content of 0%, 5%, 10%, 20%, and 40%, respectively. The lower row shows the space occupied after compression produced by a standard pressure of 1 ton per sq. ft.

Thus, it becomes evident that one of the most important properties of the soils—compressibility—has nothing to do with the effective size, the uni-

* *Proceedings*, Am. Soc. C. E., February, 1928, Papers and Discussions, p. 555.

formity, or the colloid content. It is merely the mechanical effect of a greater or smaller abundance of scale-like particles.

The property next in importance concerns the permeability of soils. The first tests that the writer made for determining the permeability of very fine-grained materials, such as clays, lasted several months.* However, a method has been devised, based on the theory of hydrodynamic stresses, by which the coefficient of permeability can be determined from not more than one dozen readings. By using the same sample that serves for investigating the compressibility, the determination can be made in 24 hours.† The test is made by first raising the pressure which acts on the sample by 100 per cent. The less permeable the material, the longer will be the time during which the excess water is squeezed out. The gradual loss of water betrays itself by a gradual settlement. By observing the settlement in specified time intervals covering a period of 24 hours, a curve of settlement against time may be obtained, as shown near the upper edge of Fig. 14. The less permeable the material, the flatter the curve will be. The equation of the curve is known. It contains only one variable quantity, the coefficient of permeability. Therefore, it is merely a matter of arithmetic to compute this coefficient from the curves. The coefficient of permeability is the second item that has to enter into a system of soil classification. It determines the speed with which the soil will settle and whether or not the settlement of a building resting on very compressible soil will be associated with an appreciable volume change. If the coefficient is high, the total volume change due to the weight of the building may be accomplished within a few years. On the other hand, if this coefficient is very low, no appreciable volume change may occur within one or two generations, and the settlements will be due almost exclusively to lateral flow of the loaded soil.

The third item of practical importance concerns the cohesion of the material. In order to determine the cohesion, methods have been devised for obtaining drill samples with their original water content in an undisturbed condition. By measuring the cube strength of these materials, the cohesion can be determined with a sufficient degree of accuracy. The results of the tests are plotted in a consistency diagram of the type of Fig. 4, or Fig. 16. By using this method of investigation it was found that there are clay deposits that are still in an undrained condition, which means that their consolidation under the influence of their own weight is still proceeding. As examples may be mentioned certain mud deposits along the shores of the Golden Horn in Constantinople; parts of the blue clay deposit which underlies Boston and Cambridge, Mass.; and a clay deposit in Detroit, Mich. There is no doubt that many others of a similar kind exist. The surface of such deposits would gradually subside even if no buildings were erected on them, and the construction of buildings accelerates the process, involving considerable settlements regardless of the type of foundation.

* "Die physikalischen Grundlagen des Technisch-geologischen Gutachtens," by Charles Terzaghi, M. Am. Soc. C. E., *Zeitschrift* des Oesterreichischen Ingenieur- and Architekten Vereins, September, 1921.

† "Die Berechnung der Durchlässigkeitsziffer der Tone aus dem Verlauf der hydrodynamischen Spannungserscheinungen," *Sitzber.* der Akad. der Wiss. in Wien, Math. Natur., Abt. IIa, 1923.

The first two items, compressibility and permeability, determine the type of soil with a greater precision than the concrete term, "1 : 2 : 4", describes the property of artificial stones. A third item, cohesion (shearing resistance) for clays, and density for sands and quicksands, determines the state in which the soil occurs. The methods for measuring the density (firmness) of sandy materials have not yet been developed, but there seems to be no insurmountable obstacle to the solution of the problems involved.

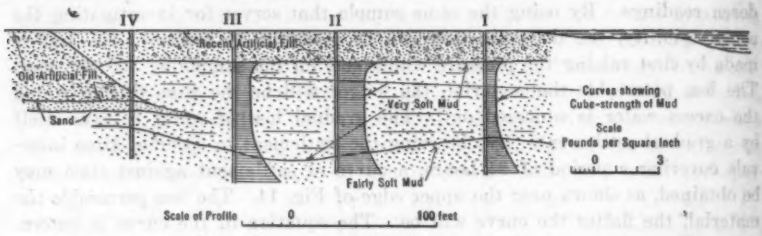

FIG. 16.—CONSISTENCY DIAGRAM FOR A NEW MUD DEPOSIT AT AÏWAN SERAÏ, NEAR CONSTANTINOPLE, TURKEY.

With these three items as a basis, a soil classification could be devised which would serve to bring soils into as rational a system as that which covers artificial construction materials, because soils with equal compressibility, equal permeability, and occurring in the same state, will behave, under load, in an identical manner, regardless of what the ultimate causes of their properties may be.

However, in practice, there are two serious difficulties associated with any attempt to classify soils according to the method proposed in the preceding discussion. The first is the difficulty of obtaining undisturbed samples of certain soils. According to the results obtained by Swedish investigators, disturbing a soil without changing its volume of voids and its water content may cause the cohesion (consistency) of the soil to be reduced by an amount ranging between 75 and 96% of its original value. Hence, the conclusions derived from testing the consistency of a drill sample may be very misleading unless one has succeeded in securing the sample in an undisturbed state.

The second difficulty is due to the fact that the character of the natural ground varies to a greater or less extent from foot to foot, in a horizontal and in a vertical direction, the variations depending on how the soil deposit was formed. In order to get an accurate conception of the average character of the soil, a considerable number of samples ought to be tested. The tests required for determining the constants mentioned in the preceding discussion are too expensive, in time and money, to be performed on every individual sample. Hence, efforts are made to work out certain simple routine tests, the results of which would furnish the approximate information desired at a reasonable amount of time and labor.

CONCLUSIONS

Considering the present state of knowledge in the field of soil mechanics, the prospects concerning the future of foundation engineering as an applied

science are decidedly encouraging, the principal obstacles against progress in this field having been removed. The elastic properties of the most troublesome soils, clays included, are now at least as thoroughly known as those of concrete or steel. The methods of soil classification and soil identification have reached a point where it can be clearly seen what is needed for identifying soil materials. The relations between the size of the loaded area, depth of foundation, character of the soil, and intensity of the load are well analyzed, at least in principle, and the physics of the time effects are clearly understood. Yet, stress must be laid on the fact that the knowledge thus obtained merely serves as a means for uprooting certain persistent prejudices (for instance, concerning the value of pile-driving formulas, or the interpretation of the results of loading tests) and establishing a more accurate interpretation of actual construction experience. The bulk of the work—the systematic accumulation of empirical data—remains to be done.

Foundation problems, throughout, are of such character that a strictly theoretical mathematical treatment will always be impossible. The only way to handle them efficiently consists in finding out, first, what has happened on preceding jobs of a similar character; next, the kind of soil on which the operations were performed; and, finally, why the operations have led to certain results. By systematically accumulating such knowledge, the empirical data being well defined by the results of adequate soil investigations, foundation engineering could be developed into a semi-empirical science, comparable in its character to certain branches of medicine. For the first time a large-scale effort of this kind was made by the Swedish Geotechnical Committee, in its epochal investigation of Swedish landslides, 1914-22.* In connection with its work, the Committee has tested a vast number of soil samples, extracted from more than 10 000 drill holes, at different depths below the surface. On account of the time (five years) that has elapsed since the Committee finished its work, some of the experimental methods have been superseded. Nevertheless, the work of the Committee could serve as a noteworthy example for the way in which a similar enterprise should be organized in the field of plain foundation engineering.

At present (1927), the data derived from previous experience in foundation engineering are of as little value as were those derived from Swedish landslide experiences prior to the work of the Geotechnical Committee. The information concerning soil character is inadequate, and the interpretation of the observed facts is very often arbitrary and inconsistent with the laws of physics and mechanics. Hence, the first requirement for improving conditions consists in standardizing the methods of soil classification, and, the second, in consistently applying present knowledge of soil mechanics to observations in the field.

DISCUSSION

CHARLES R. GOW,* M. AM. SOC. C. E.—The theories advanced in explanation of the behavior of soils under various conditions of use open up many new and interesting avenues of approach in the solution of foundation problems involving the predetermining of soil behavior under specific applications of loads. Undoubtedly, from the standpoint of definite and accepted standards of practice, the general status of foundation engineering is at present in the most unsatisfactory condition of any branch of the science with which engineers are called upon to deal.

There is no recognized authoritative source of information available to the foundation engineer by means of which he may act with the reasonable assurance that the requirements of his problem will be properly and efficiently met. Reliance must be had, in general, on observed experience with regard to previous construction undertakings in the same locality, and where such histories are lacking the designer must often proceed on a basis of uncertain assumptions, which may or may not ultimately prove to have been justified.

Heretofore, soils have usually been classified according to their visible physical properties, and engineers have acted on the supposition that these easily recognized characteristics furnished them with a sufficiently satisfactory guide by which to differentiate between soils and identify those possessing similar properties and behaviors.

The results now made available to the profession as a consequence of the author's research investigations throw much new light on the subject. The conclusions thus far would indicate that the essential factors affecting the behavior of soils under pressure are rather more obscure and complex in their nature than has hitherto been generally assumed.

Obviously, such factors as voids ratio, permeability, compressibility, and elasticity, cannot be determined by any superficial examination of soil samples. Intricate and somewhat elaborate laboratory experiments are necessary for securing this information. Yet, assuming the validity of the author's reasoning, these elements must be known before it is possible to predict, with any degree of accuracy, the capacity of a given soil to support a specified load.

The most encouraging feature of this paper is the evidence that the subject of soil mechanics is at last being studied in a scientific manner and that, as a consequence, there are now some positive experimental data which serve to explain many well recognized but heretofore little understood phenomena.

It is known, for example, that sands of similar appearance as to shape and size of grain may behave quite differently under equal conditions of loading. Likewise, certain clays appear to be highly compressible, whereas, other soils of identical appearance will sustain considerable loads without appreciable consolidation. Again, the driving of piles into a given soil may result in a pronounced upheaval at the surface level, while another apparently identical set of conditions produces little or no such action.

It is not suggested that the author's analysis presents a practical method of forecasting these variations in soil behavior; but it indicates the direc-

* Pres., The Gow Co., Inc., Boston, Mass.

tion of inquiry that should be followed in order to discover a satisfactory answer for apparent inconsistencies.

It is true that a determination of the essential factors that would make soil identification positive would probably involve more elaborate and expensive procedure than the ordinary engineer could be expected to command. Nevertheless, once the correctness of the author's theories have been established by a sufficient number of laboratory experiments on soils of known behavior, it should be possible, by means of further research, to calibrate these results against more simple rule-of-thumb tests that could be applied in the field. If a satisfactory method can be developed for accomplishing this result, engineers will have made the greatest single step in foundation engineering that has so far been taken.

The author's analysis of the relation between settlement and foundation area is extremely interesting and more or less in agreement with accepted beliefs; yet it probably will be unwise to assume too readily that such settlements can be reduced to common formulas until at least there has been more practical corroboration of the theory by actual experience.

The author's observations respecting the application of the customary pile-driving formulas are probably justified by the facts, since there are few engineers, having occasion to drive piles under varying conditions, who have not been impressed by the variation between actual and computed capacities. Fortunately, the so-called *Engineering News* formula has usually given results that are at least on the safe side, and until engineers become more enlightened respecting the factors that produce the observed departures from theory, they will probably do well to stick to that formula as the most dependable guide available.

The author does well to emphasize once again the fallacy of relying too strongly on the results of individual pile tests in determining the average pile load of the cluster. His analysis of the distribution of soil stresses, as well as his explanation of the variation between dynamic and static resistance, is especially interesting and enlightening.

Of unusual significance is the author's presentation of the compression and rebound curves (Fig. 14) developed by laboratory experiments on varying types of soil, particularly the comparison presented by similar experiments made on synthetic clays produced by mixing different percentages of powdered mica with fine sand. To those who have been seeking an explanation of the characteristic behavior of clays, as compared with sands, this presentation is especially interesting.

On the whole, it may be said that the author has, by means of this paper, added another important contribution to the clarification of the engineer's understanding respecting many of the most troublesome features of foundation engineering.

E. P. Goodrich,* M. Am. Soc. C. E.—About 1900, the speaker abandoned the use of the *Engineering News* formula. A demonstration of its ineffectiveness was had in connection with some work that was being supervised by a

* Cons. Engr., New York, N. Y.

certain governmental group. Certain requirements were laid down as to the supporting power of the piles, and the *Engineering News* formula was to be used. Those responsible were asked if they would be satisfied with a certain weight of hammer, dropping a certain number of feet. They said they would. The speaker then told them to apply the formula and they found that the result was a negative quantity.

Some data with reference to one of the questions that Professor Terzaghi has propounded, that is, a test of the distribution of stress under a square foundation under which the soil was rather cohesive, are as follows: Some years ago the speaker took a timber platform 4 ft. square, penetrated it by plungers located along a diameter and a diagonal and found that the diagonal stresses were larger than the diametrical ones. In other words, the corners of the square foundation supported more in proportion than any other part, either the center or the sides.

VICTOR A. ENDERSBY,* ASSOC. M. AM. SOC. C. E. (by letter).—The profession should feel indebted to Professor Terzaghi for the clear line he draws between soils to which the *Engineering News* formula is applicable, and those to which it is not. Among field engineers directly in charge of pile-driving, there are a great number who regard this formula as applicable, without modification or question, to every circumstance. There is an equal number who —perhaps more logically—refuse to believe in any formula whatsoever, and who regulate their pile-driving by guess, by the penetration they can force a contractor to attempt, or by the approach of five o'clock. Every practical engineer finds, sooner or later, that there is a great difference in the reliability of formulas in different soils, but there are not many who have any very clear idea as to general distinctions.

It seems very true that the most that can be hoped in regard to the science of foundations is that it become a reasonably reliable empirical system. One is especially impressed with this after such an experience as the writer had on one structure. Certain piles came to refusal in sand at a penetration which he considered unsatisfactory. A jet not being available at the time, he acted on a highly irrational "hunch" and suggested that the piles be left over night and an attempt be made to drive them next day. When this was done, the piles continued to drive with surprising ease, application of the *Engineering News* formula showing that as they stood they had lost 40% of their theoretical bearing power in a few hours. The excavation in which they were being driven was at the time 25 ft. below sea level, and 27 ft. below permanent water line, so that there could have been no question of a change in the texture of material due to subterranean water flows. There was evidently a decompression of some kind, but the occurrence is still a mystery to the writer, which he would like very much to have definitely explained. According to Professor Terzaghi's thesis, this might occur in some soils, but not in sand. The writer has heard a rumor of a similar occurrance on the Gila River in Arizona.

He has had occasion also to test the driving in adjacent and uniform material under three different hammers, a Union No. 2, double-acting, and Vul-

* Constr. Engr. of Bridges, Southern Section, State Div. of Highways, Los Angeles, Calif.

can Nos. 1 and 2, single-acting. The theoretical bearing power for piles of uniform size at uniform penetration with these three hammers was practically the same; the result was a good test for consistency of the formula as applied to various types of hammers.

GEORGE PAASWELL,* M. AM. SOC. C. E. (by letter).—The paper, being synoptical in character, the author, naturally, omitted many vital points which bear on foundation practice as well as on the type of laboratory and field tests which supplied the data for the theory developed. The paper must be a great disappointment to engineers who look for a simple set of rule-of-thumb notes to embrace all foundation practice. It is no mean accomplishment of the author that he has demonstrated the fact that foundation design and construction is as exacting in analysis and as worthy of study as the design of the structures resting on these foundations.

The essential difference between superstructure and sub-surface design is that one may fit the materials to the design of the former; one must fit the design to the materials of the latter. The engineer cannot fit a foundation to a rigid set of formulas. The material must be studied in the site and the foundation must be fitted exactly to it. A code set of bearing values is more than worthless; it is dangerous. The author has illustrated this point very well. Settlement in a foundation has been viewed as an unfortunate and usually unavoidable concomitant of foundation construction; yet such settlement is as inevitable as the deflections and distortions of the supported structure. Provision must be made for them. That makes it necessary to formulate means to determine foundation distortions. The author has briefly indicated how such studies may be made.

The study of soils has indicated that two broad types exist: (1) Those in which the usual stresses of elastic solids are found, modified, of course, by proper elastic coefficients; and (2), those in which hydro-mechanical stresses are set up. Both types can be uniquely identified by sample tests for composition and loading, but neither can be safely described by grain size or moisture contents alone. The author's striking experiment on sand and mica mixtures has demonstrated fully the futility of mere sieve analysis as a basis of soil classification. He has put to rest also the colloid theory as the basis of coherent action in soils.

In his paper entitled "Transmission of Pressure Through Solids and Soils and the Related Engineering Phenomena,"† the writer attempted an analysis of stress distribution through soils and found that certain characteristic failure surfaces existed, similar in type to those found in elastic solids. It was also demonstrated that a uniform distribution of pressure under a load was a fiction of design. Numerous experiments preceding and following the paper have amply demonstrated the truth of this statement.

The huge subway construction program of Greater New York is unquestionably the world's best laboratory for the study and illustration of all types of foundation problems and the writer hopes to see, in the course of the next few years, the crystallization of a definite soil mechanics and the complete abandonment of bearing value codification as a foundation formulation.

* Engr., Corson Constr. Corporation, Brooklyn, N. Y.

† *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1563.

The author well points out that, given a complete soil identification, there is sufficient mathematical and physical science available to complete the practical investigation, of the foundation. It remains to codify soil identification.

The use of piles has been a blind foundation expedient, save where such piles were driven to absolute refusal. The anticipated capacity of a pile whether determined by formula or by actual field test has been of so indeterminate a character that most foundation failures may be laid to miscalculated pile-bearing values. It has been frequently emphasized by the writer that no adequate pile theory could be formulated until a rational soil mechanics had been developed, for the author has well demonstrated the fact that there is no separate theory for piles and for soil behavior. The development of the pile for underpinning buildings has evolved a better understanding of soil behavior than any other single phenomenon in engineering foundation practice. It is not a question of bearing capacity alone, but of actual load settlement behavior which determines the ultimate safety of the foundation underpinned. The study of the loaded soil and its distortions under the pile toe brought out the reasons for progressive settlement even if a pile had already been tested for a safe load, and there was evolved the ingenious "pre-test" pile, a scientific application of soil mechanics.

The writer is heartily in favor of the abandonment of the *Engineering News* formula for piles, and the adoption of one similar in nature to that suggested by the author, although he would prefer to disregard pile formulas entirely and make a separate study for each foundation type. That would eliminate the dangerous conditions resulting from group application to single pile tests or formulas.

There remains the extremely interesting subject of temporary earthwork supports, such as sheeting and bracing. In this work modern soil mechanics, has been given ample demonstration of its validity. The failure of earth banks is not a simple application of the Rankine or Coulomb special soil-type theory, but is one that can be easily formulated by a study of the elastic properties of the soil. The absolute limits of ground movement are predictable, and that gives a rational method for determining the maximum pressures that may be induced in the sheeting and timbering. This, of course, leads to a far safer and more economical layout of such bracing; but, on the other hand, it requires more study and more design than is usually given to such structures. The use of large excavating machinery, which requires large clearances because of working room, calls for a very careful investigation of load distribution through wales and braces. It must be borne in mind that a movement in the sheeting that permits movement of the earth behind it, also permits the grain re-arrangement of the soil and consequent increase in pressures as is well illustrated by the famous "dilatancy" experiment of Osborne-Reynolds.

C. C. WILLIAMS,* M. AM. SOC. C. E. (by letter).—The principles of soil mechanics presented in this paper should serve as a rational basis for correlating observed facts concerning foundation tests and behavior, and should thus contribute to making the design of foundations more scientific.

* Dean, Coll. of Eng., Univ. of Iowa, Iowa City, Iowa.

That the supporting capacity of soil is not, in general, directly proportional to the area of the foundation, has long been recognized, but the true relationship is not even yet entirely understood. In experiments on alluvial soil made in 1851-52 at New Orleans, La.,* in which areas varying from 0.25 sq. in. to 576 sq. in. were used, the penetration under a constant unit load increased practically with the area. Observations made in France† on alluvial soil indicated similar results. From these and other data,‡ the late Randell Hunt, M. Am. Soc. C. E., drew the conclusion: "Large areas of soft soil will not support as much weight per unit of surface as more limited areas of the same soil." Reflection on the manner of distribution of a local load through an indefinitely extensive solid or semi-solid, would indicate such to be the case.

The relation between the plastic and the elastic deformations of soil should first be recalled. The former is due to displacement of soil particles, whereas the latter is due to the resilient deformation of the particles, without slipping, relative to each other. Contrary to the behavior of steel, the plastic flow precedes the elastic, the latter constituting a small proportion of the total compression. Fig. 17, taken from a test made under the writer's direction by Mr. H. T. Heald, a graduate student, illustrates this relationship for loam and for sand. The experiment consisted of applying and releasing a load which was increased with each application and never entirely removed, the compression and the recovery being recorded at each application.

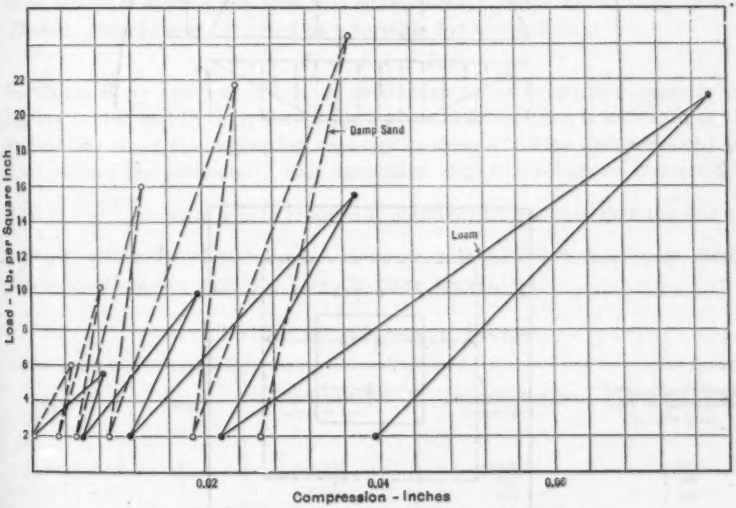

FIG. 17.—COMPARISON OF LOAD COMPRESSION CURVES.

If a load is applied over an area, A, at the surface, the inter-reactions of soil particles along the perimeter of this area are such as to spread the load laterally by virtue of shear over an ever-increasing area of bearing planes at

* *Van Nostrand's Magazine*, Vol. 27.
† *Annales des Ponts et Chaussées*, 1864.
‡ *Proceedings*, Assoc. Eng. Soc., 1888.

successive depths. The rate of this spread depends on the characteristics of the soil, being greatest for coarse fragmental materials, less for granular, and least for silt. Moreover, the spread is only approximately linear and the surface of uniform pressure is curved rather than plane, but the variation from the conception indicated in Fig. 18 is not sufficient to affect seriously the conclusions based thereon. Although the rate of spread is dependent on the soil characteristics, the depth of soil affected, and hence the total spread, depends on the depression of the soil under the load. This deformation increases until the spread distributes the load over an area sufficient to bring the intensity within the elastic resistance of the soil. When a homogeneous soil is assumed, an expression for the total deformation may be obtained as follows:

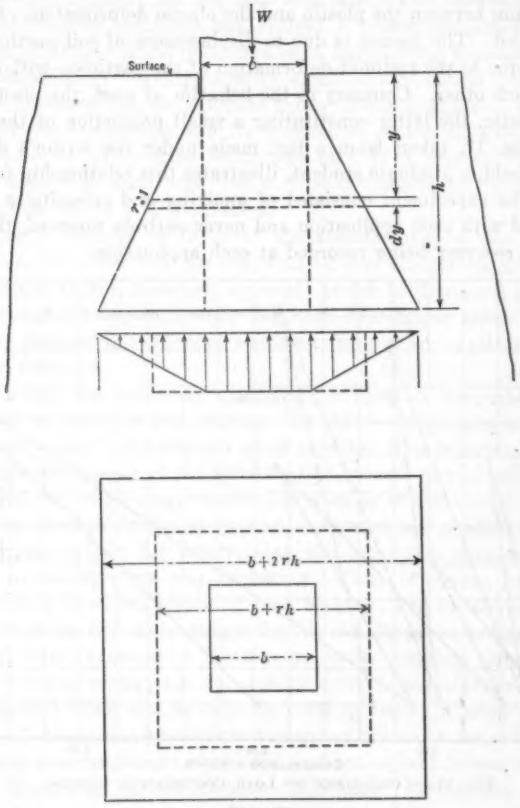

FIG. 18.

Let W be the load applied; h, the total depth of soil compressed; y, the depth to any plane considered; r, the tangent of the angle of spread; and C, the modulus of compressibility. The distribution of pressure on any horizontal plane may be assumed equivalent to a uniform intensity over a width

of $b + r\,y$. Then, for a square surface with side, b, the deformation of an elementary horizontal prism bounded by the sides of the frustum of the pyramid is $\frac{W\,d\,y}{C\,(b + r\,y)^2}$, and the total deformation in a depth, h, is $\frac{W}{C}\int_0^h \frac{d\,y}{(b + r\,y)^2}$, which when integrated gives $\frac{W\,h}{C\,(b^2 + b\,r\,h)}$. This expression shows that the deformation varies inversely with the perimeter, b, as well as with the area, b^2.

If w is the pressure intensity at the surface and p the intensity that the soil will sustain elastically without deformation (at a given depression), then, $w\,b^2 = p\,(b + r\,h)^2$, whence $h = \frac{b}{r}\left(\sqrt{\frac{w}{p}} - 1\right)$, neglecting the weight of the soil itself. If, as for sand under certain conditions, $r = \frac{1}{2}$, and $h = 2$, the deformation would be $\frac{2\,W}{C\,(b^2 + b)}$. In this case the denominator contains simply the sum of the bearing area and the perimeter multiplied by a strip $\frac{1}{4}$ ft. wide.

Thus, an elementary analysis indicates that the supporting capacity of soil depends on two factors: (1) The bearing area; and (2) the perimeter of the bearing surface. However, on account of the variableness of soils, it is impossible to assign values that will be universally applicable to these factors. The relationship may be stated as a formula for convenience,

$$W = A\,p + L\,f$$

in which, W = load; A = area of application; p = supporting capacity per square foot of soil in compression for a given deformation; L = length of the perimeter; and f the supporting capacity in shear (friction and cohesion) per foot around the perimeter. This expression might be otherwise conceived as $\left(A + \frac{L\,h\,r}{2}\right)p$, since p is in reality the intensity of pressure that the soil will sustain within its elastic limit. However, although this form may clarify the conception, the previous form is more convenient.

TABLE 2.—Supporting Factors.

Sand.	Clay.	p, in pounds per square foot.	f, in pounds per linear foot.	Total superimposed load, in pounds per square foot.
0	1	110	400	1 710
1	1	120	280	1 240
5	1	500	160	1 140

These supporting factors, p and f, vary with the character of the soil (mineral and granulometric composition, compactness, water content, etc.), and with the depth to which the load penetrates the soil. The two terms are indeterminate, their relative values depending on which represents the more rigid element in the total support. For the more rigid soils, the direct compressive

resistance becomes the greater, for any considerable compression. Thus, the tests made by A. T. Goldbeck, Assoc. M. Am. Soc. C. E., quoted by the author, give, approximately, the results shown in Table 2 for 0.1-in. penetration and for the various mixes of sand and clay.

At 0.05-in. penetration and less, the marginal shear, in these experiments, carried nearly all the load. Inasmuch as Mr. Goldbeck worked with small compressions, these facts explain the apparent importance of the diameter, $(\sqrt{A})$.

Tests (see Fig. 19) made on a uniform clay soil containing 7% sand in undisturbed condition, using bearing areas of 1.0, 2.25, and 4.0 sq. ft., showed for 0.3-in. depression, $p = 3\,500$ and $f = 1\,500$. For depressions of less than 0.1 in., the perimeter factor carried nearly all the load. In still another test in clay soil, $p = 3\,400$ and $f = 2\,300$ for a settlement of $\frac{3}{8}$ in. While the Austrian experiments quoted by the author are rather fragmentary, the corresponding values at 1.0-in. settlement are approximately, $p = 2\,800$, and $f = 700$.

Of these two elements, p varies almost directly with the settlement in sand and dry clay soils, while, on the other hand, f remains fairly constant, varying, if at all, with some low power of the depth of settlement, in some cases about as the fourth root.

If these elements were determined, the bearing capacity of a larger area could be predicted from a test on a small area. Thus, based on the test on 7% sand soil mentioned previously, using the data from the 0.3-in. penetration, $p = 3\,600$ and $f = 1\,500$, a footing 8 ft. square might be expected to sustain (with 0.5-in. penetration),

$$3\,600 \times \frac{5}{3} \times 64 + 1\,500 \sqrt[4]{\frac{5}{3}} \times 32 = 432\,000 \text{ lb.}$$

or, approximately 5 400 lb. per sq. ft. of superimposed load. The broken-line curves of Fig. 19 show calculated bearings assuming p to vary as the depth, and f as the fourth root.

The correlation between calculated and observed data is high within the ultimate bearing capacity of the soil. The writer has applied this theory to the other test data available, with similar results.

The most reliable practical basis for comparing the supporting capacity of two areas on the same soil, therefore, is the factor, $A + K \times L$, in which, K is a soil coefficient. If, as for a certain sand, K is $\frac{1}{4}$, then a 36-sq. ft. foundation can be expected to sustain on this soil, $\frac{36 + 6}{1 + 1}$, or 21 times the test load on a post 1 ft. square with the same settlement, instead of 36 times as much according to the usual assumption, or instead of 6 times as much, which would be the case if the supporting capacity varied with the diameter for a given penetration.

While for small settlements and for small test areas, observed data, such as those of Mr. Goldbeck's experiments, indicate settlement, under a constant

FIG. 19.

unit loading, to vary with the diameter of the bearing area, the writer believes that a general conclusion to this effect is unwarranted, even for soils having great cohesion. In the tests on the 7% sand-clay soil mentioned, the relations between loads and settlement were as given in Table 3.

TABLE 3.—Relation Between Load and Settlement.

Load, in pounds per square foot.	Settlement Under Different Areas, in Inches.		
	1 sq. ft.	2.25 sq. ft.	4.00 sq. ft.
3 000	0.082	0.042	0.112
4 000	0.054	0.082	0.155
5 000	0.075	0.132	0.210
6 000	0.110	0.205	0.265
7 000	0.152	0.325	0.340
8 000	0.225	0.385	.....

These results, like those quoted by the author, indicate that, for small settlement and small areas, the movement is approximately proportional to the diameter, but that, for larger loadings and larger areas, this relationship tends to disappear. This latter indication is further supported by the fact that, in the test on clay, the settlement under actual load of 5 500 lb. per sq. ft. on 68 sq. ft. was only about 1.5 times that under the same unit load on the test post covering 4 sq. ft., instead of 4 times as great as would have been the case if the settlement had been in proportion to the diameter.

In the seventeen-story office building of the Michigan Central Railway Company at Detroit, Mich., settlement under a bearing post, 2 ft. square (not back-filled) was 0.02 ft. for 5 000 lb. per sq. ft., but under the mat foundation of the building loaded to 4 000 lb. per sq. ft. there was no appreciable settlement.* Indeed, numerous instances might be cited where an actual load on large footings amounts to one-half or even a larger fraction of a test load on a small area, and yet the settlement is not noticeably greater than that with the test load.

Where care is exercised to load the soil around the test footing, the discrepancy between the settlement under test and actual load on the structure is reduced. Unfortunately, too few correlated observations have been made on the settlement of the completed structure, and that of the test load at similar intensities of pressure. It is the writer's opinion, however, based on the rather meager data available, both theoretical and observational, that, for areas of practical size, the settlement does not vary greatly for comparable sized footings carrying a uniform intensity of pressure on the same soil.

If, as seems to be the case from this discussion, the bearing capacity varies with both the area and the perimeter of the footing, then, for larger foundations, the bearing for constant settlement varies nearly with the area. For instance, with two footings on sand, as previously assumed, one 10 ft. square

* *Engineering News*, September 3, and October 1, 1914.

and one 20 ft. square, the respective bearing capacities would be about as $\frac{100 + 10}{400 + 20} = 1 : 3.8$, instead of 1 : 4 when based on the area directly, or 1 : 2 if based on the diameter relationship.

While both theoretical analyses and experimental observations show, as the author states, that the bearing intensity is not uniform under a pier, it is the writer's opinion that the error in the moment calculated for a continuous beam or mat, on the assumption of uniform distribution, is not as serious as that shown in Fig. 3. The author neglects the fact that such a foundation beam or slab deflects upward, and that this deflection is generally sufficient to relieve the pressure at the mid-span, and, therefore, operates to effect more nearly a uniform distribution, by increasing the intensity of pressure at the (downward) supports of the slab. This deflection upward operates to decrease the pressure at mid-span, because of the fact that the soil is only slightly elastic and does not follow the deflected member, the loading of the beam differing therein from a gravity or constant-pressure load. For spans of 16 to 20 ft., or more, which the writer has had occasion to investigate, this upward deflection of the beam is sufficient to nullify greatly the error in moment on the assumption of uniform distribution.

Two other phases of the science of foundations, both suggested by the author, enter into foundation design to an important degree. These are: First, the relative effect on settlement of a constant dead load and of a transitory conjectural live load to which foundations are subjected; and, second, the prediction of foundation behavior in order to calculate the effect of settlement on the superstructure. One has but to visit the basements of almost any of the older structures in Chicago, Ill., and cities similarly situated, to witness the effects of lack of knowledge on this subject. Eccentric live loads, due to wind and other elements, are usually unavoidable, and a prediction as to the behavior of the foundation under such conditions and the consequent effect on the superstructure is necessary in order to prevent distortion, if not failure, of the structure. To secure uniform minimum settlement under a structure may be desirable, just as rock foundations may be desirable; but, since such foundations are not always obtainable, the problem then resolves itself into designing the structure for actual foundation conditions. Therefore, studies of soil behavior should include more detailed information than the usual observations accompanying test loading.

HERBERT CHATLEY,* ESQ. (by letter).—Whether or not some of the finer points of Professor Terzaghi's hypotheses will stand prolonged investigation is a matter for the future to decide, but no one can question that his masterly exposition of the manner in which the flow of water through fine-grained soils is related to their bearing capacity has thrown a brilliant light on what had previously been a most misunderstood subject.

The conditions in Shanghai, China, are those of a saturated soft alluvium of indefinite depth, and the major conclusions drawn by Professor Terzaghi as to the behavior of surface loads and piling under such conditions are of the greatest interest and value to engineers there. Through the initiative

* Acting Engr.-in-Chf., Whangpoo Conservancy Board, Shanghai, China.

of A. V. H. von Heidenstam, M. Am. Soc. C. E., pile tests on rather a large scale have been made for some years in Shanghai by the staff of the Whangpoo Conservancy Board. Professor Terzaghi has been good enough to speak very appreciatively of these tests. Broadly speaking, they have confirmed his views as to piling in soft soils.

The slowness with which fine alluvium expels its contained water is well shown in Shanghai by the behavior of hydraulic fills formed by the pumping up of dredge spoil. Where these fills are above the ground-water level they do become dry, but below the top 2 or 3 ft. some years may elapse before the deeper material becomes fully consolidated. This is true in spite of the fact that the hydraulic filling process tends to remove an appreciable part of the colloid content.

As to the use of piling formulas, the cogency of the reasoning as to the variation of the hydro-dynamic resistance with the duration of the applied force is complete. The new "derivation" of the *Engineering News* formula is most interesting and calls attention to the fact that the assumed constancy of the second term in the denominator of that formula is even more arbitrary than is generally supposed.

In the work on the internal friction of granular masses the author has seen fit to adopt the writer's conclusion* as to the importance of single molecular bonds in uniting particles the weight of which is of the same order as those bonds. The writer has since gone much further into the question, and these studies fully sustain his earlier conclusions as to the magnitude and importance of these forces in granular masses.

In regard to the classification of soils the new data as to the effect of mica are most important. There is one point to which attention might very well be directed and that is the possibilities of change of grain size by the permanent aggregation of particles. Putting it very crudely, one might imagine that, under certain circumstances, a fine clay could gradually be transformed into a loam by the adhesion of the particles.

Engineers would be very glad if the author would give some practical rules for the design of sheet-piling, which acts as a retaining wall.

J. Albert Holmes,† M. Am. Soc. C. E.—Although this paper relates particularly to foundations, it has, together with the author's previous investigations, a bearing on another engineering activity, the investigation, design, and construction of earth dams.

While earth dams of moderate height, built 2 000 years ago and more, are still impounding water and have continued to do so for the greater part of their existence, it is only within the memory of most of the older engineers and within the lifetime of many of the younger ones, that modern engineering thought has been directed toward the problems involved. One of these problems, and the principal one, is the selection and proper placing of materials in a structure. Theory and experience have demonstrated that pressures, tending to disruption, exist in the materials being placed in an earthen dam.

* "On Cohesion", *Philosophical Magazine*, Vol. XL, August, 1920, and "Silt", *Minutes of Proceedings*, Inst. C. E., Vol. CCXII, p. 400.

† Hydr. Engr., Pearse, Greeley & Hansen, Chicago, Ill.

To control this tendency a thorough knowledge of the medium used is as essential as in other engineering works. In investigating and studying the character of materials, permeability or ability to resist the flow of water through them, must be determined.

Several factors enter into the phenomena of flow through soils, as actual size of grain, relative sizes of grain, compactness, and colloidal content. A measure of relative size is indicated by the uniformity coefficient, which means a range of sizes such as will produce a dense mass resulting in small passageways and low percentage of voids. In their natural condition (and it is in this condition that use is made of them), soils have a tremendous range in the size of particles. Writers on the subject of colloids have maintained until quite recently that soils contain not more than 2% of material in a colloidal state. To account for the capacity of soils to absorb dyes and gases, it was assumed that they contained absorptive minerals known as zeolites. Upon investigation no zeolite minerals could be identified in soils. Instead it was found that soils contain from 6 to 70% of colloidal material, in which lies their entire absorptive ability. The inorganic colloidal material in soils is chiefly made up of the products of chemical weathering and decomposition of soil-forming minerals, together with organic matter and perhaps some soil minerals of colloidal size.

An average diameter of 1 micron is arbitrarily fixed by the U. S. Department of Agriculture as the upper limit of colloidal size. At and below this dimension the particles cease to be affected by gravity and are subject to Brownian movement when in suspension in a liquid. Also, at the dividing line of 1 micron between colloidal and non-colloidal particles, microscopical control is good, while, with less diameter, points of emanating light might be mistaken for the particle itself. In solution, those particles that diffuse slowly and, after being deposited, are evaporated and separate into a shapeless jelly, are of one class or group. Those that diffuse rapidly and, under the same process, crystallize, are of a second group. Because of their resemblance to glue the substances of the first group are called colloids, from the Greek word, "Kolla", and for the same reason the second group is called crystalloid. Colloidal material occurs in soils in the gel condition.

Professor W. D. Bancroft, of Cornell University, states that colloidal chemistry is the chemistry of every-day life. It certainly touches engineering frequently and at many points: Pavements; water supply; sewage disposal; foundations; concrete and water-proofing of concrete; earth dams; and agriculture.

The U. S. Department of Agriculture, in its Bureau of Soils* and Bureau of Roads, at Washington, has been investigating the subject of colloids for some time, as has the Society's Special Committee on the Bearing Value of Soils for Foundations, etc. The Department of Agriculture is interested in the subject because it bears on the fertility of soils. The retention of moisture and the chemical action of fertilizers are dependent on the quantity and character of colloidal matter present in soils. The colloidal condition of soils enters very materially into the problem of dam construction.

* *Bulletins 1122, 1193, 1311, 1452*, U. S. Dept. of Agriculture.

One of the recent accomplishments of the U. S. Department of Agriculture in its Bureau of Soils was to determine the chemical composition of forty-five samples of soils and subsoils, collected from widely distributed points in the United States and representing many types. Peats and mucks were not included. The colloidal material was extracted from these samples and the chemical composition of both soils and colloids determined. It was found that soils and extracted colloids alike contained the following simple chemical compounds and elements, but in varying quantities:

Silica	SiO_2	Soda	Na_2O
Titanium	TiO_2	Phosphoric acid	P_2O_5
Alumina	Al_2O_3	Sulfur	SO_3
Ferric oxide	Fe_2O_3	Chlorine	Cl
Manganese	Mn O	Water	H_2O
Lime	Ca O	Nitrogen	N
Magnesia	Mg O	Organic matter	....
Potash	K_2O		

Carbon dioxide, CO_2, was obtained from three soil samples and one sample of colloid.

Silica is the principal constituent of soils, and it was found that the colloidal matter is composed mainly of silica, alumina, iron oxide, and combined water, the percentage varying in the samples as follows:

	In Soils.	In Extracted Colloids.
Silica	51.32 to 93.66	31.84 to 55.44
Alumina	2.57 to 22.92	16.42 to 38.28
Iron oxide	0.93 to 13.82	4.66 to 16.67
Combined water	.....	3.33 to 16.56

The colloids in the soils ranged from 6.2 to 57.8 per cent.

The colloidal material differs chemically from the larger soil particles, but separate and distinct compounds were not identified. The colloidal mixtures are very intimate and are without tendency to break up into known compounds. Table 4 illustrates the differences in composition of colloidal matter and whole soil and the coarser particles of soil.

TABLE 4.—AVERAGE COMPOSITIONS OF SOILS, COLLOIDS, AND COARSER MINERALS COMPARED AS PERCENTAGES.

	SiO_2.	Al_2O_3.	Fe_2O_3.	CaO.	MgO.	K_2O.	Na_2O.	Combined H_2O.
Colloidal matter from 45 samples	43.34	26.84	10.41	1.04	1.72	1.43	0.38	9.93
Coarser mineral particles from 35 of the 45 samples	87.2	6.0	1.9	0.5	0.5	1.5	0.9	0.6
Mineral particles in fine sands and silt of a different series of 26 soils	83.3	7.3	1.5	2.0	1.7	2.9	0.9	0.4

The nature of soil colloids is destroyed by heat. Two samples, one of colloidal or ultra-clay, the other of clay soil, made into a number of test

pellets, were subjected to carefully controlled heat. At desired temperatures a part was removed and the temperature was stepped up on the remainder. As the pellets were removed from the furnace, ammonia absorption determinations were made, with the following results:

Colloid Sample:

Temperature, in degrees centigrade	110	265	374	559	754	1130
Cubic centimeter of NH_3 absorbed per cubic centimeter of colloid	110.3	100.8	80.0	74.1	57.5	2.2

Soil Sample:

Temperature, in degrees centigrade	110	190	265	374	522	673	844	1130
Cubic centimeter of NH_3 absorbed per cubic centimeter of soil	27.7	25.3	24.8	19.7	14.9	13.6	7.4	1.4

The colloids were progressively destroyed, and under the high temperatures quite completely destroyed.

Extracting the colloids from a soil to determine the amount of colloidal material is a long and laborious process. A more rapid method, checked by the extraction process, is the use of dyes, gases, and water vapor.

It was found that practically all the colloids in a soil are associated with the finer particles, and very few or none with the coarser parts. Certain ratios were found between component parts of the colloids which gave a correlation. This correlation, associated with rainfall, temperature, and color, has been presented as an index of the soils for agricultural purposes.

The speaker studied the data presented by the experiments with the object of finding a relation that might be used in the selection of soils for dam building. The most satisfactory is that existing between the colloidal content and loss by ignition. The process of incinerating samples of soil to determine their "organic" content is not a new idea, but a knowledge of the colloidal content, carefully determined, of a series of soil samples that have been incinerated, is new.

The relation between colloidal content and ignition loss is shown in Fig. 20, which indicates the determinations from thirty-five samples. The diagram is offered as a means of determining approximately the amount of colloidal material in soils proposed to be used in dam construction. The incineration of a soil can be accurately and quickly done. The extraction of colloidal material from the thirty-five soil samples was almost complete. It may be seen by the diagram that practically all the samples range between 2 to 8% ignition loss and 5 to 35% colloidal content.

The process of sluicing earth by the semi-hydraulic or the hydraulic method, would probably separate less than one-half the amount of colloid that is removed from a soil by laboratory methods; that is, an ignition loss of 5% would not mean that 25% of the colloids could be separated by sluicing, although approximately that amount is in the soil. All of it would be

sluiced, with the finer particles, into the core where, by its gel-like condition and by swelling, it would fill the voids between the particles. It is as undesirable to have too little colloidal material in a dam as too much. Both these extremes should be avoided by the selection of a material containing the right amount of colloids. The colloidal content of core material being placed in a dam may be ascertained by incineration with the assurance that the result is reasonably correct.

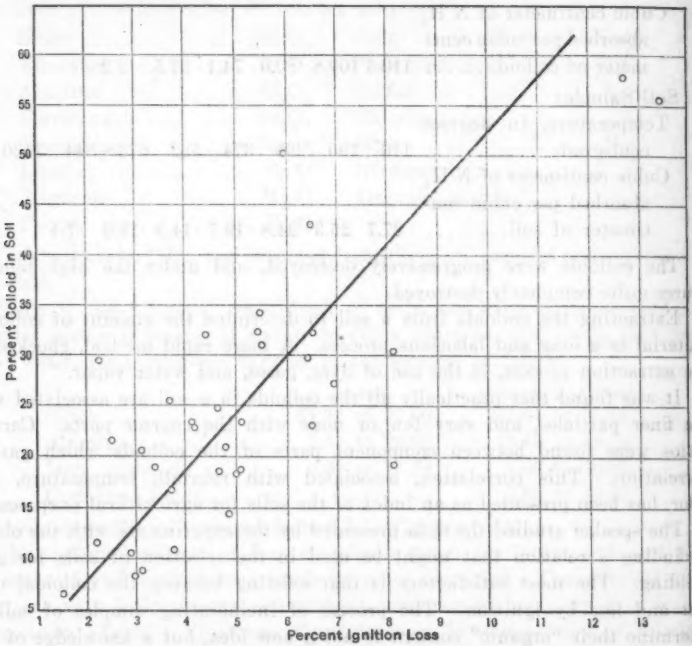

FIG. 20.—RELATION BETWEEN IGNITION LOSS AND COLLOIDAL CONTENT OF SOILS.

No permeability tests were made by the U. S. Department of Agriculture on the soils investigated for colloidal content and chemical composition. The speaker has compiled data, from various sources, on the relation between ignition loss and permeability. These data are given in Table 5, in Columns (5) and (6) of which it may be seen that the percentage of ignition loss increases in reasonable regular order as the permeability rate decreases.

Having this knowledge and having determined the colloidal content of a soil as indicated by Fig. 20, or by a more precise method, a solution of the problem of selecting a proper material for an earth dam is made more possible. Effective size and the uniformity coefficient of a fine-grained soil have no relation to its permeability rate, although a soil having a high uniformity coefficient insures small void spaces and low rates of flow.

A gramme of colloid, containing particles having an average diameter of 91 millimicrons, has a surface area of particles amounting to 24.2 sq. m. Be-

cause of this enormous area the surface forces developed are sufficient to make the colloid a stronger binding agent than Portland cement. This is true only when the material is dry. The experiment cited was not carried beyond a 10% content of the binding agent, although it was sufficient to show that colloidal material is the principal binding agent of soils, giving them cohesiveness according to the moisture content.

TABLE 5.—DATA SHOWING THE RELATION BETWEEN THE COLLOIDAL CONTENT (IGNITION LOSS), AND MAXIMUM RATE OF SEEPAGE THROUGH SOILS.

* "Effective size" is the size of grain in materials than which one-tenth of the sample is finer and nine-tenths coarser. The finer one-tenth controls the seepage rate.

† "Uniformity coefficient" is the relation, expressed as a ratio, between the grain size which has 60% of the sample finer than itself and that which has 10% finer than itself.

‡ "Maximum rate" is the quantity of water, in gallons per acre per day, that will seep through a material, with the loss of head equal to the depth of the material.

In a homogeneous structure, either compacted in layers or consolidated by irrigation, the function of water is to soften the colloids in the dry, hard soil, breaking it up and permitting its particles to re-arrange themselves in a more compact form and by the continued presence of water, in order to keep the colloidal material expanded in the voids of the soil. Colloids have capacities for swelling of from 40 to 150% and a water-holding capacity of 50 to 140 per cent.

Investigation of the permeability rate, combined with a determination of colloidal content and ignition loss, is very much needed. In making a mechanical analysis to determine the uniformity coefficient the "clay" fraction, diameter 0.005 to 0 mm., roughly checks the colloidal content.

The speaker offers the foregoing for consideration and suggests a line of research in soils, physical and chemical as well as mechanical, that will supplement the data given.

JACOB FELD,* ASSOC. M. AM. SOC. C. E. (by letter).—In 1727, Couplet published his monumental work on soil pressures, giving a "complete theoretical analysis of soil physics," and, now, 200 years later, Professor Terzaghi

* Cons. Engr., New York, N. Y.

writes that the science of foundations is of the present and future. From this it must be assumed, that the science of foundations has no past, and there is no possibility of criticizing that statement if the rigid definition of a science is insisted upon. Still, it is difficult to slight such announcements as appear in the *Annales* of the French Academy of Sciences (January 22, 1783) to the effect that the problem of determining the lateral earth pressure was susceptible of a rigorous solution for any special case by the application of the theory outlined on that date by Chauvelot.

The design of foundations has never been based on a true science of foundations, and, to disagree with the author, it is not even now (in 1928) based on any scientific principles. There are, in common use, certain methods on which various types of foundation design are based. Such methods are adaptations of principles of mechanics, taken either from statics or pneumatics, with or without correction factors.

It cannot be expected that the old, although not accurate, methods of design should be discarded in favor of principles from a "science of foundations" when such science does not exist in the common knowledge of the day. As the author states, there is insufficient data available from which even empirical rules may be deduced, and so little is known of the materials which are encountered (soils and rocks) that no skeleton or shelving of general data and hypothesis can be formed as a basis for the accumulation of missing information. Until such a framework can be formed, no one can announce even the birth of a science of foundations.

The present methods for the design of foundations are open to many more criticisms than are enumerated by the author. However, these methods have been used for the preparation of plans for many foundations which, for the large percentage of cases, have been successful. Note that this statement uses the expression "preparation of plans" and not "design". The success of a plan is measured by the result obtained in supporting a superstructure without apparent or measurable danger. The economy of a foundation plan is quite another matter.

It is quite difficult to clear away all this accumulation of precedent and "experience" and suddenly substitute a new "science of foundations." Certainly, it is not a one-man job and no one-man's work can be expected to supply all the necessary frame upon which such a science can be built. The profession should be very thankful to the author for his numerous reports of the past few years, all pointing to the desired goal. It is high time that the Society has produced some constructive results in providing a basis for the development of this much needed science.

The greater part of the work in the subject of soils during the last three centuries has been in the development of the art of foundation construction rather than in the preparation of data for the scientific development of foundation design. The method of shoring or underpinning a structure is far more advanced than the design of the foundation which may be placed under such structure. The chief drawback to the lack of scientific development has been the absence of any authoritative nomenclature or definite stand-

ardization of terms. The tendency has been to copy expressions from the mechanics of solids, although it has been many years since soil mechanics was separated from hydrodynamics and from the statics of solids. Some writers have gone far in the opposite direction, coining new expressions which, often after translation, are crude and misinterpreted or entirely incomprehensible to the reader.

The relation between the size and carrying capacity of a loaded area can never be rigidly fixed by any usable expression. The author deals only with the individual case, corresponding to the case of a single pile, and has omitted entirely the discussion of the effect of loaded areas in close proximity on each other. Even in the individual case, the author has omitted a very important factor, namely, the shape of the loaded area. In the bearing of a solid against a solid, within the elastic limits, the usual assumption that the shape of the loaded area has no effect, probably brings in no appreciable error. The study of loaded plates of various shapes leads one to doubt the accuracy of the assumption. In a perfectly elastic material, with no cohesion and no surface tension, the shape of a loaded area can have no effect. However, in a substance like a clay, there is a resistance to settlement under loads (bearing power, so-called), which is a function of the area and also a function of the perimeter. The latter term is now being disregarded. Some of the author's conclusions should be modified to suit this perimetral resistance. Two circular areas of diameters in the ratio 1:2, loaded equally per unit area, have equal resultant resistances as a function of the area, but the smaller has twice the length of edge per unit area. The smaller area will settle the least.

An equally important problem is the determination of the effect of one loaded area upon adjacent areas. The complexity of such a usual problem as the design of spread footings for the columns of a frame building with its interior and exterior footings as well as square and non-square loaded areas, is appalling when one thinks of the speed with which plans for such footings are being prepared daily. Many instances are known where unequal settlement is very evident. Unfortunately, few such cases are on record.

Still another disregarded factor is the amount and nature of cover (backfill) above the bearing area of a footing. In a few isolated ideal cases, theoretical methods seem to point to the true values of the side frictional support of piers or caissons, based on the formulas of Coulomb and others, centuries old.*

Edge resistance and side-frictional resistance tend to equalize the distribution of resulting carrying capacity per unit base area. The true state of affairs is much closer to the uniform than to the parabolic distribution of the soil reaction. The diagrams in Fig. 3 are an indirect proof of the last statement; for, if the parabolic distribution results in bending moments in continuous footings of more than twice the calculated moment (based on a uniform distribution), it is inconceivable why at least one-half such footings built have not failed. The "factor of safety" of a structure, based on good

* *Engineering News-Record*, Vol. 88, 1922, p. 1052.

concrete and a reduced load-summation design and built with concrete "not quite as good as specified", is certainly in the neighborhood of two.

The writer would like to bring up a problem which has interested him in connection with a recent arbitration in which he was involved. If one of two exactly similar six-story buildings is removed, and replaced by a taller building with footings placed at exactly the same depth as had previously existed, but with greater load intensity, should there be expected a settlement of the adjacent building, which has not been disturbed? Is such a design proper, or should some means be devised to prevent the old building from settling, even if the new footings are not built to any level lower than the sub-grade of the adjoining building? The problem has also some interesting legal aspects. The writer might mention his argument that, even if the new footings are built no lower than the sub-grade of the old ones, their necessary settlement on receiving load will cause them to take a position sufficiently lower to cause a "sympathetic" settlement of the adjoining footings.

The subject of piles for foundation purposes is very ably treated by the author. The objection to the use of the recognized pile-driving formula is a special case of the general objection made by the Belgian scientist, Boussinesq, that all soil pressure designs are fundamentally problems in statics and the experimental work on which such designs are based, is dynamic in method.

As to the basis for a soil classification, the writer* is still of the opinion that:

"* * * the classification of soils and other granular materials should be along the lines of strain characteristics rather than those of stress, namely, elastic strain, plasticity, and fluidity, for these phenomena are evident and measurable, and embrace within them the results of all the stresses which may act. Generally speaking, the elasticity factor will take care of the solid, the fluidity of the fluid, and the plasticity of the colloid properties of the material being classified."

W. S. HOUSEL,† ASSOC. M. AM. SOC. C. E. (by letter).—Without doubt, it is a source of satisfaction to many to see a revival of interest in the problem of the bearing value of soils. A number of men, including the author, have devoted a great deal of time and effort to a better understanding of foundation problems from the standpoint of soil conditions.

During 1927, the writer, acting for the Board of Wayne County Road Commissioners at Detroit, Mich., has been engaged in conducting a most extensive series of tests to determine the bearing value of soils. The work has been done in the field, under conditions governing actual construction, and, at the same time, every effort has been made to keep the accuracy of the data comparable to what might be obtained with a similar set-up in the laboratory.

More than fifty tests have been made on different sizes and shapes of bearing areas, some tests on piles, and some on combinations of bearing plates and piles. Measurements of lateral pressure and a study of the general phenomena of the transmission of pressure in soils constitute an important part of the

* *Transactions*, Am. Soc. C. E., Vol. LXXXVI (1923), p. 1567.
† Instr. in Civ. Eng., Univ. of Michigan, Ann Arbor, Mich.

investigation. The laboratory work is being conducted by the Civil Engineering Department of the University of Michigan. Through the courtesy of the Michigan State Highway Department, the facilities of the State Highway Laboratory have been made available for this work. With the field results of this investigation at hand a few comments on the principles of soil action as outlined by Professor Terzaghi may be of interest.

The most consistent results of all the tests made by the writer indicate that there are two factors of strength by virtue of which cohesive soils, such as clay, are capable of supporting loads. One of these factors is the shearing resistance on the perimeter of the bearing area; the other is the resistance of the soil to compression, due to a condition of strain set up in the soil around the bearing area. This last phenomenon has been called a pressure bulb.

During the progress of a test it is noticeable that the first failure taking place is failure in shear along the perimeter of the bearing area. In the latter part of the test there is a noticeable upheaval of soil surrounding the bearing area which indicates that a condition of strain exists. That this upheaval cannot be classified merely as flow of soil from beneath the bearing plate is shown by the fact that for some time after the upheaval is first noted the bearing plate continues to support the increased load applied with relatively small settlements. This action continues with increased loads up to a rather definite point of failure, at which point the soil flows from beneath the bearing plate with apparently no restraint. This marks the point at which the pressure bulb fails.

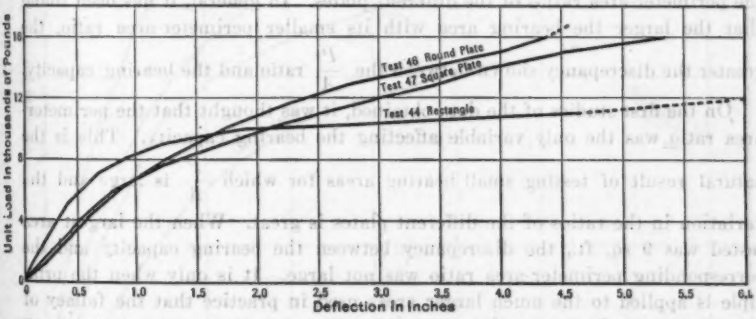

FIG. 21.—COMPARISON OF DIFFERENT SHAPED PLATES OF SAME AREA, 4 SQUARE FEET.

The load deflection diagrams obtained by the different tests bear out these general observations. Fig. 21 shows a set of typical load deflection diagrams, in this case for three different bearing plates, each with an area of 4 sq. ft. As shown, one plate was round, one square, and the third rectangular, with a ratio of width to length of 1 to 7. The round plate has a perimeter-area ratio, $\frac{P}{A}$, of 1.78; the square plate, of 2.0; and the rectangular plate, of 3.04. The material is stiff yellow clay and the size of the test pit is the same as the bearing plate, 4 sq. ft.

It is significant that, in the first part of the tests, the range of bearing capacity in which shear failure about the perimeter is taking place, the relation between the bearing capacity of the several plates is similar to the relation between the values of x for the different plates. The bearing capacities are not in exact proportion to x because, even in their lower ranges, the pressure bulb is beginning to have some effect as a factor of strength.

In the latter part of the test, in the range of bearing capacities where the pressure bulb is a controlling factor, there is a complete reversal of bearing capacity relations. The plates with the largest $\frac{P}{A}$ values have the smallest bearing capacities. The important consideration in upper range of capacities is the effectiveness with which the different shaped plates adjust themselves to the pressure bulb. The strained condition in the soil, giving rise to the phenomenon of the pressure bulb, tends to become circular. Thus, the round plate is the best shape to take advantage of this factor of strength, the square plate is not quite so good, and the rectangular plate is the least effective of all.

Fig. 22 shows the load deflection diagrams obtained by testing areas of 1, 2, 4, and 9 sq. ft. in the same shape of plate. As in Fig. 21, the material is yellow clay and the pit is the same shape and size as the bearing plate in each case. The decreased capacity of the larger plates with smaller values of $\frac{P}{A}$ is the first impression gained from a study of these diagrams. Again, it is significant that the variation in bearing capacity is not in direct proportion to the perimeter-area ratios of the different plates. In general, it has been found that the larger the bearing area with its smaller perimeter-area ratio, the greater the discrepancy shown between the $\frac{P}{A}$ ratio and the bearing capacity.

On the first studies of the data obtained, it was thought that the perimeter-area ratio was the only variable affecting the bearing capacity. This is the natural result of testing small bearing areas for which $\frac{P}{A}$ is large and the variation in the ratios of the different plates is great. When the largest area tested was 9 sq. ft., the discrepancy between the bearing capacity and the corresponding perimeter-area ratio was not large. It is only when the principle is applied to the much larger areas used in practice that the fallacy of this assumption becomes apparent.

However, for the purpose of discussion, it may be profitable to start with this assumption, which is admitted to be false, and develop the principle as applied to the action of soils and see where it leads. It is assumed that the bearing capacity of two spread foundations of different sizes is proportional to their perimeter-area ratios, the settlement being constant in both cases.

Let p be the bearing capacity, P, the perimeter, and A, the area of the footings considered. Then, for a constant settlement in the two footings, and according to the assumption,

$$\frac{p_1}{p_2} = \frac{P_1}{A_1} \div \frac{P_2}{A_2} \quad \ldots \ldots \ldots \ldots \ldots \ldots \ldots \ldots \ldots \ldots (7)$$

If the bearing areas considered are round: $P_1 = \pi D_1$; $P_2 = \pi D_2$; $A_1 = \frac{\pi D_1^2}{4}$; and $A_2 = \frac{\pi D_2^2}{4}$. Substituting these values in Equation (7) and simplifying:

$$\frac{p_1}{p_2} = \frac{D_2}{D_1} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

If the bearing areas are square: $P_1 = 4 D_1$; $P_2 = 4 D_2$; $A_1 = D_1^2$; and $A_2 = D_2^2$. Again, substituting in Equation (7) and simplifying:

$$\frac{p_1}{p_2} = \frac{D_2}{D_1} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

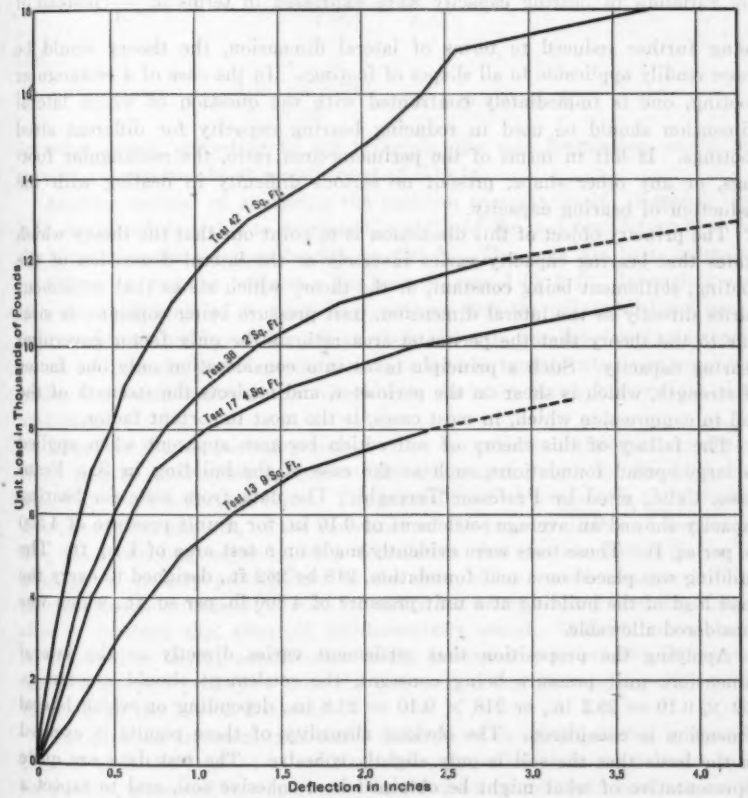

FIG. 22.—COMPARISON OF ROUND PLATES WITH DIFFERENT AREAS.

Thus, it would seem that bearing capacity varies inversely as the diameter in round plates, and inversely as the lateral dimension in the square plates, when the settlement is constant. If the bearing capacity or unit pressure were kept constant, the settlement would vary directly as the lateral dimension, being of course greater for the larger bearing areas. This conclusion,

based on an assumption which is believed to be false, corresponds exactly to the theory as stated by Professor Terzaghi. As has been shown, this mistaken theory is the natural result of insufficient data on small sizes of test areas.

Aside from the consideration that the theory is based on a false assumption, there seems to be additional objection to the use of such data as have been obtained, in terms of settlement for different sizes of foundations. To state the theory in terms of bearing capacity for a given settlement seems to be more direct and better adapted to application to practical problems than to leave it in terms of settlement for a given unit pressure. In addition, if the variation in bearing capacity were expressed in terms of $\frac{P}{A}$, instead of being further reduced to terms of lateral dimension, the theory would be more readily applicable to all shapes of footings. In the case of a rectangular footing, one is immediately confronted with the question of which lateral dimension should be used in reducing bearing capacity for different sized footings. If left in terms of the perimeter-area ratio, the rectangular footings, or any other shape, present no serious difficulty in dealing with the reduction of bearing capacity.

The primary object of this discussion is to point out that the theory which states that bearing capacity varies inversely as the lateral dimension of the footing, settlement being constant, or the theory which states that settlement varies directly as the lateral dimension, unit pressure being constant, is similar to the theory that the perimeter-area ratio is the only factor governing bearing capacity. Such a principle takes into consideration only one factor of strength, which is shear on the perimeter, and neglects the strength of the soil in compression which, in most cases, is the most important factor.

The fallacy of this theory of soil action becomes apparent when applied to large spread foundations, such as the case of the building in San Francisco, Calif., cited by Professor Terzaghi. The data from tests for bearing capacity showed an average settlement of 0.10 in. for a unit pressure of 4 800 lb. per sq. ft. These tests were evidently made on a test area of 1 sq. ft. The building was placed on a mat foundation, 218 by 252 ft., designed to carry the dead load of the building at a unit pressure of 4 800 lb. per sq. ft., which was considered allowable.

Applying the proposition that settlement varies directly as the lateral dimension, unit pressure being constant, the settlement should amount to $252 \times 0.10 = 25.2$ in., or $218 \times 0.10 = 21.8$ in., depending on which lateral dimension is considered. The obvious absurdity of these results is excused on the basis that the soil is only slightly cohesive. The test data are quite representative of what might be obtained in a cohesive soil, and to expect a settlement under such conditions comparable to the results obtained from the equations given, would be no less absurd, even if the soil were of the most cohesive type.

To analyze the test data obtained in the example under consideration in terms of bearing capacity instead of settlement leads to an interesting result. Suppose that it was decided to set 0.10 in. as the limiting settlement, and it

was desired to find the bearing capacity of a mat foundation, 218 by 252 ft., which would not exceed this limiting settlement. It is assumed that the tests were made on a round plate (1 sq. ft.) with $\frac{P}{A}$ equal to 3.55. The perimeter-area ratio of the mat foundation is,

$$\frac{(218 \times 2) + (252 \times 2)}{218 \times 252} = 0.017$$

Let p be the bearing capacity of the large foundation. Using the direct ratio of bearing capacities to perimeter-area ratios:

$$\frac{p}{4\,800} = \frac{0.017}{3.55}$$

and,

$$p = \frac{0.017 \times 4\,800}{3.55} = 23.0 \text{ lb. per sq. ft.}$$

In other words, according to the principle, the mat foundation would not support its own weight at a settlement of 0.10 in.

Another method of analyzing the problem presents itself. Suppose that it is considered desirable to increase the width of the mat foundation by 1 ft., the dimensions would then be 219 by 252 ft. The area has been increased by 252 sq. ft. and the perimeter has been increased by 2 ft. In such a case it would be difficult to convince any engineer that the only additional carrying capacity gained by adding 252 sq. ft. to the area was the shearing strength on an additional 2 ft. of perimeter. Yet that is exactly what the principles under discussion mean, inasmuch as x is the only factor involved in their application.

In spread foundations of practical sizes, the perimeter-area ratio is always small and in such cases to neglect the shearing strength on the perimeter would not lead to serious error. The other factor of strength is the compressive strength of the soil, or the resistance of the pressure bulb to deformation. The total carrying capacity of a foundation due to this second factor of strength is directly proportional to the area. This would seem to indicate that the much criticized practice of using the same bearing capacity for all sizes of footings was, after all, fundamentally sound. This statement could be defended as having considerable merit, inasmuch as it involves less departure from sound principles than the proposition that bearing capacity varies inversely as the lateral dimension.

The greatest criticism that could be made of existing practice in foundations is that the selected allowable bearing capacity is in most cases based on a guess, governed by experiences in previous foundations, and not on the most reliable information. It seems fair to make the statement that, at present, the only reliable method of determining bearing capacity is by actual test.

Inasmuch as it is not feasible to test areas as large as the practical footing, the tests on smaller areas seem to be the only solution. The small areas involve a large perimeter-area ratio and the shearing strength on the perimeter

is a very considerable factor of strength. It thus becomes necessary in reducing the bearing capacity to practical sizes, to consider this factor, but not to the exclusion of the other and more important factor of strength due to the resistance of the soil to compression.

The equation for bearing capacity that the writer has found most useful in interpreting test data, and which fits the test data most satisfactorily, includes both factors of strength.

Let p = bearing capacity, in pounds per square foot.
m = shear on the perimeter, in pounds per linear foot.
n = resistance of the soil to compression, in pounds per square foot.
P = perimeter of bearing area, in feet.
A = area of footing, in square feet.
W = total allowable load on the footing.

Then,

$$W = A\,p = P\,m + A\,n$$

and,

$$p = \frac{P\,m}{A} + n \qquad (10)$$

Let the perimeter-area ratio, $\frac{P}{A} = x$; then,

$$p = m\,x + n \qquad (11)$$

A study of the form of Equation (11) reveals that it is a linear function involving two variables, namely, bearing capacity and perimeter-area ratio. If the bearing capacity for a certain type of soil is determined by test for two bearing areas having different perimeter-area ratios, it is possible to solve the two resulting equations for the constants, m and n. Having thus determined the shearing strength on the perimeter and the compressive strength of the soil for which the tests were made, the bearing-capacity equation (Equation (11)) can be used to determine the allowable unit pressure for larger footings such that the limiting settlement will not be exceeded.

In Fig. 23 bearing capacity has been plotted against perimeter-area ratio and the corresponding equations for these curves are noted in Table 6. Curves 1, 2, 3, and 4 are bearing capacities for a 1-in. deflection, which was taken as the allowable settlement. Curves 5 to 10 are for the bearing-capacity limit, which is defined as that unit pressure beyond which progressive settlement takes place. It is the unit pressure beyond which the material acts as a viscous fluid, and the consolidation of the material is not sufficient to permit a condition of equilibrium to be attained with a comparatively small amount of settlement.

These equations and curves have been determined by series of tests on the three different types of soil indicated as yellow clay, stiff yellow clay, and blue clay. This classification is merely used as identification and is not intended to have any other connection with the physical characteristics of the material. These characteristics are given by Figs. 21 and 22.

There are a few points worthy of emphasis in connection with this set of bearing-capacity equations and curves (Fig. 23):

(1) As the size of the footing is increased and x approaches zero the bearing capacity approaches, not zero, but a constant value which is the compressive strength of the soil, and is indicated as the intercept on the load axis.

(2) For a type of soil which has a high degree of fluidity and low cohesive strength the bearing capacity is more nearly constant for all sizes, indicating that x is the least important factor in the bearing capacity.

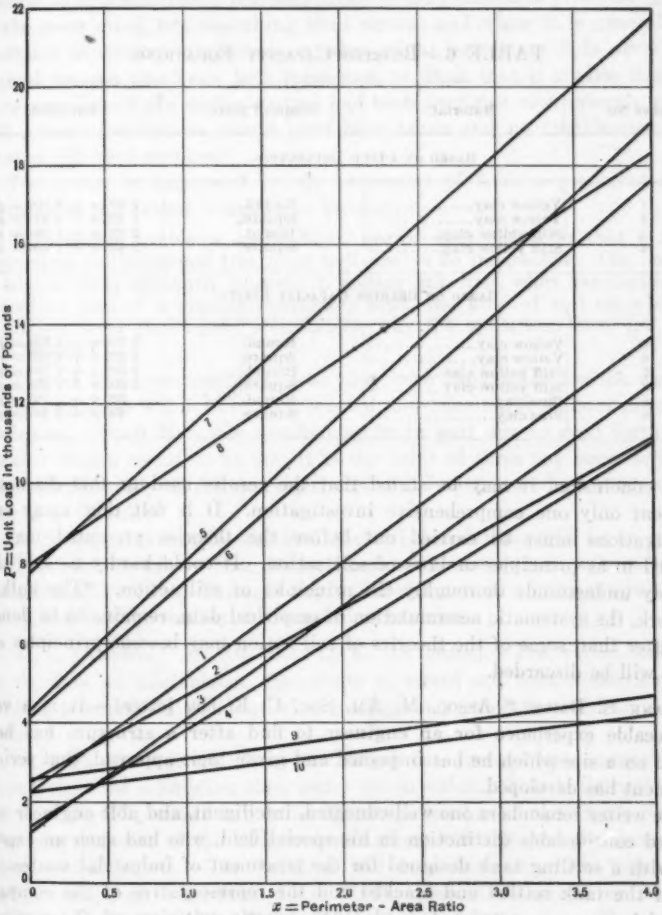

FIG. 23.—BEARING CAPACITY CURVES.

(3) In practical sizes of footings, having perimeter-area ratios between 0 and 1, the shape of the footing, whether round or square, is not so important. This is consistent with the idea that the loss in bearing capacity (as controlled by the pressure bulb), due to the sharp corners, is a smaller part of the total

bearing capacity in large footings. In the smaller areas used in the tests, the loss due to sharp corners is large in proportion to the total area of the plates.

(4) In a type of soil, such as the blue clay, having a high degree of fluidity, the pressure bulb is a controlling factor throughout, and the difference in bearing capacity, due to the shape of the plate, is practically constant. This is clearly shown by the fact that Curves 9 and 10 (Fig. 23) are almost parallel.

TABLE 6.—BEARING CAPACITY EQUATIONS.

Curve No.	Material.	Shape of plate.	Equation.
	BASED ON 1-INCH DEFLECTION.		
1	Yellow clay	Round.	$2\,880\,x + 2\,260 = p$
2	Yellow clay	Square.	$2\,150\,x + 2\,530 = p$
3	Stiff yellow clay	Round.	$2\,820\,x + 1\,260 = p$
4	Stiff yellow clay	Square.	$2\,420\,x + 1\,420 = p$
	BASED ON BEARING CAPACITY LIMIT.		
5	Yellow clay	Round.	$3\,700\,x + 4\,300 = p$
6	Yellow clay	Square.	$3\,370\,x + 4\,170 = p$
7	Stiff yellow clay	Round.	$3\,500\,x + 7\,780 = p$
8	Stiff yellow clay	Square.	$2\,600\,x + 7\,950 = p$
9	Blue clay	Round.	$520\,x + 2\,580 = p$
10	Blue clay	Square.	$490\,x + 2\,250 = p$

In conclusion, it may be stated that the results used in this discussion represent only one comprehensive investigation. It is felt that many such investigations must be carried out before the theories presented may be referred to as principles or laws of soil action. It could hardly be said that anybody understands thoroughly the principles of soil action. "The bulk of the work, the systematic accumulation of empirical data, remains to be done"; and, after that, some of the theories of soil action may become principles and others will be discarded.

FRANK S. BAILEY,* ASSOC. M. AM. SOC. C. E. (by letter).—It is a very disagreeable experience for an engineer to find after a structure has been erected on a site which he has inspected and given tacit approval, that serious settlement has developed.

The writer remembers one well-educated, intelligent, and able engineer who attained considerable distinction in his special field, who had such an experience with a settling tank designed for the treatment of industrial wastes. A part of the tank settled and cracked and the representative of the company for which it was constructed, made such caustic criticism of the engineer that he, in turn, was filled with resentment and anger. This engineer died at a comparatively early age and a promising career was cut short.

Another well and favorably known engineer who reached still greater distinction, had a similar experience on a larger scale when a considerable por-

* Structural Designer, New England Power Constr. Co., Boston, Mass.

tion of the sewage treatment plant which he had designed also settled enough to require much expenditure for repairs. This engineer died before his prime, and in both these cases the disappointment and chagrin caused by the imperfection of their finished work may have been contributory causes to their unfortunately early deaths.

Both these engineers may have given and probably did give what they believed to be a sufficiently thorough study to the foundation problems involved in the cases cited, but something went wrong, and while it is generally unprofitable to attempt conjecture on what might have been, it is nevertheless natural for one who knew both these men to think that if studies similar to those recorded in the author's paper had been available soon enough, perhaps still greater precautions would have been taken and no troublesome settlement would have occurred.

The writer is impressed by the statement of such a proficient mathematician as the author is known to be, that,

"Foundation problems, throughout, are of such character that a strictly theoretical mathematical treatment will always be impossible. The only way to handle them efficiently consists in finding out, first, what has happened on preceding jobs of a similar character; next, the kind of soil on which the operations were performed; and, finally, why the operations have led to certain results."

The writer knows engineers who have been responsible for the design of many structures which have been erected and have stood without appreciable settlement. Such favorable results may be in part due to good fortune, but another reason seems to be that it is the habit of these engineers to make a most careful study of the characteristics of the earth on which a given structure is to be built.

Although it cannot be expected that all foundations will be so perfectly designed in the future that no settlements of consequence will occur, it is certain that Professor Terzaghi has acquired much new information that can be applied to improvement in foundation practice.

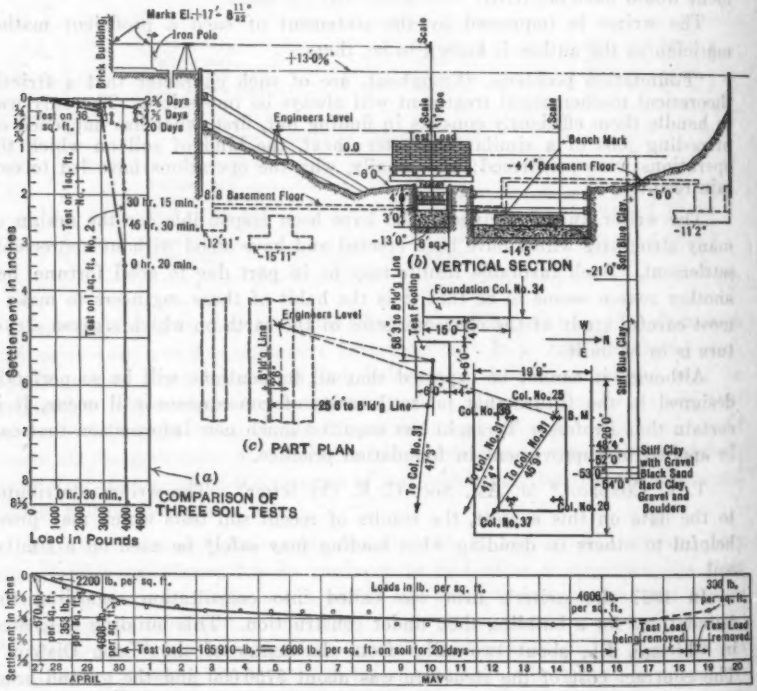
T. L. Condron,* M. Am. Soc. C. E. (by letter).—The writer contributes to the data on this subject, the results of recent soil tests which may prove helpful to others in deciding what loading may safely be used on a similar soil.

In 1927 the writer's firm was called into consultation regarding the foundations for a building then under construction. This building is located in Chicago, Ill., about two miles from the center of the "Loop District". The contract cost of the structure was about $750 000 and the ground area, about 13 000 sq. ft. The building had been designed with "spread footings", resting on clay, from 20 to 30 ft. below street grade, or from 6 to 16 ft. below Chicago City Datum (Lake level). At the time the consultants were called in, the general excavation was nearly completed down to Elevation — 6.0, or 20 ft. below street grade, and five of the footings, or about 20% of the foundations, were in place. Some question had arisen as to the bearing power of the soil and two soil tests had been made by the Contractor

* Cons. Structural Engr. (Condron & Post), Chicago, Ill.

under the direction of the Architect. The results of these two soil tests caused great concern to all. For each test, a load of 4 000 lb. was placed on an area of 1 sq. ft. The settlement under the first test was reported as $8\frac{1}{2}$ in. in 30 min., and for the second test, $2\frac{9}{16}$ in. in 45 hours. The second test was reported as being made in accordance with the recommendations of the Society's Special Committee on the Bearing Value of Soils for Foundations. The results of these two tests as reported to the writer are shown in Fig. 24(*a*), as well as the result of a third test which is described later.

In view of the very unfavorable showing of these two tests, it was proposed to remove the five spread footings that were in place and substitute for all foundations, concrete cylinders extending down to hardpan, at an estimated extra expense of $55 000 to $60 000.



(*d*) DIAGRAM OF SETTLEMENT UNDER TEST LOAD ON 36 SQ. FT.

FIG. 24.

It seemed surprising that the clay, which was fairly stiff and difficult to excavate, offered no better support than was shown by the two tests reported, since they had presumably been made on undisturbed clay at the depth of the proposed footings. However, as the situation was apparently so serious and the expense for the proposed change so large in proportion to the total cost of the project, the writer proceeded to investigate the condition of other

buildings of similar height and character in the immediate vicinity. The proposed building was intended for non-commercial use and was to be only six stories high, except for a tower to enclose tanks. Several buildings were found near-by resting on spread footings designed for a soil pressure of 4 000 lb. per sq. ft. and none of these buildings showed any evidence of unequal settlement although they were from 10 to 15 years old. The footings for the proposed building were to be loaded to not more than 3 000 lb. per sq. ft. Consequently, the consultants recommended that a further soil test be made before arriving at a decision.

In making this test it was felt that, so far as possible, the conditions should be as nearly identical as possible with those for the designed footings. Consequently, a location was selected (see Fig. 24 (*c*)), where a test footing 6 ft. square could be built and left in place without interfering with any part of the general foundation work. An excavation was made from Elevation — 6.0 to Elevation — 13.0, a depth of 7 ft. The upper 4 ft. of this excavation was sheeted and braced and the lower 3 ft. carefully cut to size and filled with 1 : 2.5 : 3.5 concrete (Fig. 24(*b*)). The lower end of a 1½-in. steel pipe, 20 ft. long, to which a gauge was to be attached for readings, was embedded in the concrete block. When the concrete had hardened, a timber grillage was built on which was placed a timber platform to receive the test load of pig iron. Bench-marks were established on one of the footings in place and on near-by buildings and light poles. The arrangement of this test and its location with reference to two footings then in place and to proposed footings, is clearly shown in Fig. 24(*b*) and Fig. 24(*c*). On this diagram is also shown to scale the result of a typical boring which disclosed "blue clay" increasing in stiffness down to Elevation — 52.0, where clay mixed with gravel was found.

Careful level readings were taken on this test footing as the test load was applied, as shown on Fig. 24(*d*), the initial reading being taken when the load of the concrete and platform was 23 970 lb., or 670 lb. per sq. ft. on the soil. On the third day the total load, including the pig iron, was 165 910 lb., or 4 608 lb. per sq. ft. on the soil. At that time the settlement recorded was one-thirty-second more than ¾ in. After the test load had been in place 12 days, the total settlement was measured as one-thirty-second more than ¾ in. and no further settlement could be measured during the next 7 days. The test load was then removed and a rebound of ⅛ in. was recorded. It is interesting to compare the results of this test with the results of the first two tests, as shown in Fig. 24(*a*).

In the writer's opinion this test warrants the conclusion that 3 000 lb. per sq. ft. would be an entirely safe load on this soil. The client was so advised and work was resumed on the building. The full weight of the building has now (1928) been on the foundations for a month or two and no measurable settlement has been reported during the period of construction.

LAZARUS WHITE,* M. AM. SOC. C. E. (by letter).—In the Nineties, when the writer was an undergraduate student, he was thoroughly imbued with the classical methods of computing earth pressures, bearing values of soil,

* Pres., Spencer, White & Prentis, Inc., New York, N. Y.

distribution of pressures, and pile-driving formula commonly taught—Rankine, Baker, Cain, and Wellington—and, after his graduation, he set about to apply them. Fortunately, he was also imbued with the scientific philosophy of Tyndall and Huxley—to accept no theories or formulas unless borne out by experiment. Huxley stated that one clear experiment not accounted for by the accepted theory might forever upset that theory.

The writer's first foundation experience, involving much wood pile-driving, had a disastrous effect on his faith in the *Engineering News* formula. No single experiment conformed to it and to "hit the target" of an observed result, was like shooting at a distant pin with a blunderbuss. Later, during subway construction, he observed that contractors completely and successfully ignored Rankine and Cain in timbering work, and "got away with it" in so many instances that by no scientific philosophy could their theories be justified. Again, his faith in Baker's "Masonry" was upset by the observation that uniform loading did not produce uniform settlement. Hence, with practically all the classical notions upset, the writer decided to observe foundation phenomena for himself and to accumulate data bearing on a new science of foundations.

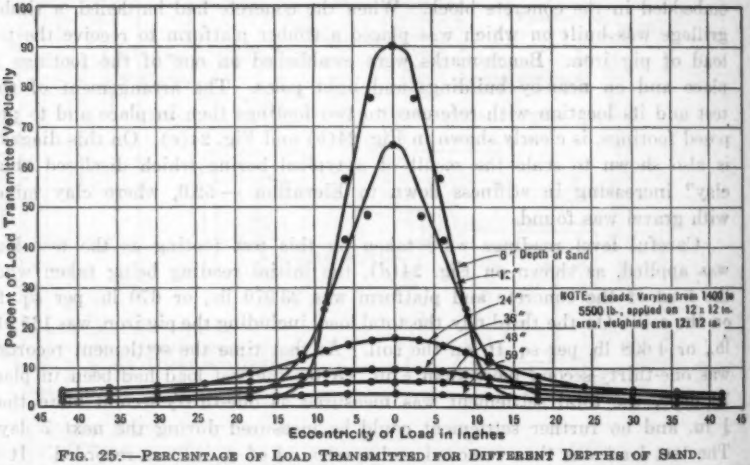


FIG. 25.—PERCENTAGE OF LOAD TRANSMITTED FOR DIFFERENT DEPTHS OF SAND.

In 1914, during extensive underpinning operations along William Street, in New York City, many steel cylinders, 14 in. in diameter, were driven by hand hydraulic jacking into ground composed of varying mixtures of sand and clay. This afforded an opportunity to measure accurately the pressures applied. During the work the elastic properties of earth were observed, especially the rebound after releasing the load, and these were plotted by the engineers of the Public Service Commission of New York.* In 1915, Mr. J. A. Moyer and Professor Fehr, at Pennsylvania State College, published the results of tests† in the distribution of soil pressures measured at various

* *Engineering News*, Vol. 85, No. 27, p. 1268, Fig. 2A.
† *Engineering Record*, Vol. 71, No. 11, March 13, 1915, p. 330.

depths and various eccentricities in relation to the applied loads. (See Fig. 25.) Using these observations as a basis, John F. Greathead, Assoc. M. Am. Soc. C. E., Section Engineer in the days of the William Street Subway, plotted lines of equal vertical pressure beneath a 13½-in., circular plate,* disclosing in a manner which can be readily grasped the general distribution of pressure beneath a footing. This he called the "bulb of pressure"; so far as is known, it was the first time such a diagram was published. (See Fig. 26.) Due to the manner in which the experiments were made—the pressure being recorded on an area equal to the area originating it—Fig. 26 does not show the variations in pressure immediately beneath the footing.

M. L. Enger, M. Am. Soc. C. E., published another bulb of pressure and, because of the use of smaller recording areas, was able to show variations in pressure immediately below the footings. (See Fig. 27.) In general form his diagram is similar to that of Mr. Greathead, but it is more accurate.†

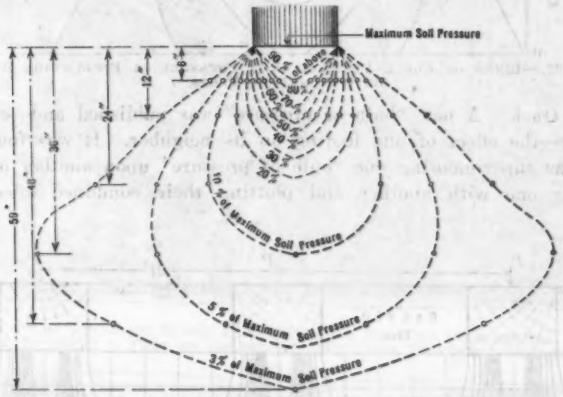

FIG. 26.—LOAD DISTRIBUTION BY BULB OF PRESSURE.

At the same time Professor Enger discovered the great variations in intensities of pressure under footings of different areas, as compared with average unit loads. His formula for such variations is $p = 91 \frac{d^{1.86}}{h^{1.95}}$, in which, p is the ratio (percentage of average unit load) at the depth, h, immediately below the center of the footing, and d is the diameter of the footing. This is of great interest, because if it is assumed that the soil has elastic properties and that a stress-strain relation exists (the applied loads giving the stress and the settlements, the strain or compression), the bearing value of large footings cannot be directly proportional to their areas.

Later, the Joint Committee on Stresses in Railroad Track of the Society and the American Railway Engineering Association in its report,‡ showed the stresses in ballast below railroad ties as ascertained by an elaborate

* *Engineering News-Record*, December 30, 1927, Fig. 3, p. 1037.
† *Engineering Record*, Vol. 73, No. 4, January 22, 1916, p. 106.

apparatus. Of special interest was a pressure capsule by which intensities of pressure at various points through a mass of ballast could be determined simultaneously. This report is a mine of information for the foundation engineer, especially the full demonstration of the elasticity of the soil beneath

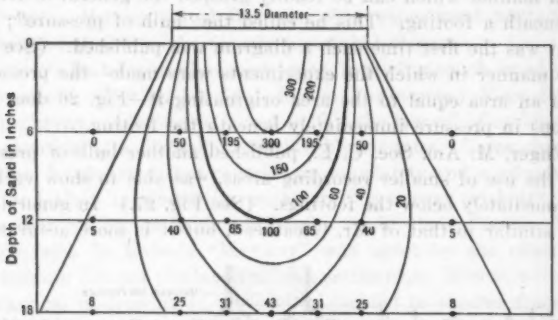

FIG. 27.—LINES OF EQUAL VERTICAL UNIT PRESSURE IN PERCENTAGE BASED ON 4-INCH PLUG TESTS.

a railway track. A new "bulb of pressure" was published and—even more interesting—the effect of one footing on its neighbor. It was found to be the same as superimposing one "bulb of pressure" upon another or, rather, overlapping one with another and plotting their combined effect. (See Fig. 28.)

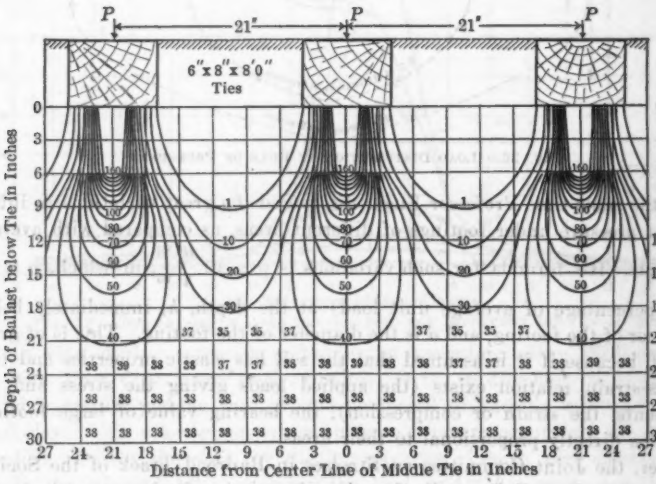

FIG. 28.

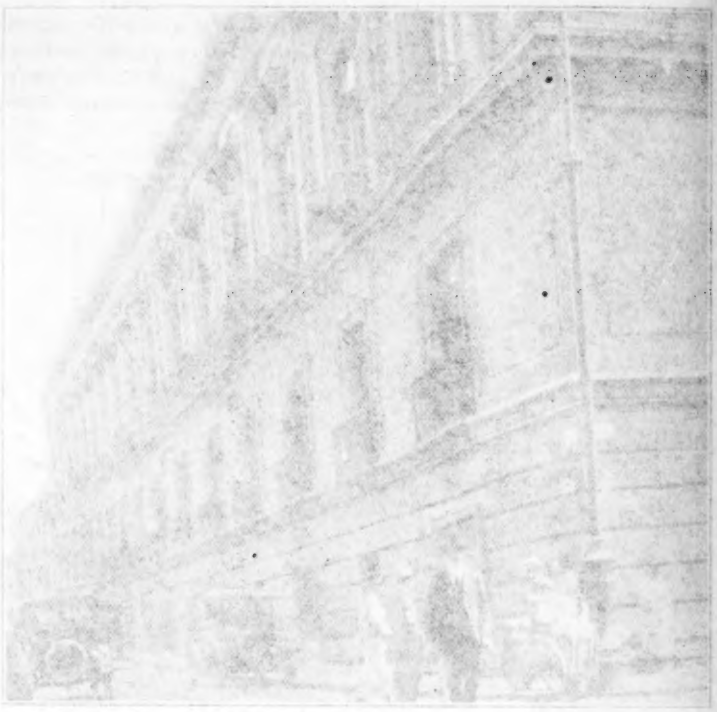
In 1925, A. T. Goldbeck, Assoc. M. Am. Soc. C. E., published* a curve indicating that the bearing values of footings or loads for equal settlement

* *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 264.

FIG. 29.—VIEW OF SCHOOL OF MINES, CITY OF MEXICO, SHOWING DIFFERENTIAL SETTLEMENT OF ABOUT 3 FEET AT CENTER OF A BUILDING UNIFORMLY LOADED.

FIG. 30.—VIEW OF NATIONAL THEATRE, CITY OF MEXICO, SHOWING 6-FOOT SETTLEMENT OF BUILDING AND ENTIRE AREA AROUND IT.



were not proportional to areas, but to diameters. Mr. Goldbeck invented a pneumatic pressure gauge, with electrical contacts,* which gave very accurate results. For bearing blocks of 0.371 to 8.33 sq. ft., the device checked the Enger formula quite closely.

In the writer's experience, buildings on compressible soil do not settle uniformly, but in parabolic or catenary curves; the center of the building settles much more than the perimeter. This is particularly marked in the City of Mexico where numerous structures show the characteristic curve in their courses. The reason for this should be apparent from data given herein. Since buildings exert pressure on huge areas, the intensity of pressure at the center is very great, and they cause a corresponding compression of the ground, so that the building finally assumes a dished shape. (See Fig. 29.) The fallacy of the old assumption that structures, uniformly loaded, settle uniformly, is thus graphically shown. Fig. 30 shows the settlement of a building with the entire area around it. The original level of the building was the same as the sidewalk. The total settlement was approximately 6 ft.

The Society's Special Committee on Bearing Value of Soils for Foundations, etc., has performed its work painstakingly, but in a field very difficult and rather barren of results; that is, soil classifications and nomenclature to define soils. An infinite number of definitions can be made and yet one may be "left in the dark". Professor Terzaghi has taken foundation engineers "out of the woods" as far as nomenclature is concerned, and, by establishing a few simple physical classifications, it now seems possible to evaluate soils in terms of bearing power.

In describing the characteristics of clay and its behavior in the presence of water due to viscosity and surface tension, he performed a valuable service. Recently, in Detroit, Mich., while excavating in clay and tapping wet areas under pressure, subsidence of surrounding buildings was observed which conformed to the principle laid down by Professor Terzaghi. A wet clay layer, in which water was supplied from seamy bed-rock below, when tapped at a depth of about 100 ft., yielded a considerable quantity of water. Simultaneously with the pumping of this water, settlements of neighboring buildings, several hundred feet away, were noted. Through the underlying rock the water beneath the subsiding area was partly drained—thus causing shrinkage in the wet clay layer above, which was equivalent to superimposing a load sufficient to squeeze the same volume of water out of the clay.

Another effect, noted at Detroit and Albany, N. Y., was that the wrecking or removal of buildings was followed by slight settlement of neighboring structures, where the region was underlaid by a stratum of wet clay.

It has been long observed that buildings on compressible soil do not settle uniformly as to time, but rapidly at first and then more and more slowly. This has been vaguely ascribed to the fact that water is squeezed from the saturated soil below; but by means of the "thermodynamic parallel", Professor Terzaghi has been able to evaluate this phenomenon and to plot a theoretical time-settlement curve of great value. This also has a geological application to alluvial deposits, and indicates that thousands of years may

* *Proceedings*, Am. Soc. for Testing Materials, Vol. XVI, p. 309, 1916.

elapse before an alluvial deposit is consolidated. In this connection the geology of a stratum is of great significance in locating valuable structures. Nearly all old geological strata are fully consolidated and, therefore, have great bearing capacities, whereas recent alluvial deposits bordering streams, old ponds, or lake beds are dangerous. The latter are not fully consolidated, and their excess of water beyond that which is normal for the old strata is not yet squeezed out. Although the deposit may seem stable, an additional load will cause a flow of water and a subsidence or settlement. In some situations a trained geologist may be a better guide than the engineer, even if the latter has had much experience with foundations, and none in theoretical geology.

To illustrate how a structure settles, the information given in Figs. 31 and 32 is very interesting. Fig. 31 is the plan of a building on which settlements were observed between 1920 and 1924. Fig. 32 (*a*) to Fig. 32 (*g*), inclusive, illustrates the catenary curves of walls resting on compressible soil. The various curves show that the time settlements are rapid at first and then become slower.

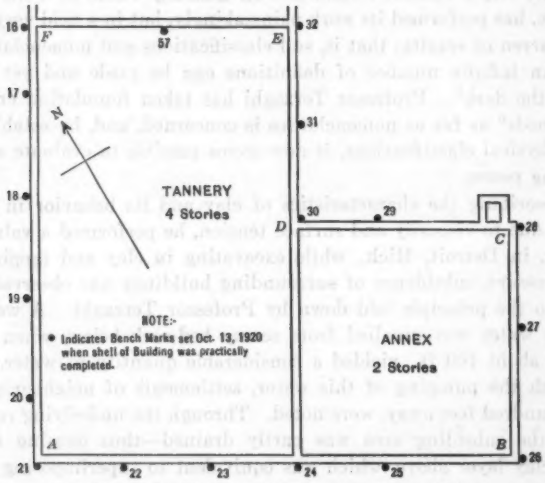


FIG. 31.—PLAN SHOWING LOCATION OF BENCH-MARKS.

The materials beneath the building were thoroughly explored. All test holes (see Fig. 32 (*b*)) were drilled 7 ft. south of the face of the south wall (*A-B*) and about 1 ft. inside the curb line. At Bench-Mark 20 (Fig. 32 (*b*)), a pipe was pushed to about 37 ft. Light driving sent it down to 41.7 ft. At this point the penetration was about $\frac{3}{4}$ in. per blow until, at a depth of 47.2 ft., the last twenty blows sent the pipe down $\frac{5}{16}$ in. and the driving was stopped.

At Bench-Mark 24 (Fig. 32 (*b*)), a pipe was pushed to 33.7 ft. before it was necessary to strike a blow. Then, for each successive increment of twenty blows, the penetration was as follows:

Total penetration, in feet.	Penetration for twenty blows, in inches.
35.5	6.5
40.7	4.5
46.1	3.5
46.9	2
48.0	1
48.29	0.19

After a total penetration of 48.29 ft., the next twenty blows failed to move the pipe. A 12-lb. sledge-hammer was used for driving.

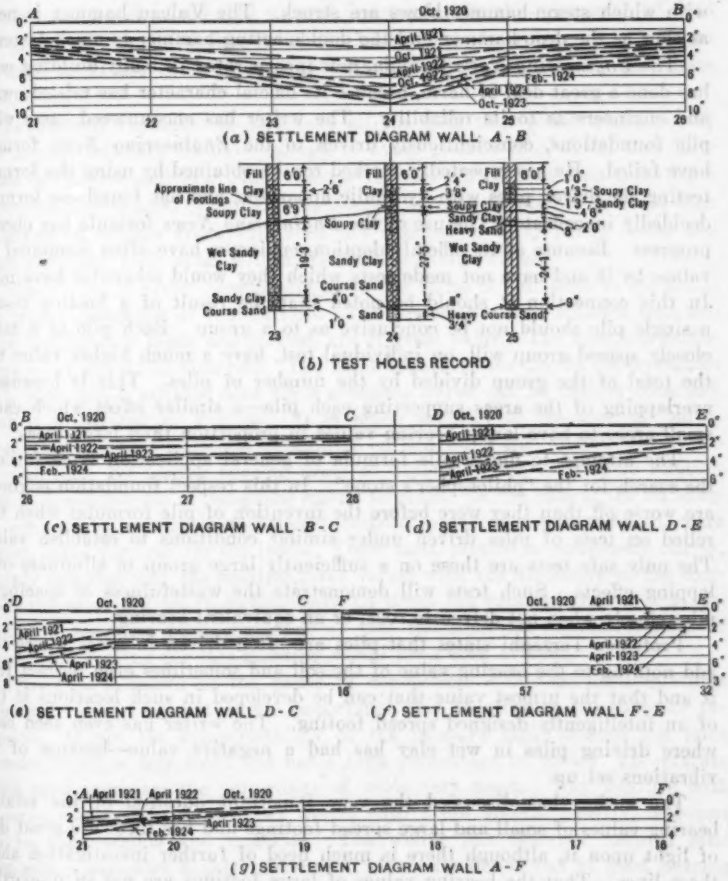

FIG. 32.—RECORD OF SETTLEMENTS OF BUILDING IN SHEBOYGAN, WIS.

The author has dealt the *Engineering News* formula "some staggering blows". Would that it had been "knocked out" completely. It was originated

by Wellington, who really intended it to be applied only to uniform materials like sand, with the drop-hammer then used. He introduced constants to give it a reasonable value. Theoretically, it has a factor of safety of 6, that is, a wooden pile which, by the *Engineering News* formula, gives a working value of 15 tons, has an ultimate value of 90 tons, which is absurd for a small wooden pile.

To cover the use of steam hammers, then coming into use, Wellington arbitrarily changed his denominator, $S + 1$, to $S + 0.1$, giving no good reason except that the more rapid blow of the steam hammer ought to give that much better results. As a matter of fact, there is much variation in the rapidity with which steam-hammer blows are struck. The Vulcan hammer is nearly as slow as the drop-hammer and the double-acting hammer is much faster.

The *Engineering News* formula, now incorporated in many building codes, has done a great deal of harm, because its official character has misled owners and engineers as to its reliability. The writer has encountered cases where pile foundations, conscientiously driven to the *Engineering News* formula, have failed. He has repeatedly checked results obtained by using the formula, testing the driven piles with hydraulic apparatus, and has found the formulas decidedly inaccurate. The use of the *Engineering News* formula has checked progress. Because of its official adoption, engineers have often computed pile values by it and have not made tests which they would otherwise have made. In this connection it should be noted that the result of a loading test on a single pile should not be conclusive as to a group. Each pile of a rather closely spaced group will, on individual test, have a much higher value than the total of the group divided by the number of piles. This is because of overlapping of the areas supporting each pile—a similar effect which causes small areas to have larger bearing values in proportion than large areas.

The attempt to find a pile formula of general application is as futile as the search for the "philosopher's stone". In this respect foundation engineers are worse off than they were before the invention of pile formulas when they relied on tests of piles driven under similar conditions to establish values. The only safe tests are those on a sufficiently large group to eliminate overlapping effects. Such tests will demonstrate the wastefulness of spacing of piles closely when not driven to rock, or an equivalent bearing.

Professor Terzaghi states that piles are often driven in areas where they add nothing to the bearing value of the soil and sometimes even detract from it and that the utmost value that can be developed in such locations is that of an intelligently designed spread footing. The writer has even seen cases where driving piles in wet clay has had a negative value—because of the vibrations set up.

The author has discussed the very important question of the relative bearing values of small and large spread footings and has thrown a great deal of light upon it, although there is much need of further investigation along these lines. That the bearing values of large footings are not in proportion to their areas as compared to small footings is to the writer, sufficiently proved. He has encountered many cases where settlements of large footings were much more than those for smaller ones. In a case where a high building

was founded on a soft coral rock, the smaller footing settled about ½ in. and the larger, 6 in., although in this case the larger footings were designed with lighter unit loads than the smaller ones. Similar results were observed in buildings underlaid by peat, soft silt, etc.

In designing spread footings the old and easy assumption for the designer (that all that is necessary is to assume a working unit load—so many tons to the square foot—and then to divide this into the column loads to get the areas of spread footings) has led, and will continue to lead, to failures. The heavier the loads the more conspicuous the failures. Account must be taken of the shape of the footings, their relative sizes, their spacing, whether or not they are too close together to work independently, the proportion of dead and live load, etc. On this point the writer begs to differ with Professor Terzaghi as to the value of loading tests. If intelligently made, they have great value.

Foundation engineers do not have all the data they could wish—not by any means; but they do have enough to avoid pitfalls into which they have fallen in the past and to produce designs far more intelligent than those heretofore considered good practice. Engineers may even decide not to build high buildings on certain areas with soils not adapted to carry heavy loads, and there are many such areas within the limits of large cities.

The author is rather pessimistic as to the value of soil tests as an aid to the proper designing of foundations. The writer, however, believes that soil tests, intelligently made and plotted, are of great value. The complete settlement curve should be obtained. The ideal apparatus for this is the hydraulic jack, with which reliable data for a complete curve can be rapidly obtained. This is illustrated in Fig. 33. It is much superior to the method* advocated by the Society's Special Committee on Bearing Value of Soils for Foundations, etc. By testing bearing areas of different sizes, a valuable relation may be found for use in designing spread footings. In the case of the building on coral rock, previously mentioned, bearing areas of 1 and 2 sq. ft. were tested, using pig iron for the loads. These tests, plotted as settlement curves, plainly revealed that the bearing value varied with the diameters of the footings, the area of 2 sq. ft. having only 1.4 times the value of that of 1 sq. ft. Had the designers been cognizant of this relation, the impracticability of any spread footing for this building would have been evident.

The results shown in the paper in connection with sand-mica mixtures are most interesting, but undue importance may be given to the shape of the grains. Is not the compressibility of the mixture high because the mica powder itself is very light and has a high percentage of voids? Its mixture with sand increases the percentage of voids very much. Any mixture with a large voids-ratio, or, in other words, with a low specific gravity, is bound to be compressible and unstable. The writer has observed natural sand deposits, apparently highly micaceous, which are dense and of good bearing value, although it may be that actual measurement would show the percentage of mica to be small.

* *Proceedings*, Am. Soc. C. E., March, 1922, Papers and Discussions, p. 527.

The writer does not wish to disparage the use of sand-mica mixtures to simulate earthy materials with various voids-ratios, but wishes to express an opinion that the compressibility of soils is due more to lack of consolidation or to abnormally low specific gravity for the material rather than to the presence of mica or flat grains, although that is a factor in compressibility.

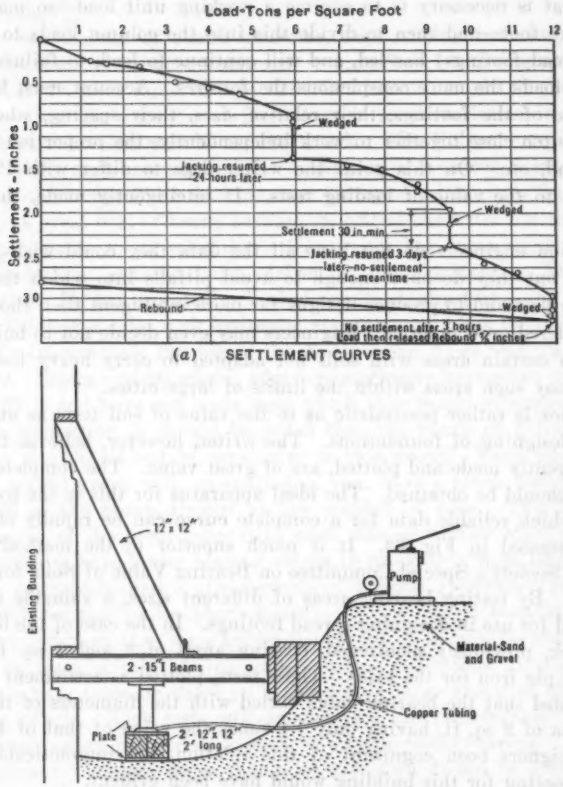

FIG. 33.

In the paper the three properties that determine the behavior of the soil in the foundation pit are given as: First, the volume change produced by an increase of pressure acting on the soil, etc.; second, the permeability of the soil, etc.; and third, the cohesion or shearing resistance of the soil.

The writer would like to add a fourth, which may perhaps be a combination of the first two, but which is nevertheless important and easily ascertained; that is, the density of the soil or rock in relation to an old and well consolidated soil of similar nature. For instance, if the material is sand, determine its weight as compared to a sand of an old and well consolidated geological

period, and if it is clay, find a similar relation. A very wet, compressible clay will necessarily be lighter because of its water content than a dry well consolidated clay of an old period; silt will be very light when compared to a consolidated earth, and, similarly, a coral rock will be very light compared to an old limestone. This relation is not hard to find, because old earths and rocks have a surprisingly uniform specific gravity.

The author draws a very sharp distinction between cohesive and cohesionless soils. That there are great differences in cohesiveness between different soils is not open to question, but in the writer's experience there is quite a residue of cohesion in all soils. Even clean sand such as that suitable for concrete will break in the bank with a curved fracture and stand vertical for a certain height. The writer is inclined to doubt the great effect of depth on settlement, unless the added excavation reveals a decided improvement of the ground. For instance, Professor Terzaghi states that, for a footing in perfectly cohesionless material, a depth of $\frac{t}{d} = 1$ reduced settlements to only one-third of what they would be if the footing rested on the surface of the ground.

Engineers are greatly indebted to the author for his discussion of the distribution of soil reaction over rigid loaded slabs. He has shown clearly (for the first time to the writer's knowledge) the difference between the result as ordinarily computed with the common theory of uniform pressures and that of the much more correct theory of Professor Enger. A great difference is shown, the more correct theory yielding greater bending moments. This may explain why, in Detroit, a concrete mat supporting a large office building on clay is reported to show numerous cracks indicating failure. Single spread footings, such as the ordinary case of an individual footing for each column, the loads being concentrated under the center of application, will yield smaller bending moments than under the theory of uniform loading.

The writer feels with Professor Terzaghi that the future of foundation engineering as an applied science is decidedly encouraging and also that engineers are merely on the threshold of this science. The principle obstacles to progress having been removed, that is, various century-old assumptions that do not conform to Nature, the engineer can now go ahead.

Much can be added to the present knowledge of foundations by applying the methods originated by Professor Enger and Mr. Goldbeck for determining soil pressure. By placing pressure capsules in the soil beneath actual footings the distribution of stress can be determined so that it is possible to compute correctly the bending moments in footings. The relation of depth of footing to settlements and that of areas of footings to settlements, can also be determined, if not by this method then by direct loading tests on footings of different sizes and at different depths. By the use of hydraulic apparatus it is possible to obtain a wide range of tests in a limited time. By this method the effect of various shapes of footings on bearing capacities and settlements may also be found, and by testing groups of piles singly and in combination, the investigator can determine overlapping effects, etc., the proper spacing of

piles for the best results, and the relation between the bearing capacities of a single pile and a group.

In the past engineers were content to state that a building settled very little, but accurate levels recorded, with comparatively little cost, would yield valuable and surprising data. In the future, various representative buildings should be chosen for the purpose of making accurate observations as to settlement. Professor Terzaghi is correct; foundation problems are of such a character that strictly theoretical mathematical treatment will always be impossible, but by systematically accumulating field data it will be possible to approach this ideal much more closely.

The writer hopes that the problem of soil classification will soon be solved along the lines suggested in the paper. He feels that the Engineering Profession is much indebted to Professor Terzaghi, first of all for uprooting certain persistent prejudices and then for leading engineers forward in new directions toward "the promised land" of a real science of foundations.

R. D. N. SIMHAM,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer desires to limit his observations on this interesting paper to the most important question of settlement of soils and its relation to the area of bearing and intensity of loading. It is a fallacy to generalize from experimental results without thoroughly understanding the premises on which, and the objects for which, the experiments are conducted. There are limitations to experimental researches that require corresponding limitations to be made in the laws deduced from them.

In the first place, any results that have been determined by individual experiments under limited considerations and very often in a slipshod manner, that is, without any attempt to follow a general or comprehensive plan and co-ordinated line or method of experimentation, cannot be complete evidence on which to establish any general or fundamental law of science. The writer has learned from experience that any attempts to deduce, from an uncoordinated set of experiments, some sort of a general formula or law that would explain the entire phenomena of soil behavior, has invariably raised serious complications. Therefore, experiments can afford no relief to the present imperfect state of the science of foundations unless they are based on: (1) Constructive lines of thought; (2) a thorough realization of the assumed conditions; (3) a careful diagnosis of every factor that influences the behavior of a soil; and (4) a thorough co-ordination of all the information gained. "Knowledge comes, but wisdom lingers."

There is always a tendency to take some plausible results of experiments and immediately deduce laws of relationship between certain factors involved and then apply them to every single condition that occurs thereafter. Whenever inconsistencies are discovered, all kinds of sophistical arguments are made to explain matters, either by suggesting that the variations are exceptional, that they are unexpected, or are due to defective experiments, or other causes, but all the time insisting that the law, once derived by some mathema-

* Town Planning Asst., Madras, India.

tical manipulations of a set of convenient results, must apply to all sets of conditions.

In an ideal soil, uniform in every respect, it is possible to state that settlement is proportional to intensity of loading in some way and to the area in some other way. With regard to the area, the shape of the bearing surface has an influence on settlement; that is, the settlement of a foundation with the same load and bearing area would be different for dissimilar shapes of the bearing surface. Thus, in a simple way, the relationship between settlement of soil, s; load intensity, w; bearing area, A; and the ratio of mean width to mean length of bearing section (or some other relation that would truly represent the effect of variation in shape and the consequent variation of volume of depth of soil affected), r, may be given in the general form:

$$s = \frac{w^x A^y r^z}{k} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

In this equation, k is a constant that expresses the characteristics of the soil.

If this may be taken as truly representing a law of behavior for given soils, then it would be easy to direct some experiments along definite lines and to arrive at the range between which the values of x, y, and z vary. However, in the determination of the value of k, the investigator would probably get into difficulties. The writer thinks that it is impossible to secure identical behavior of soils throughout the processes of varying load, area of bearing, and shape. Any settlement may be the result of several different reactions within the soil. There may be (1) a subsidence due to closer re-arrangement of materials of soil during a particular stage; (2) settlement due to plastic or flattening effect at some other stage, or combined with the former; (3) sinking due to escape or lateral flow of water or escape of other loose materials in the composition of soil; (4) shrinking due to compressibility of soil materials; and (5), under extraordinary circumstances, reduction caused by the crushing of the granules or disintegration of soil materials. Equation (12) may perhaps be modified further to cover these factors also,

$$s = \frac{w^x A^y r^z}{k - (c_1 + c_2 + c_3 + c_4)} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

In Equation (13), k may represent a value for soil under standard conditions, or a certain condition of soil behavior when settlement is a minimum. c_1, c_2, c_3, c_4, etc., may represent the reductions necessary in the values of k to allow for subsidence, settlement, shrinking, reduction, etc.

Any soil that is confined before loading to the limit of the natural angle of repose, $x\,O\,A$ (Fig. 34), when loaded, slowly or rapidly adjusts itself in different angles until it attains the limiting angle of compactness of soil materials as indicated by the position, OB, in Fig. 34. Beyond this, a loading will cause the soil to flatten to the limiting position of plasticity, $C'C$. During this period, there may not have been any change in the volume of soil, but merely a bulging outward. Then sinking of soil occurs by the escape of water or loose material within the soil, until the limiting angle of permeability or soil escape, $x\,O\,D$, is reached. Further loading creates pure compression of the soil materials, and the soil shrinks to the

limit of compressibility, $E'E$. Beyond this stage the soil sinks by the crushing of the granular shape. Thus, the actual curves of settlement *versus* load, based on experimental results, would seem to illustrate, not one uniform law throughout, but different laws at different stages. Knowing exactly what is taking place within the soil itself, it should be possible to determine these laws independently through carefully planned experiments, and then, by an easy mathematical computation, a combined or general law of relationship might be deduced.

In another way, assuming that the total settlement of the soil is the combined effect of these factors, it may be found convenient to express the relation for determining the settlement in a somewhat better form, thus:

$$s = \frac{w^{x1} A^{y1} \gamma^{z1}}{k_1} + \frac{w^{x2} A^{y2} \gamma^{z2}}{k_2} + \frac{w^{x3} A^{y3} \gamma^{z3}}{k_3} + \frac{w^{x4} A^{y4} \gamma^{z4}}{k_4} \quad \ldots\ldots(14)$$

in which the quantities, $\frac{w^{x1} A^{y1} \gamma^{z1}}{k_1}$, etc., represent the settlement due to the individual effects of each of the factors mentioned.

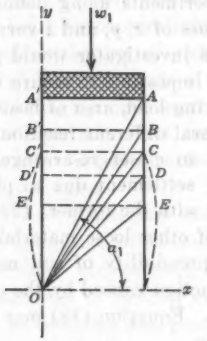

FIG. 34.

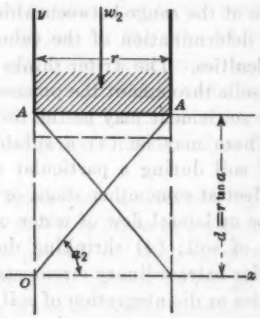

FIG. 35.

There are two more considerations which, instead of increasing the settlement, would reduce it. The side soil protection and frictional resistance offered by the marginal soil should modify the settlement directly below the foundation, and then Equations (13) and (14) will be further generalized to the following forms:

$$s = \frac{w^x A^y \gamma^z}{k - (c_1 + c_2 + c_3 + c_4)} - \frac{V^m}{C} - \frac{P^n}{D} \quad \ldots\ldots(15)$$

and,

$$s = \frac{w^{x1} A^{y1} \gamma^{z1}}{k_1} + \frac{w^{x2} A^{y2} \gamma^{z2}}{k_2} + \frac{w^{x3} A^{y3} \gamma^{z3}}{k_3} + \frac{w^{x4} A^{y4} \gamma^{z4}}{k_4} - \frac{V^m}{C} - \frac{P^n}{D} \quad \ldots(16)$$

In Equations (15) and (16), V and P represent, respectively, the effective volume of soil contributing to the side protection of the compressed soil and the perimeter of the bearing section; while m, n, C, and D are constants.

These do not necessarily comprise all conceivable factors affecting soil behavior. There is no doubt a difference in the behavior of soil under dead

and live load and slowly or rapidly applied load. Eccentricity of loading and character and nature of distribution of thrusts on soil have also to be considered. In fact, it is necessary to know the law connected with each individual factor that influences the soil, and then only can any comprehensive law or laws, which would correctly represent the soil behavior, be attempted. Any such attempt at the present state of knowledge on this subject will naturally be abortive. However, for practical purposes, it may perhaps be sufficient to know what volume of soil will be affected by any load over any bearing area and deduce, with reference to it, some simple relation for the settlement of soil of any specific composition under different loads.

The volume of soil that is directly affected by load is as shown in Fig. 35. This concept does not take into consideration the soil that receives any indirect or virtual effects of load. It limits the volume to that portion lying constrained laterally within the vertical planes bounding the bearing area. The bottom would be defined by a horizontal plane (Ox, Fig. 35) passing through the highest point of intersection of the plane (OA, Fig. 35) of shearing or cohesion and the vertical plane, Oy. The direct settlement of the soil may be considered the result of (1) a closer re-arrangement of soil material; (2) actual compressibility; and (3) reduction due to permeability of this volume of soil or a large proportion of it. Any relation so determined will be useful in a practical way in studying comparative settlements or comparative bearing values of soil.

With these assumptions the relation between settlement and volume for any specific composition of soil may be simply written,

$$s = \frac{w^p\,(c\,V)^q}{k} \qquad (17)$$

in which, V is the volume defined in connection with Fig. 35, and p, c, q, and k are constants. In Fig. 35, let A = the area of the bearing surface; r, the mean or limiting width of soil that restricts the depth, d, of soil affected directly by the load; and a, the angle between the plane of shear or cohesion and a horizontal plane through O. Then,

$$V = A\,r\tan a \qquad (18)$$

Substituting this value of V in Equation (17),

$$s = \frac{w^p\,(c\,A\,r\tan a)^q}{k} \qquad (19)$$

For any specific soil c, tan a, and k will be constant, so that settlement in such case would be represented by the relation,

$$s = \frac{w^p\,A^q\,r^q}{C} \qquad (20)$$

in which, C is a general constant for the characteristics of the specific soil.

As an example, select two kinds of soils to be compared for bearing values. Assume that s, p, c, A, r, and q remain the same in both cases; w_1 and w_2 are the supported loads; a_1 and a_2, the shearing angles; and

k_1 and k_2, constants for the soil in each case. Then,

$$\frac{w_1}{w_2} = \frac{k_1}{k_2}\left(\frac{\tan a_2}{\tan a_1}\right)^{\frac{q}{p}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (21)$$

Equation (21) explains in a simple way the values found by A. T. Goldbeck, Assoc. M. Am. Soc. C. E., with various mixtures of sand and clay.*

FRANK A. MARSTON,† M. AM. SOC. C. E. (by letter).—Considerable progress has been made by Professor Terzaghi in determining adequate and practical methods of classifying soils. For several years, the writer's firm has been carrying on laboratory and field studies on soils with the assistance of and by means of apparatus devised by the author.

In doing such work, there is a real benefit derived from the actual handling of the soil samples. It is not enough to have a trained laboratory man perform certain tests, but, in addition, some work should be done by the engineer responsible for the final decisions in order to acquire the "feel" of the various soils and to observe closely their characteristics as evidenced by varying behavior under test. While the external appearance of a soil sample should be studied, it may be most deceiving as to the actual characteristics and cannot be depended upon solely as a means of grouping soils.

As time goes on, methods and apparatus will be further simplified and their use will be more widespread. The great difficulty at present in the practical use of these improved methods of soil analysis is in the interpretation of the results. Only the gradual accumulation of data will provide the means for accurately translating laboratory results into terms of large-scale field experience. In preparing papers such as this, Professor Terzaghi is rendering the profession a real service by arousing the interest of many investigators. If, as a result of these discussions and investigations, soil studies can be conducted according to standardized methods, records will be made that can be compared and used as a basis for judgment by engineers generally. A tremendous amount of data has been published regarding experiences with foundation conditions, but the lack of a suitable classification for the individual soils has made many of these data of little value.

An illustration can be cited showing the slowness of consolidation of the core material in a certain hydraulic-fill dam, with some data as to the character of the material according to these new lines of classification. All the material for this dam was obtained from a borrow-pit in shale located on a steep hillside which was covered with a layer of disintegrated material 3 to 4 ft. thick. This layer was the principal source of the core material.

Ten samples of the core material were taken at intervals from the top to a depth of 15 ft., at two points (Holes Nos. 1 and 2, Table 7), on the center line of the dam. These holes were 12 ft. and 150 ft., respectively, from the point of overflow of water from the pool during construction.

Samples of core material from the upper parts of the holes were obtained by pushing down a 3-in. pipe and withdrawing it filled with material. This

* *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 271.
† Cons. Engr. (Metcalf & Eddy), Boston, Mass.

method was continued until a depth was reached at which the core material was so soft that it would not remain in the pipe. Below this point, the holes were excavated by means of an earth auger which worked with fair success, except that some soft material slid off the auger as it was pulled up. The sampling tubes, 1 in. in diameter and 12 in. long, were used with some difficulty, due to the soft condition of the material which did not always fill the entire length of the tube.

When a ball of the core material was squeezed in the hand, it was found to be so plastic that it flowed out between the fingers. In one test hole, the material at a depth of 12 ft. contained so much water that, after standing over-night, the hole was found to be filled with water to the level of that in the reservoir. Table 7 gives the results of some of the tests of the core material.

There was little difference in the character of the samples from the two holes. The moisture in the samples as taken from Hole No. 1 varied from 19.3 to 42.4% and averaged 33.5% of the weight of dry solids. The samples from Hole No. 2 varied in moisture content from 26.4 to 48.2 and averaged 35.5 per cent. The moisture content did not vary uniformly from the top to the bottom of the holes. The average volume of voids in the samples from Holes Nos. 1 and 2 was 48.6 and 48.0%, respectively, computed on the volume of the wet material as sampled. The specific gravity of the dry core material was 2.748.

A comparison of the liquid limit given in Column (5), Table 7, with the moisture content given in Column (11) (both being expressed in the same terms), shows that about one-half the samples contained more moisture when taken out than at the lower liquid limit.

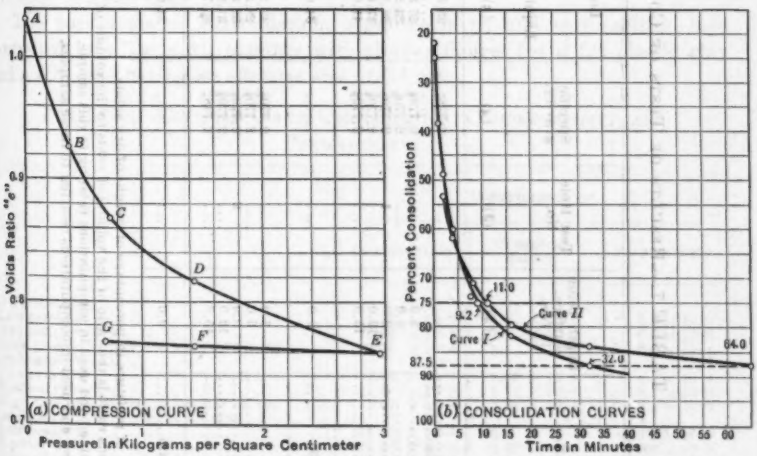

FIG. 36—SAMPLE NO. 712 FROM TEST HOLE NO. 2.

A compression test was made on Sample 712 of this core material for the purpose of determining the compressibility and permeability of the material (see Fig. 36 and Table 7).

* Weight of moisture in percentage of weight of dry solids.

† The voids ratio is the ratio of the volume of voids to the volume of solids.

‡ Determined and used in computations relating to this sample.

§ Assumed and used in computations relating to these samples.

The dry material was made into a paste and placed in the cylindrical container of the compression apparatus in such a manner as to exclude air and completely fill the space. The paste was approximately at the liquid limit. Pressure was then applied at 0.39 kg. per sq. cm. Observations were made, by means of Ames dials, of the decrease in thickness of the specimen at frequent time intervals until there was no further consolidation. The load was then increased immediately to 0.74 kg. per sq. cm. and similar observations of thickness were made. Similarly, the test was repeated for loads of 1.44 and 2.96 kg. per sq. cm.

When consolidation had been completed, the load was reduced by the same increments by which it had been increased, allowing sufficient time for the sample to expand or rebound to a constant volume between changes in load. The moisture content of the sample was determined before and after testing. Other values used in the analysis were: Specific gravity, 2.748; plastic limit, 25.2 ($e = 0.693$); liquid limit, 35.7 ($e = 0.982$); diameter of the sample, 7.00 cm.; and reduced thickness, 0.705 cm. In Fig. 36 (*b*), Curve I is the consolidation curve when the pressure was increased from 0.74 to 1.44 kg. per sq. cm., and Curve II is the consolidation curve when the pressure was increased from 1.44 to 2.96 kg. per sq. cm.

Point *A* (Fig. 36 (*a*)) represents the voids ratio at the beginning of the test; Points *B*, *C*, *D*, and *E* represent the voids ratios of the completely consolidated specimen under the loads of 0.39, 0.74, 1.44, and 2.96 kg. per sq. cm. Points *F* and *G* represent the voids ratios when the specimen had rebounded after removing loads of 1.52 and 0.70 kg. per sq. cm., respectively. These observations indicate that the material consolidates almost as slowly as a highly colloidal clay.

The coefficients of consolidation, compressibility, and permeability were computed (see Table 8), together with similar figures for a fat plastic clay and a fine sand having an effective size of 0.1 mm.

TABLE 8.—Coefficients of Consolidation, Compressibility, and Permeability.

	Coefficients of.		
	Consolidation.	Compressibility.	Permeability.
Fat Plastic Clay:			
Low pressure	1.72×10^{-3}	4.4×10^{-4}	7.6×10^{-7}
Medium pressure	2.62×10^{-3}	2.3×10^{-4}	6.0×10^{-7}
High pressure up to 2.96 kg. per sq. cm.	2.10×10^{-3}	1.1×10^{-4}	2.3×10^{-7}
Core Sample No. 712:			
Low pressure	2.78×10^{-3}	1.69×10^{-4}	4.7×10^{-7}
Medium pressure	11.7×10^{-3}	0.74×10^{-4}	8.7×10^{-7}
High pressure up to 2.96 kg. per sq. cm.	5.87×10^{-3}	0.38×10^{-4}	2.2×10^{-7}
Fine Sand, Effective Size = 0.1 mm.:			
Low pressure	$171\,000 \times 10^{-3}$	0.5×10^{-4}	$85\,300 \times 10^{-7}$
Medium pressure	$378\,000 \times 10^{-3}$	0.22×10^{-4}	$83\,300 \times 10^{-7}$
High pressure up to 2.96 kg. per sq. cm.	$500\,000 \times 10^{-3}$	0.16×10^{-4}	$80\,000 \times 10^{-7}$

It will be seen that the coefficients of consolidation and permeability for the core material are similar to those of the fat plastic clay and vary greatly

from those of the fine sand. The greater the coefficient of consolidation, the more rapidly consolidation will take place. For the core material, the rate of consolidation is exceedingly slow. The indications are that the core in the dam built with this material to a depth of 15 ft. at least, is in about the same state of consolidation as it was when the dam was built, eight years before the samples were taken.

The influence of grain size on the variation in lower plastic and liquid limits and the difference between these limits is illustrated by data given in Table 9. These data were obtained by separating into its respective portions (according to grain size) a sample from the borrow-pit from which the core material was obtained. This material is a bluish or greenish shale which breaks into bulky pieces.

TABLE 9.—LOWER LIQUID AND PLASTIC LIMITS OF THE SEVERAL FRACTIONS OF FINE MATERIAL FROM BORROW-PIT.

Size, in millimeters.	Proportion of total weight, percentage.	Liquid limit.	Plastic limit.	Difference.
Composite sample	100	33.0	24.7	8.3
0.1 — 0.02	35.2	26.9	29.8	0
0.02 — 0.006	22.2	38.2	36.8	1.4
0.006 — 0.002	17.2	42.2	29.6	12.6
Less than 0.002	25.4	66.8	36.1	30.7

For material between 0.1 and 0.02 mm. in size, the liquid and plastic limits should be practically identical. The discrepancy shown in Table 9 is due to the difficulty in determining accurately the plastic limit in such material. The effective size of the fine material was 0.00075 mm., and the uniformity coefficient was 20.6. The coarsest fraction, 0.1 — 0.02 mm., had relatively low liquid and plastic limits and the difference between them should have been practically zero. The very fine material (less than 0.002 mm.) had high liquid and plastic limits and there was a wide difference between them.

An examination of the borrow-pit material before construction by the methods indicated would have made it possible to forecast the behavior of the material.

ARTHUR M. SHAW,* M. AM. SOC. C. E. (by letter).—This paper is quite unique in that it discusses clay and other soils in the same terms as have been used in the discussion of other materials of construction. While many experimental data have been compiled concerning the bearing power of soils, it ordinarily has not occurred to the engineer dealing with these widely used materials to investigate such properties as tensile strength, elasticity, and especially strength in shear, although the author shows that all these properties are of vital importance in at least some types of soils. The writer was particularly interested in the discussion of the relation of area to the supporting power of soils, having noticed the apparent inconsistent behavior of

* Cons. Engr., New Orleans, La.

weak soils under loads of uniform weight per square foot, but varying materially in area covered.

The following discussion will be limited to muck soils, overlying soft clay, the type of soils commonly found in the "prairie" areas of the lower delta of the Mississippi River.

A number of years ago, it became necessary to place a fuel-oil tank convenient to a pumping plant on a reclamation project near New Orleans, La. The soil, of the type described, had been drained only partly and under a test load (placed on a 3 by 3-ft. platform) appeared to be safe for a load of approximately 500 lb. per sq. ft. A spread foundation was designed to limit the load to 400 lb. per sq. ft., but before the tank was quite three-quarters full, it began to settle unevenly and to an undesirable degree. Hasty shoring brought the tank to a vertical position, an occasional re-adjustment of the shores being necessary to keep it plumb. After about six months of subdrainage, and compacting by the superimposed load, the soil was capable of supporting the full load of 400 lb. without material additional settlement. The total settlement was 2.5 ft.

On a similar reclamation project, experiments were made with the freshly drained muck soil to determine loads which might be used in the construction of light buildings for housing employees. A limit of 250 lb. was adopted and results indicated that this was about correct. General settlement was expected because of the drainage and shrinkage of the muck, but this was fairly uniform and did not cause any serious complications except in connection with one or two buildings which were provided with brick flues. These were carried on short posts (old pile-heads) which rested on a thin local stratum of sand only about 5 ft. below the surface. The considerable separation of grade of the living-room floor and the fireplace has resulted in a novel architectural effect. The Superintendent (who has been in charge since the work was started in 1917) advised that he now (1928) is using a load of 500 lb. per sq. ft. for small footings, but for large footings, he has found it necessary to adopt a considerably lower load limit.

In the construction of levees on similar foundations, the expedient of driving sheet-piles to prevent lateral movement or "bulging" of the muck has been adopted in local practice although it has been found that this is necessary only in extreme cases. Just as good results usually can be secured, and at much less cost, by constructing the levee in multiple layers and by adopting a design that will tend to increase the resistance of the soil to horizontal stresses. Fig. 37 illustrates the section and the method which the writer has used successfully in the construction of levees on exceptionally soft muck lands. The levee section was controlled by the limit of reach of available dredging equipment, as it is seldom practicable to secure a dredge in this section with a reach from the side of the hull in excess of 60 ft. By the use of longer boom dredges, such as were advocated by the writer a number of years ago,* a material increase in height of levees in such soils should be possible. A special type of dredge, which has been in use in California for many years, is well adapted

* "The Selection and Operation of Dredges", *Engineering Record*, December 16, 23, and 30, 1916.

to levee building in soft soils or under other conditions requiring an exceptionally long reach. Following are the principal dimensions of this dredge: Width of hull, 70 ft.; length of hull, 140 ft.; maximum reach from side of hull, 180 ft.; and nominal capacity of bucket, 6 cu. yd.

Repeated experiments have shown that both the spread base and the construction of levees in multiple operations have a beneficial effect in increasing the stability of muck and soft clay soils. With regard to the spread base, the gradually increasing weight, from toe of levee toward the crown, apparently compresses the muck in the zones subjected to only partial loading and renders it more resistant to lateral movement. The gradual application of the load in multiple layers permits the excess water to be expelled from the subsoils and increases their supporting power.

In the lands referred to, there is a great variation in the weight of materials entering into levees, due to different proportions of muck top-soil and clay subsoil. There also is a wide range in weight of the muck soils, some containing a considerably larger proportion of silt than others. As would be expected, the muck soils dry out rapidly after being placed in embankments, above water level, but the "sharkey" clay gives off its water content very slowly. Excavations into clay levees more than two years old have shown a "gummy" condition at points 5 ft. above soil-water level.

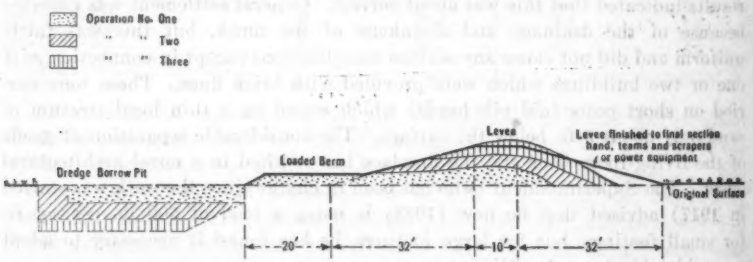

FIG. 37.—CONSTRUCTION OF A LEVEE BY MULTIPLE OPERATIONS.

While concentrated loads, such as those of embankments, may result in failure of the lower strata by a horizontal movement, fills over large areas may be constructed to a considerable height on muck soils with no danger of settlement beyond that caused by the squeezing out of some of the water. The writer has had occasion to make many hydraulic fills over soft muck lands, the added material frequently being clay or sand, but he has never experienced difficulty from excessive subsidence in such cases, provided the fills extended to hard ground or were tapered off gradually at the edges, thus securing the gradual loading mentioned in the foregoing as being desirable for levee construction in similar soils.

Most engineers who have had experience in the construction of railroad embankments across river bottoms have known of localities where embankments 6 to 10 ft. in height could be built without complications, but where a fill of 15 or 20 ft. in height would subside (sometimes suddenly). This subsidence usually would be accompanied by an upheaval of the natural surface,

20 to 50 ft. beyond the toe of the slope. Two such phenomena occurred during the construction of the Illinois Central Railroad from Fort Dodge, Iowa, to Omaha, Nebr., in 1900, one at a point about ten miles north of Council Bluffs, Iowa, and the other in the South Omaha cut-off line, near the bluffs in East Omaha. In the latter case service on the near-by tracks of the Missouri Pacific Railroad was interrupted by the upheaval.

D. P. KRYNINE,* M. AM. SOC. C. E. (by letter).—The author's works† have opened a new era in the study of soils for engineering purposes. Investigations of 10 or 15 years ago generally dealt only with sands, with no consideration for physical properties. Owing to the studies of Professor Terzaghi, the search has penetrated into the interior of clays and sands, the physical properties of which are now being studied by the civil engineer. The present generation is witnessing the birth of a new science, which may be called, "Engineering Soil Science", or "Engineering Soil Theory", and which represents applied soil physics and soil mechanics. It is similar to agricultural soil science; but the latter, by considering principally the influence of water and air on the soil, leaves unstudied the load factor, which is the most important for a civil engineer. Therefore, the establishment of a new science has been inevitable.

Slab Foundations.—In general, the writer agrees with the following statements made by the author:

(1) For soils with great cohesion the settlement produced by a given load increases in direct proportion with the diameter of the loaded area (Fig. 2).

(2) The distribution of the soil reactions over the base of a rigid slab is not uniform. The pressures are equal to zero at the edge of the slab and greatest at the center (Fig. 3).

(3) The settlement of a building is due to consolidation of the soil and to the lateral flow (Fig. 5).

However, there are some objections to each of these conclusions.

First.—Attention is called to a paper by Dr. Ing. Koegler,‡ in which it is stated that the settlement produced by a given load seems to increase directly in proportion with the diameter of the loaded area only to a certain value of this area, after which it becomes more or less constant. In the opinion of Dr. Koegler the elastic condition under a great slab does not permit lateral flow, and the vertical settlement takes place as if the supporting soil were confined laterally. Naturally, the opinion of Dr. Koegler, which seems to be based on his experiments, must be verified.

It also must be noted that his experiments were performed with sands, that is, cohesionless soils. Therefore, the results cannot be generalized until a greater number of experiments with different soils are made; but the example of the settlement of the Standard Oil Building in San Francisco, Calif., leads the writer to believe in these theories. Under a load of 4 800 lb. per sq. ft., the average settlement of the bearing plate was 0.10 in. The settlement of the building should be $152 \times 0.10 = 15.2$ in.; but the actual settlement was only 2 in. If the soil were homogeneous, this fact must be con-

* Prof. of Highway Eng., Moscow Superior Technical School and Moscow Inst. of Transportation Eng., Moscow, Union of the Socialistic Soviet Republics.

† "Erdbaumechanik," Vienna, 1925, and others.

‡ "Die Belastung des Baugrundes," *Der Bauingenieur*, October 27, 1927.

sidered as a proof of Dr. Koegler's statement, but phenomena considered in practice are not as simple and schematic as those studied in a laboratory.

In the example cited the soil was not homogeneous, the settlement of the bearing plate ranging from 0.04 to 0.17 in. The difference is not very great, but in any case there were hard and soft spots in the soil, so that the process of settlement was complicated by the presence of the hard spots which probably produced negative vertical forces acting on the slab. The writer thinks that in the given case and in similar ones it would be better not to deal with the average settlement of the bearing plate, but to elaborate a method of slab design, taking into account the lack of uniformity in the soil.

In regard to the settlement of the caissons at the Chicago Union Terminal, in Chicago, Ill., the writer is not in a position to give a definite opinion on the subject inasmuch as he does not have the description of the work at his disposal. Therefore, he does not know how, where, and when the settlement of the caissons was measured. However, he believes that a caisson cannot follow the law of proportionality of the settlement to the diameter of the loaded area because of the friction against the soil.

Let,

H = the height of the circular caisson, in feet (at the Chicago Union Terminal, $H = 60$);

d = the diameter of the circular caisson, in feet;

f = the average frictional force, in pounds per square foot, of the superficial area of the caisson; and,

q = the load, in pounds per square foot.

Then, the resultant vertical force, q', would be not q, but:

$$q' = q - \frac{f H \pi d}{\frac{\pi d^2}{4}} = q - f \frac{4 H}{d} \quad \ldots\ldots\ldots\ldots\ldots\ldots (22)$$

Equation (22) is an approximate formula which shows that the resultant vertical force acting per unit of the loaded area increases with the increase of the diameter of the caisson. Therefore, the settlement of a large caisson seems to be more considerable than that calculated by Equation (2) not only because of the direct influence of the diameter, but also because of the great resulting force acting on a unit of loaded ground area in comparison with that acting on a smaller one.

Second.—If a slab that is considered uniformly loaded is placed on top of the ground in an excavation, a reaction of the soil develops. Consider only the vertical component of this reaction. The vertical reaction may be confined directly beneath the loaded area (as shown in Fig. 3); or it may be effective beyond this area (see Fig. 38). In the latter case a condition must be satisfied, such that,

$$P + Q_1 + Q_2 = Q_0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (23)$$

The case shown in Fig. 38 evidently corresponds to the upheaval produced by the vertical component of the reaction. Since it is admitted that the bulging is due to the lateral flow only (Fig. 5), it must be concluded that: $Q_1 = 0$; $Q_2 = 0$. This being the case the derivative of the distribution curve,

$y = f(x)$, at the edge of the slab, which represents the ratio of an infinitely small increase of the reaction force to the corresponding increase of the abscissa beyond the edges, must be equal to zero:

$$f'(b) = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

in which, $2b$ is the width of the slab (Fig. 39). As a matter of fact some soil investigations indicate that Equation (24) must be satisfied.*

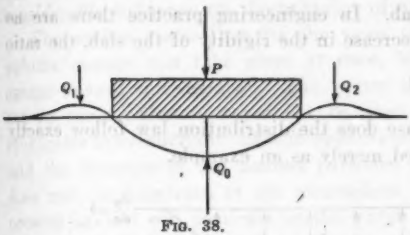

FIG. 38.

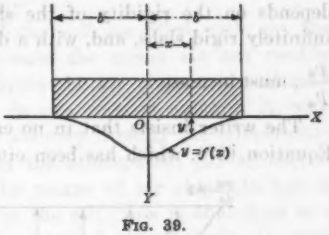

FIG. 39.

As to the curve of pressure distribution, the writer's opinion is that it cannot have a parabolic shape for the following two reasons:

(*a*) The ordinates of a parabola may be calculated accurately according to the equation:

$$y = y_0 \left(1 - \frac{x^2}{b^2}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (25)$$

in which, y_0 is the greatest ordinate in the center; x is the distance from the center of the slab; and $2b$ is the width of the slab. The first derivative of y in Equation (25) is:

$$\frac{dy}{dx} = -y_0 \frac{2x}{b^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

which is not equal to zero, when $x = b$.

In order to satisfy the conditions in Equation (24), the shape of the distribution curve may be modified slightly, for instance, so that:

$$y = y_0 \left(1 - \frac{x^2}{b^2}\right)^m \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (27)$$

For any value of $m > 1$, and for $x = b$, the derivative of this function is equal to zero:

$$\frac{dy}{dx} = -\frac{2mxy_0}{b^2}\left(1 - \frac{x^2}{b^2}\right)^{m-1} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (28)$$

Fig. 40 represents two curves placed side by side for comparison. Equation (25) expresses the left half and Equation (27) the right half. Equation (27) recalls that of the error function, or, better, of the second curve of Pearson.†

(*b*) The area of the curve of pressure distribution, as drawn on the author's Fig. 3, represents the load on a strip of slab 1 ft. wide. If the average pressure on the slab is p_a, it may be written:

$$2b\,p_a = \frac{2}{3} \times 2b\,p_0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (29)$$

* Koegler, "Uber die Verteilung des Bodendruckes unter Gründungskörper," *Der Bauingenieur*, February 5, 1926.

† *Philosophical Transactions*, Royal Soc. of London, Series A (1895), Vol. 186, Pt. I, pp. 360 and 372; also, Fig. V, p. 365.

and, furthermore,

$$p_0 = \frac{3}{2} p_a \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (30)$$

Equation (30) signifies that the pressure at the center of the slab is always 50% greater than the average. In the writer's opinion the ratio, $\frac{p_0}{p_a}$, depends on the rigidity of the slab. In engineering practice there are no infinitely rigid slabs, and, with a decrease in the rigidity of the slab, the ratio $\frac{p_0}{p_a}$, must increase.

The writer insists that in no case does the distribution law follow exactly Equation (27), which has been cited merely as an example.

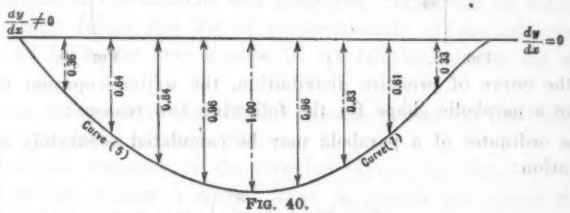

FIG. 40.

Third.—The writer believes that the two parallel lines corresponding to two principal sources of settlement (see Fig. 5) are not really parallel, and that the settlement at the center of a slab is greater than at its edges. For this belief he presents the following reasons: (1) In the middle of a building, because of symmetry, there can be no lateral flow; hence, the deflection in the middle of a slab depends only on the vertical component of the pressure; (2) the vertical pressure at the edge being equal to zero, there can be no settlement due to the vertical pressure; hence, the deflection at the edge of a slab depends only on the lateral flow; (3) if the curve of deflection due to vertical pressure (compression) be drawn, it will represent a curve with ordinates decreasing from the center to zero at the edges; on the contrary the ordinates of the curve of deflection due to lateral flow must increase from zero at the center to a certain value at the edges; and (4) if Koegler's theories are correct, the lateral flow does not increase from the center toward the edges of the slab during the entire time, but stops when $x < b$ (see Fig. 39). Hence, the settlement at the center of the slab seems to be greater than at the edges. The settlement of small rigid disks, 3 or 5 ft. in diameter, naturally cannot give any idea of the difference of settlement in the center and on the perimeter of the slab.

Generally, a foundation slab is a statically indeterminate structure. The distribution of soil reaction depends on the rigidity of the slab. Therefore, bending moments and shearing forces vary with the change in its rigidity. The distribution of soil reactions is intimately bound to the deflection of the slab, although Hooke's law is not applicable to soils. Hence, the soil deflections, reaction distribution, and stresses in the slab are interrelated. This idea is not new. In 1914, Brugsch and Briske published a paper on the

influence of the deflection of the foundation on the design of statically indeterminate structures.*

Entrapped or "Pinched" Air.—Professor Terzaghi greatly merits the approval of the Engineering Profession for demonstrating that clay and water form an intimately connected system. Hence, the mechanics of clay, without considering the influence of water, practically became absurd. The writer desires to show that in some cases not only the water, but also the air, has a considerable influence on the behavior of clay.

The author states that "if the voids of the soil are filled with air, the volume change can take place at once, because the excess air can readily escape toward the surface". The writer thinks the air present in soil may act in three different ways: (1) So that, in one way or another, it communicates to the surrounding atmosphere and assumes directly the temperature and the pressure of the nearest particles of the atmosphere; (2) so that it does not communicate to the atmosphere by means of air channels, but is pressed against soil particles by the water in the soil; this is analogous to a bubble in a spirit-level, and may be termed entrapped or "pinched" air; such air bubbles may often be microscopic in size; and (3) as adsorbed air which sticks to the particles of soil.

The first of these conditions is the one recognized by Professor Terzaghi. As to the second, which naturally must have great influence on the elastic properties of soils, the writer is not sure of its presence in the deep layers of the ancient natural clays. As to relatively modern deposits, however, and especially the artificial fills, there is no doubt as to the presence of entrapped air. Therefore, an investigation of the effect of air and, if necessary, the introduction of the element, "air", into the system, "soil ÷ water", seems to be of definite importance.†

The writer believes that a study of capillarity as applied to water in the soil, leads to the conclusion that there is also a certain quantity of entrapped air.‡ If the clay pores are not completely filled with water, there must be air present. Furthermore, because clay pores represent excessively thin clefts, it is very difficult to imagine that the air may easily escape from them. At any rate, the influence of the entrapped air on the elastic properties of soils should be investigated.

Pile Foundations.—It is interesting to consider the author's views on pile foundations in reference to the pile-driving formula of Professor Guersevanoff, which is widely used in Russia.§ Professor Terzaghi's notations are used with the following additions:

r = rebound of the hammer after the blow; and

a = coefficient of the lost work, depending on the nature of the pile, method of its driving, etc.

* Brugsch and Briske, "Einfluss der Nachgiebigkeit des Baugrundes auf die Berechnung äusserlich statisch unbestimmter Bauwerke," *Beton und Eisen*, 1914, pp. 15, 53, 85, and 183.

† D. P. Krynine, "On the Technical Rôle of Air in Soils" (in Russian), *Transactions*, Inst. of Structural Research, 1928.

‡ D. P. Krynine, M. V. Ivanova, and T. A. Ovsiannikoff, "On the Capillary Rise" (in Russian), *Transactions*, Inst. of Structural Research, 1928.

§ *The Cement* (Russian Magazine), 1916; First issue, p. 2; Second issue, p. 73. This magazine is no longer published.

The work done by the drop of a hammer consists of three parts: (1) Pile penetration; (2) elastic deformation; and (3) lost work; for instance, increase in temperature, etc. This may be expressed:

$$R\,h = [A] + [B] + [C] = Q_d\,s + R\,r + a\,R\,h \ldots\ldots (31)$$

In his analysis, Guersevanoff ignores the term, $R\,r$, so that Equation (31) becomes:

$$(1 - a)\,R\,h = Q_d\,s \ldots\ldots (32)$$

The coefficient, $1 - a = b$, depends on the value of Q_d and the cross-section of the pile, F; that is,

$$b = f\left(\frac{Q_d}{F}\right) \ldots\ldots (33)$$

By making various assumptions he comes to the conclusion that the shape of the curve of Equation (31) is a hyperbolic one:

$$b = \frac{R + m^2\,G}{R + G} \times \frac{1}{1 + \dfrac{Q_d}{F}\,n} \ldots\ldots (34)$$

The coefficient, n, depends both on the nature of the pile and on the method of its driving. For instance, for wooden piles without followers, $n = 10\,\dfrac{K\,g}{c\,m^2}$; for concrete piles with followers, $n = 0.5\,\dfrac{K\,g}{c\,m^2}$. Definitely, the formula, in kilograms and centimeters, is:

$$Q_d = -\frac{n}{2} + \sqrt{\frac{n^2}{4}F + n\,\frac{F}{s}\,R\,h\,\frac{R + 0.2\,G}{R + G}} \ldots\ldots (35)$$

This formula has somewhat the appearance of Equation (3), but Equation (35) neglects partly the length of the pile, and the modulus of elasticity of the pile material enters implicitly into the value of n.

The author's concept of hydrodynamic stresses induced in soils is truly brilliant, but there is some question as to the squeezing of water out of soil beneath the point of the pile. Suppose the pile is driven into clay containing 50% of voids which are completely filled with water. Then, the thickness of the film of water around the pile must be, approximately (deformations of the pile disregarded):

$$T = \frac{0.5\,\dfrac{\pi\,d^2}{4}\,h}{\pi\,d\,h} = \frac{d}{8}$$

in which, d is the diameter of the pile. In Fig. 41 the full line represents the position of the pile before the blow, and the dotted line the position after the blow. Thus, the film of water around a 10-in. pile would be 1¼ in. thick, which seems to be too much. Therefore, the writer thinks that the vertical force transmitted by the pile: (*a*) Compresses the soil, thereby causing the pile to move downward and producing a certain lateral flow of hard particles; and (*b*) acts on the soil water just as in any case of clay loading.* In Fig. 42 the part of the vertical force acting on the water is divided into two components:

* Terzaghi, "Erdbaumechanik," Abschnitt 12, 20, and others.

(1) The horizontal force, moving water away from the pile and thus compressing the entrapped air; and (2) the force parallel to the surface of the pile. The reaction against this component of force is what causes the film to form on the surface of the pile. The posterior absorption of the film by the soil may occur, in the writer's opinion, only if there is air in the voids. The layers of clay in Fig. 42 are assumed to be approximately horizontal.*

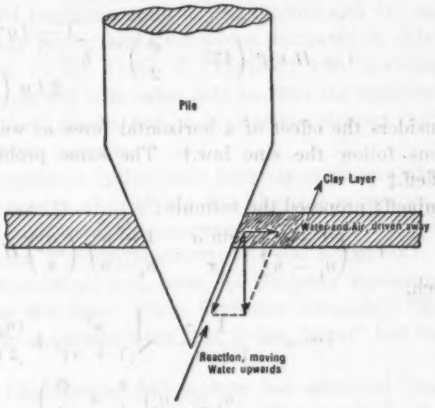

FIG. 42.

Russian Contribution to the Science of Foundations.—The author deals with the present status of the science of foundations as well as with its future.

Russian engineers have made some noteworthy contributions to the theory of pile-driving.† They have also published some works dealing with the determination of the depth, t, of the foundation. Through a paper by Professor Kjürdümoff‡ three formulas, those of Paucker and Jankowsky, came from Russia into European literature.§

Let,

t = the depth of the foundation;

H = the height of a sand prism, with base area and weight equal to those of the building; and,

ϕ = the angle of the internal friction.

Then, Paucker's formula is:

$$t = H\, t g^4 \left(45° - \frac{\phi}{2}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (36)$$

The first formula of Jankowsky is:

$$t = \frac{H}{2}\, t g^4 \left(45° - \frac{\phi}{2}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (37)$$

* D. P. Krynine, "Elementary Proof of Shale-Likeness of Clay Particles," *Public Roads*, January, 1928.

† Jankowsky, "On the Resistance of Pile Foundations," *Journal*, Ministry of Ways of Communication, 1887; Guersevanoff, the previously cited paper, 1916; Dmohovsky, Papers on the influence (*a*) of the geometric shape of piles; and (*b*) of the eccentricities of loads, Works of the Moscow Inst. of Transportation Eng., 1927. There are also other papers by the same author and his textbook on "Engineering Foundations," 1928.

‡ Kjürdümoff, "Zur Frage des Widerstandes der Gründungen auf natürlichen Böden," *Der Civilingenieur* 1892.

§ The derivation of these formulas is to be found in Terzaghi's "Erdbaumechanik," 1925, p. 229.

and his second formula is:

$$H = 2\,t\,\frac{t\,g^2\left(\frac{45^\circ + \phi}{2}\right)}{t\,g^2\left(\frac{45^\circ - \phi}{2}\right)} \qquad (38)$$

Belzetsky's formula* is:

$$t = H\,t\,g^4\left(45^\circ - \frac{\phi}{2}\right) - b\,\frac{1 - t\,g^4\left(45^\circ - \frac{\phi}{2}\right)}{2\,t\,g\left(45^\circ - \frac{\phi}{2}\right)} \qquad (39)$$

He considers the effect of a horizontal force as well and admits that the soil reactions follow the sine law.† The same problem has been outlined by Prokofieff.‡

Miniaeff§ proposed the formula:

$$t = \left(\frac{1+n}{n_1 - n}\right)\left(\frac{\sin\alpha}{\pi} - \frac{1-n}{n_1 - n}\right)\left(\frac{\alpha}{\pi}\right)H - \frac{b}{2}\,C\,t\,g\,\frac{\alpha}{2} \qquad (40)$$

in which,

$$\cos\alpha = \frac{1}{1+n} - \sqrt{\frac{n^2}{(1+n)^2} + \frac{(n_1 - n)\,\pi\,\alpha}{2\,(1+n)\,H}}$$

$$n_1 = t\,g^2\left(\frac{\pi}{4} + \frac{\phi}{2}\right)$$

and,

$$n = t\,g^2\left(\frac{\pi}{4} - \frac{\phi}{2}\right)$$

Equation (40) is based on the following hypotheses: (1) The distribution of stresses in soils follows the same laws as in a solid; (2) "sets" in a dry substance are not functions of forces; and (3) stresses in dry substance are determined only by elastic deformation. The problem consists in determining if, under a given set of forces, an elastic deformation of the soil takes place. If not, a supplementary set of forces must be applied, namely, the weight of the soil above the level of the bottom of the foundation.

Pouzyrewsky‖ considered a condition of the soil when all the deformations are elastic only, and proposed the formula:

$$t = H\,\frac{C\,t\,g\,\phi + \phi - \frac{\pi}{2}}{C\,t\,g\,\phi + \phi + \frac{\pi}{2}} \qquad (41)$$

In his paper on the theory of dry substances, Nemiloff¶ developed a formula which, like the formula of Belzetsky, takes into account the width, b, of the foundation. It is worthy of note that, in 1913, he proposed an apparatus

for determining the coefficient of internal friction* based on practically the same idea as that for the apparatus used in 1917 by the Society's Special Committee to Codify Present Practice of the Bearing Power of Soils for Foundations, etc.†

This fact shows that there is a need for a scientific center to look after the technical literature in civil engineering the world over, in order to avoid the duplication of work and to utilize the technical ideas of different nations.

Generally, Russian civil engineers seem to like the soil and dry substances theory, and there are many papers and discussions dedicated to this subject. The writer calls attention to the works of Prilejaeff‡ and Spalving.§ The latter gives a new theory; he not only takes into account the equilibrium of a soil prism as Paucker and others do, but he studies the stresses that develop in the interior of this prism as well.

Since 1922, Russian engineers (principally highway engineers) have given their attention to the necessity of studying the physical properties of soils. The writer was the first in Russia who expressed in printed form the necessity of co-operation between highway engineers and soil scientists.‖ In 1923, the Russian Highway Department and, later, its Highway Research Bureau, began its activities along this line. When Professor Terzaghi's "Erdbaumechanik" appeared in 1925, it became clear that a new "slant" had been given to this science.

Soil Classification.—Engineering soil science has advanced considerably in recent years; but a definable system of soil classification had not appeared until this paper was presented. The research engineer is in a difficult position when receiving a sample of soil from a job. He may tell the builder as much as he wishes about the internal friction of the soil, about its compressibility, its permeability, etc.; but the only question asked is, "How many pounds pressure will this soil support?"

A laboratory cannot produce the answer to this question categorically. The most practical solution of the problem seems to be to elaborate a combination of simple laboratory experiments with a simple routine test in the field.

S. P. WING,¶ ASSOC. M. AM. SOC. C. E. (by letter).—The writer is connected (1928), with the design of a dam that is to be located at what is known as Site No. 7 at Bridge River in British Columbia. This work is at the lower end of a 30-mile glaciated valley that is about ½ mile in width, with surrounding hills of granites and schists. The actual dam site is about 800 ft. in width between granite outcrops. Borings showed that the rock on either side pitched

¶ Engr., Constr. Dept., British Columbia Elec. Ry., Vancouver, B. C., Canada.

sharply downward, and drilling in the center was stopped when bed-rock was not reached at a depth of 225 ft.

As borings showed a heavy bed of clay lying about 30 ft. below the surface, numerous other test holes were sunk, and a clear conception of the underlying beds was obtained. At the neck of the valley are beds of coarse talus and gravel, perhaps 200 ft. deep as a maximum, resting on bed-rock. Overlying these strata is a continuous bed of glacial or post-glacial clay perhaps 10 ft. thick at the valley neck, but rapidly deepening to a thickness of 90 ft., or more, up stream and forming an impervious blanket in contact with rock on either side. Overlying this are recent deposits of silt and sand and gravel from 20 to 30 ft. thick, forming the present valley floor.

Tests were made with a view to determining the bearing power and settlement of both the clay and the overlying beds. The amount of settlement is considered of great importance because the project calls for a rock-fill dam with concrete facing and a water-tight apron extending up stream to a point where cut-off can be made into deep clay. The design of this lining will have to provide for any differential settlement.

The soil-pressure testing apparatus was similar to that recommended by the Society's Special Committee on the Bearing Value of Soils for Foundations, etc.,* but was designed for a maximum load of 60 tons, so that loading areas of 1, 2.5, and 4 sq. ft. could be used. In general, the apparatus proved satisfactory, but in future tests an oil-jack would probably be substituted for the screw-jack which was used as a fulcrum, because the force required to move the latter in leveling induced extra settlement of the test post.

Test Pit No. 3.—The first tests were made at Test Pit No. 3. Fig. 43 shows the log of the test hole at this location. The material was sand and was composed of sharp angular fragments, largely quartz. Eight feet of the top-soil was removed and the tests on different areas were made in the bottom of the open pit on the undisturbed bed of sand. The mechanical analysis of this sand was as follows:

Sieve No.	Percentage retained.
4	1.4
8	4.2
14	6.5
28	15.8
48	42.5
100	26.9
200	2.2
200	0.5†
Total sample	100
Percentage of mica	0.6

This sand was saturated and the pit required sheet-piling and continuous pumping to keep it unwatered. However, during tests the pit was allowed

* *Proceedings*, Am. Soc. C. E., March, 1922, Papers and Discussions, p. 529, Fig. 1.
† Percentage passing.

to fill with water. Figs. 43 and 44 give the results of the loading tests. An attempt was made to measure the flow of the surrounding soil during the loading of the 4-ft. square plate. Stakes were driven 18 in. into the ground at a distance of 1 ft. from the loaded area. These did not show consistent results, but at the end of the test they had risen an average of 0.015 ft. This settlement may have been due to the effect of unwatering.

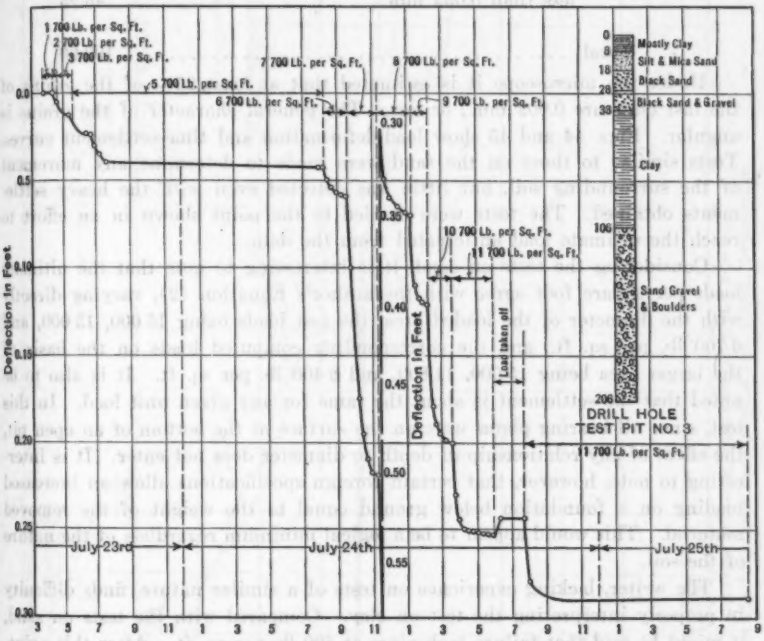

FIG. 43.—TIME SETTLEMENT CURVE FOR SILT AND GRAVEL.

Test Pit No. 2.—Fig. 45 shows the test-hole log at Test Pit No. 2. A pit, 5 by 7 by 13 ft. deep, was sunk, sheet-piled, and pumped dry to a depth 3 ft. below the area being tested and the test was made on a 2-ft. square area of undisturbed clay in place.

The material was clay and was stiff and difficult to spade, but under the men's feet it became plastic. Its characteristics follow:

Weight of clay as sampled, in pounds per cubic foot	112
Percentage of water (in terms of weight of dry material in 1 cu. ft.)	40
Percentage of lower limit of liquid state	42.5
Percentage of lower limit of plastic state	36.6

A change in moisture content from 37 to 26% causes shrinkage of 12% in original volume.

The mechanical analysis by elutriation is as follows:

	Percentage.
Particles, 0.075 to 0.050 mm	0.063
" 0.050 to 0.025 mm	1.32
" 0.025 to 0.010 mm	16.43
" 0.010 to 0.005 mm	35.52
" less than 0.055 mm	45.25
Total	100.00

Under the microscope it is estimated that at least 25% of the grains of the last class are 0.002 mm., or less. The general character of the grains is angular. Figs. 44 and 45 show load-deformation and time-settlement curves. Tests similar to those on the sand were made to determine any movement of the surrounding soil, but little was detected even with the heavy settlements obtained. The tests were carried to the point shown in an effort to reach the ultimate load anticipated from the dam.

Considering the tests on sand, it is interesting to note that the ultimate loads per square foot agree with the author's Equation (2), varying directly with the diameter of the loaded area, the test loads being 15 000, 13 000, and 6 700 lb. per sq. ft., and the corresponding computed loads on the basis of the larger area being 15 000, 11 800, and 8 400 lb. per sq. ft. It is also to be noted that the settlement is about the same for any given unit load. In this test, since all bearing plates were on the surface at the bottom of an open pit, the effect of any relationship of depth to diameter does not enter. It is interesting to note, however, that certain foreign specifications allow an increased loading on a foundation below ground equal to the weight of the removed material. This would appear to be a logical minimum regardless of the nature of the soil.

The writer, lacking experience on tests of a similar nature, finds difficulty in properly interpreting the test on clay. Compared with the tests on sand, it might be said that failure took place at 500 lb. per sq. ft. After this point, any increased load caused heavy settlements but, as the curves show, those decreased with time, and practical equilibrium was established, even with as heavy loads as 12 000 lb. per sq. ft. and total settlements of 2.3 ft., the settlement in the last ten days at this load being only 0.01 ft. It is possible that with this heavy settlement some extra bearing surface of the apparatus became effective, but it is not thought that this was important. Release of the load and its re-application caused some slight additional settlement, as shown by the curve (Fig. 45). In the main it is thought that the increased supporting power of the clay was due to local consolidation under the bearing plate. That similar results will occur with a diameter of loaded area 100 times greater, seems doubtful. As the author's formulas are only applicable to loads within what might be called the elastic limit, they give no guide as to the future behavior of this material. Fortunately, in the present case, a diversion dam of small proportions is to be built first, and it is intended to make more loading tests on the exposed foundation and then to compare those

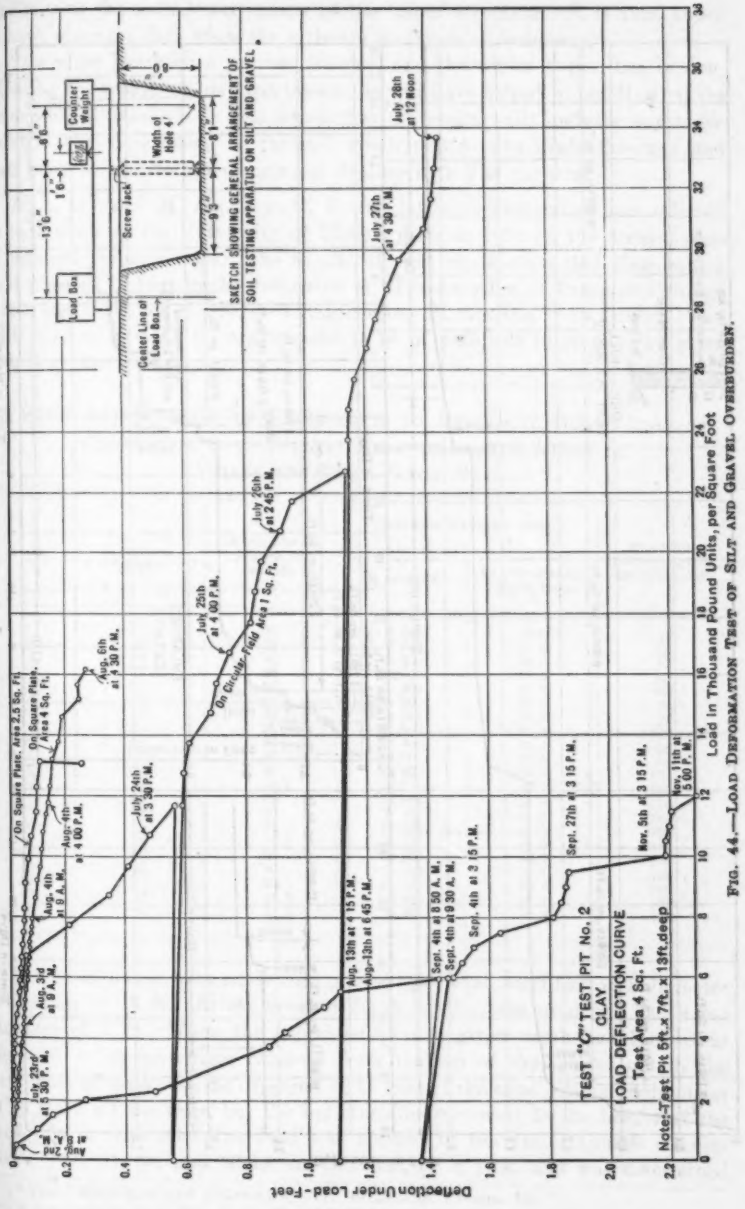

FIG. 44.—LOAD DEFORMATION TEST OF SILT AND GRAVEL OVERBURDEN.

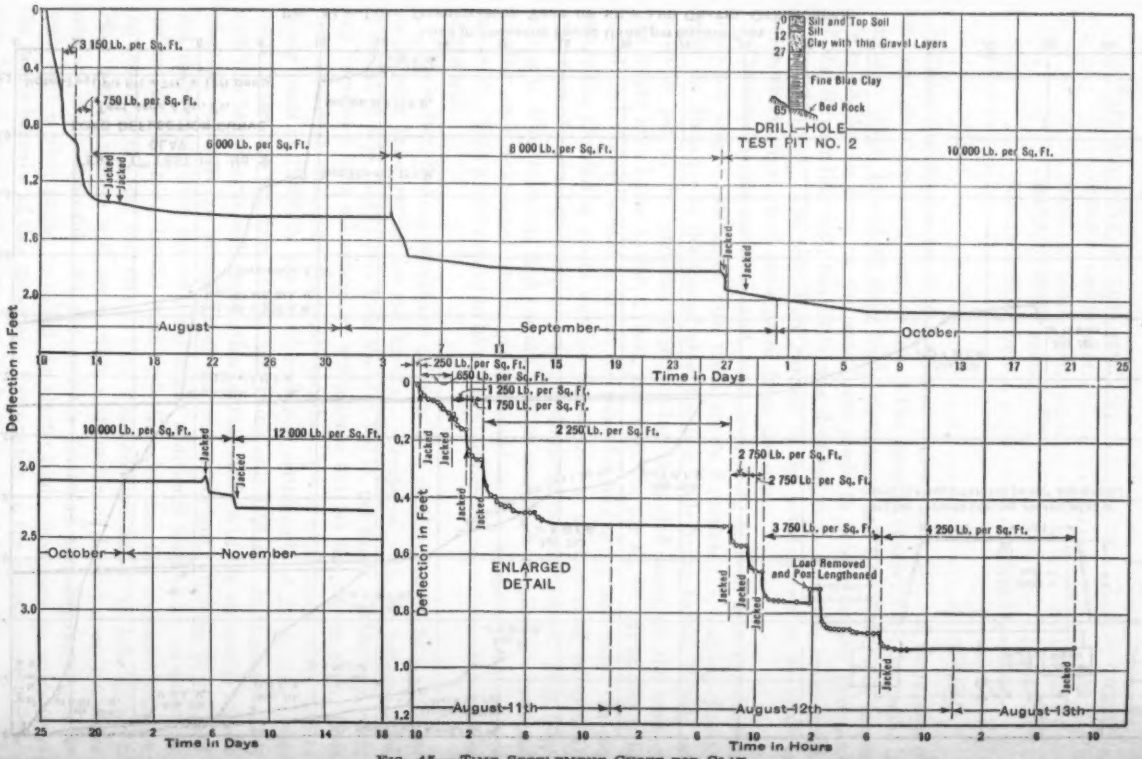

FIG. 45.—TIME SETTLEMENT CURVE FOR CLAY.

results with the actual settlements of the larger structure. It is thus hoped to have adequate data when the ultimate structure is designed.

The paper has been a provocative one, and the writer hopes that in contributing the results of his experiments, he will have helped in building up the much needed data. It is also hoped that the author will indicate any omissions in this description of the soil which would have made the data and tests more helpful to other engineers dealing with like material.

M. L. ENGER,* M. AM. SOC. C. E. (by letter).—The author has referred to tests made at the University of Illinois prior to 1916 on the transmission of pressure through sand. The results of tests made since that time, which were reported in part in the discussion of "Transmission of Pressure Through Solids and Soils and the Related Engineering Phenomena",† by George Paaswell, M. Am. Soc. C. E., are thought to be of sufficient interest to be given here in greater detail.

The experiments were made on a pile of loose bank sand having a diameter at the base of 16 ft. At the greatest depth (38 in.) the sand pile had a top diameter of 6 ft. When the experiments on a given depth had been completed, 6 in. of sand were removed from the top of the pile to obtain the next depth of sand over the capsules. The base of the sand pile had a diameter of 16 ft. in all the tests, but the top diameter increased as the height of the sand pile diminished. The load was applied to the sand through circular plates, 13.5, 21, 30, and 36 in. in diameter, by a jack, and was determined

by means of a calibrated steel spring. The arrangement of the apparatus is shown in Fig. 46.

The vertical pressures transmitted through the sand were measured by means of thirty-one pressure capsules placed in six radial lines in such a manner that there was one capsule directly below the center of the circular plate and three capsules on each circle of 3, 6, 9, 12, 15, 18, 21, 24, 27, and 30-in. radius about the center. The pressure capsules were the same as those used in the experiments reported in the Second Progress Report of the Special Committee on Stresses in Railroad Track.* They were calibrated before and after the experiments were made. The arrangement of the capsules is shown in Fig. 47.

Table 10 shows the order in which the experiments were made and the maximum load applied in each test. The upward reaction computed from the readings of the capsules, expressed in percentage of the applied load, is also shown as a check on the accuracy of the measurements. It will be noted that the reactions are too small in the first three series of tests and too large in some of the later experiments. The error in the reaction is due to the fact that the average of readings at three points on each circle may not represent accurately the actual average pressure. Furthermore, the pressure on a capsule may be different from that which would be developed at that point if there were no capsule; that is, the pressure capsule itself has an effect on the intensity of pressure which it is to measure.

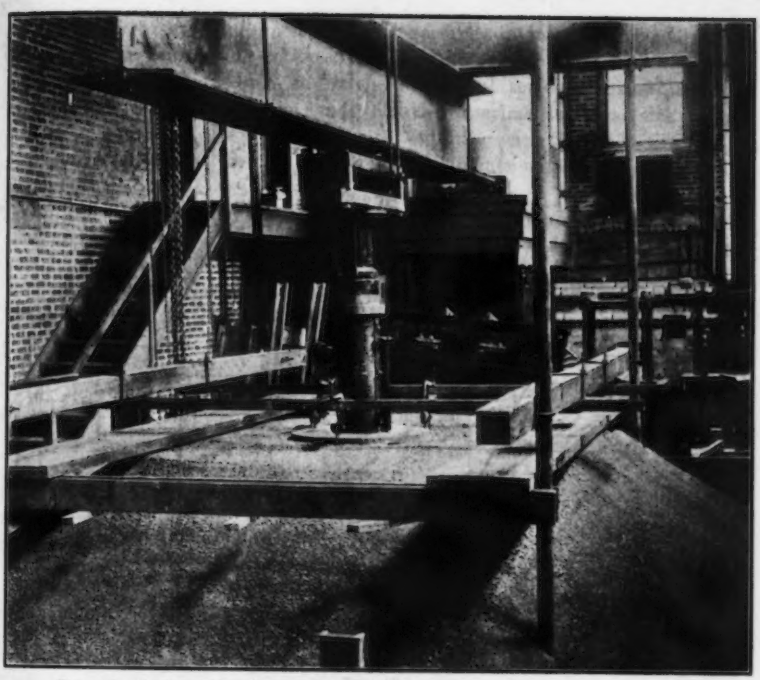

FIG. 46.—LABORATORY APPARATUS FOR TRANSMITTING LOADS THROUGH SAND.

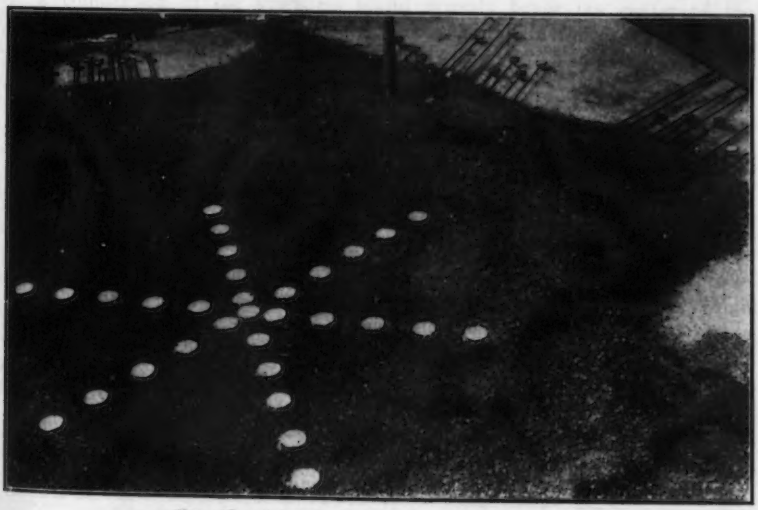

FIG. 47.—ARRANGEMENT OF PRESSURE CAPSULES.

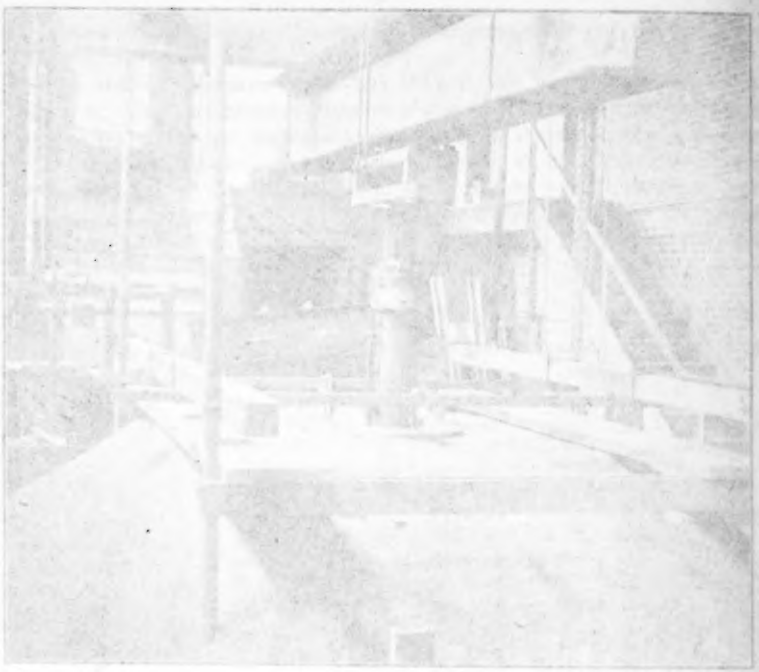

The order of the experiments is of importance in interpreting the results because of the compacting action of the plates on the sand. This fact unfortunately was not foreseen, and in the first eight series of experiments no attempt was made to loosen the sand when the experiments on one size of plate had been completed. In the experiments beginning with Series 3*a* (Table 11), the sand was loosened before beginning experiments with a plate of another diameter.

A condensed summary of the results of the experiments is given in Table 11. The average intensity of pressure at various depths and distances from the axis of the applied load is given in percentage of the average intensity of load applied by the circular plate. It will be noted that there are many inconsistencies.

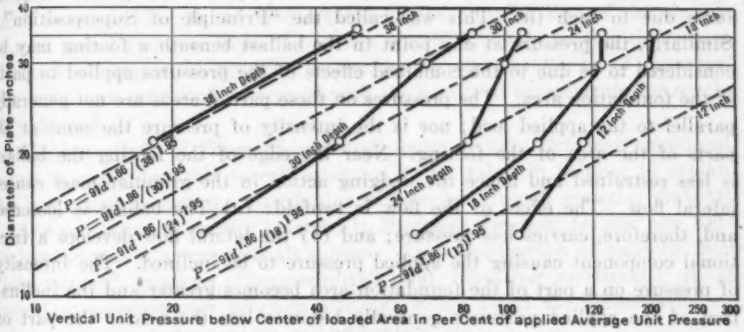

FIG. 48.

A comparison of the pressures found directly below the center of the loaded plates in these experiments with those found in the previous experiments at the University of Illinois is shown in Fig. 48. The dotted lines represent the equation,

$$P = 91 \frac{d^{1.86}}{h^{1.95}}$$

which was deduced from the earlier experiments. The agreement is not good. It was stated in the paper in which the equation was published* that, "the equation represents roughly the results of the experiments, but it is not probable that it has general application." The difference in the results of the two sets of experiments may be explained in part by the difference in procedure in making the tests. In the experiments reported in 1916 a very high intensity of pressure was applied. The plate was forced down several inches to the level used when taking readings. As a result the sand was compacted beneath the center of the plate and was loosened beneath the edge. Such a condition may exist under heavily loaded footings on sand. These heavy pressures were not used in the later experiments because of the fear that many of the capsules would be broken. It is thought that the distribution of pressure beneath circular footings used in practice will be betweeen the ex-

* *Engineering Record*, Vol. 73, No. 4, January 22, 1916, p. 106.

tremes represented by the tests reported in 1916 and the tests represented by Table 11.

The intensity of pressure at any point in the ballast beneath a footing is not a definite percentage of the average intensity of the applied load, but is different for different degrees of compactness of the ballast and for different intensities of applied pressure. It is, therefore, not possible to draw "pressure bulbs" which have general application. The high intensities in the tests at the University of Illinois before 1916 are only to be found when the plate is carrying nearly its ultimate load.

It was shown in the Second Progress Report of the Special Committee on Stresses in Railroad Track* that the intensity of pressure at any point in ballast beneath several loaded ties may be found by adding together the pressures due to each tie. This was called the "Principle of Superposition".† Similarly, the pressure at any point in the ballast beneath a footing may be considered to be due to the combined effects of the pressures applied to parts of the foundation area. The pressures on these partial areas are not generally parallel to the applied load; nor is the intensity of pressure the same at all parts of the area of the footing. Near the edge of the footing the ballast is less restrained and hence the wedging action in the granular mass causes lateral flow. The effect of the flow is twofold: (*a*) The ballast is loosened and, therefore, carries less pressure; and (*b*) the lateral flow develops a frictional component causing the applied pressure to be inclined. The intensity of pressure on a part of the foundation area becomes greater and the inclination of the applied pressures generally becomes less the nearer the part of the area is to the axis of the applied load. The flow of the granular mass away from the center of the plate is shown by heavy radial scratches on the bottom of the circular cast-iron plates used in some of the experiments. In the experiments made for the Special Committee on Stresses in Railroad Track*, heavily loaded railroad ties on rock ballast were sometimes torn in two by the frictional forces developed. The flow of the sand during a sudden failure of the ballast beneath a loaded plate is strikingly shown by illustrations given in that report.‡

The distribution of pressure in a granular mass is most easily comprehended by a study of "lines of pressure"§ which are analogous to lines of force in a magnetic field. If a load of, say, 100 lb. is applied to a granular mass, then on every horizontal plane below the loaded area there must be an added pressure of 100 lb. If the distribution of the vertical pressure is known on a number of horizontal planes at different depths, 100 diverging lines may be drawn, each of which represents 1 lb. of pressure. In regions of high intensity of pressure the lines are close to each other. If, for example, the pressure is 30 lb. on 1 sq. in. of one of the horizontal planes, then there will be 30 lines passing through that square inch. The lines spread as the distance down

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 1409.
† *Loc. cit.*, p. 1560.
‡ *Loc. cit.*, p. 1437, Fig. 9.
§ *Loc. cit.*, p. 1572.

ward increases. By subdividing a footing into small areas on which the direction and the intensity of pressure are nearly constant, a bundle of "lines of pressure" may be drawn for each of the areas and, by the principle of superposition, the intensity of pressure on any square inch of a horizontal plane may be found by counting the number of lines passing through that square inch and multiplying the number thus found by the number of pounds each line represents.

Lines of pressure for an 8-in. tie are illustrated in the Second Progress Report of the Special Committee on Stresses in Railroad Track.* The lines cross, indicating a concentration of pressure at a depth of 6 in. below the tie (found to be 163% of the average pressure by experiment). Below a depth of, say 6 in., the pressure in the ballast beneath the edge of the tie, and outward, is mostly due to the load applied by the opposite side of the tie. It may be stated that the lines of pressure should probably be slightly curved, although an empirical equation equivalent to straight "lines of pressure" gave results in very good agreement with the results of experiments for depths up to 24 in.†

The hypothesis of "lines of pressure" seems to have remained unnoticed, hence it seems desirable to call attention to its value in helping to explain the laws which govern the distribution of pressure through granular material.

The profession is greatly indebted to Professor Terzaghi for the new light he has thrown on a very difficult subject. The classification of clays by their "load-volume" relations, "permeability", and "shearing resistance", is an important advance over previous attempts which based the classification on color, grain size, water content, colloid content, etc.

The use of remixed material for determining "load-volume" relation and measuring "permeability" is open to the objection that the results do not apply to the undisturbed material. For example, in tests made on clay beneath the foundation of the new Materials Testing Laboratory at the University of Illinois, it was found that the water content of the undisturbed material was the same as that which corresponded to a pressure of more than 5 000 lb. per sq. ft. on the remixed material. The samples were taken at depths of about 3 and 6 ft. below the original surface where the pressures were, therefore, only a few hundred pounds per square foot. Both samples were taken below the water-table at the time of sampling, and the lower one was below the lowest water-table. Undisturbed clays probably have their flat, mica-like particles oriented in such a way that the voids are less than in the remixed material.

Methods should be devised for obtaining undisturbed samples for all the tests. This is very difficult even under the most favorable conditions and seems almost impossible in the case of material at great depths.

In the Red River Valley in Minnesota, North Dakota, and Canada, there is a widespread, deep bed of clay on which there have been many foundation failures. It has been found that buildings near railroad tracks have settled much more than similar buildings at a distance from the tracks, due to the

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 1577, Fig. 100.
† *Loc. cit.*, p. 1575, Table 19.

jarring action of heavily loaded trains increasing the instability of the clay mass.

Mr. Albert Jorgensen, who has conducted experiments in soil mechanics under the direction of the writer, makes the interesting suggestion that the distribution of pressure in clay beneath footings may be determined by experiments on models. A rather wet mixture of a uniform clay is to be placed in a large water-tight box with a thin layer of sand on the bottom and at the sides. A model of the particular footing to be tested is then to be placed and loaded. The surface of the clay is to be covered with water. The pressure on the footing will cause the water in the clay to flow away from the parts having the greatest intensity of pressure. When sufficient time has elapsed to reach the equilibrium condition, small samples are to be taken at various points in the mass beneath the footing and their water contents determined. From the "load-water-content" curve of the particular clay the water contents so determined may be translated into the intensities of pressure in the clay at the places from which the samples were taken. Measurements of the settlement of the footing, or of its parts, could also be taken. It is recognized that the box would have to be of large size to eliminate the effect of the boundaries on the distribution of pressure.

ALBERT JORGENSEN,* ESQ. (by letter).—This paper appeals to one who has studied it thoroughly because it shows that the author actually took some of the soil and determined its mechanical properties. He found that there is a great difference between the mechanical behavior of sands and clays and that clays vary greatly among themselves.

The capillary pressure of the water in the multitudinous, very small interstices in a clay is a factor of importance. It governs the volume occupied by a given clay under given conditions and under a given intrinsic pressure. This is one of the outstanding differences between sands and clays. The phrase, "under given conditions", is significant. The volume of a portion of clay at a given pressure (assuming that water is present) depends on the history of the clay.

If a sample of clay, in a condition near its lower liquid limit, is compressed by a certain pressure (p_1 lb. per sq. ft., for instance), it assumes a volume, definite for that clay, for the given pressure and the conditions of the test. Under the same pressure (p_1), but after having first been loaded to p_2 lb. per sq. ft., the same clay might occupy a different volume. For instance, if a sample of the same clay is made to sustain a pressure equal to p_1, but after having sustained a larger pressure (p_2), the volume will be smaller. Expressed differently, the pressure-moisture tests show that the volume at a given pressure depends on whether that pressure has been reached after positive compression only or after the clay has become re-saturated in recovering from a greater compression. The volume also depends on the intensity of the pressure attained before re-saturation was commenced and the number of times the clay has been compressed and re-saturated.

* Instr., Dept. of Gen. Eng. Drawing, Univ. of Illinois, Urbana, Ill.

The pressures may be applied mechanically in a manner designed to simulate actual conditions in the field; or they may be applied by the capillary pressure of the water which assumes enormous values if the sample is dried. Partly drying a sample would affect the clay to a degree comparable to that caused by a pressure which would produce the same change of volume.

Clay and mud beds, with the possible exception of recent delta and lacustrine deposits, have been subjected to unknown pressures and possibly may have been partly dried and re-saturated several times.

For these reasons a bed of clay below the level of ground-water is apt to be found dryer than could be explained by the existent pressure. For instance, the soil taken from beneath the location of a footing on the site of a certain building was found to be dryer even than the average unit pressure of the building would cause it to become. This soil was several feet below the level of ground-water. The pressure-moisture test, in this case at least, indicated that the soil had been compressed either by weight or capillary pressure.

The question then arises, as to what is the value of load-moisture tests in such cases. This would be answered if methods of sampling and technique for making tests on the soil in its original condition were at hand, but such methods do not seem to be forthcoming.

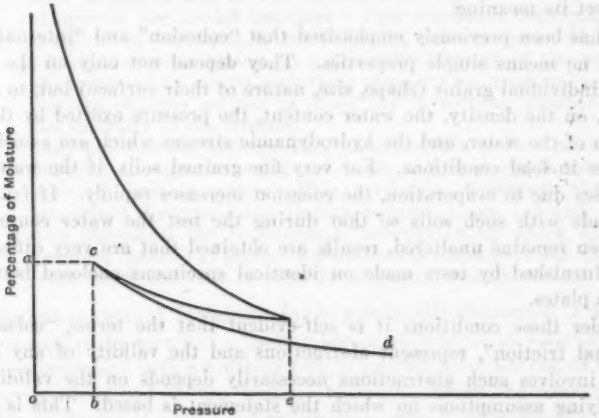

FIG. 49.

The next question which naturally arises is, "How may the tests be made on disturbed samples which will give a fair measurement of the condition of the undisturbed soil?"

The writer believes that a load-moisture test performed as follows, would give results which would aid greatly in formulating practical judgments concerning settlements due to change of volume of the soil. Wet some of the soil to a condition near its lower liquid limit and compress it in a cylinder by means of a piston. The soil should rest on a solid filter which will allow the water to pass to and from the soil as the pressure is varied. Compress the soil to such a point (Point *e*, Fig. 49) that when the pressure is reduced to *b* (that

pressure imposed on the soil in place), the moisture content will equal that of the soil in place (Point *a*). This would require nicety in testing and could probably be attained only after several trials. Then compress the soil to any desired degree.

The writer believes that the curve, *c d*, so obtained, would be accurate enough as a basis for practical judgments. It might have more value if obtained after several compressions and re-saturations.

In order to apply a pressure-moisture curve to aid in estimating settlement, it is necessary to know the distribution and intensity of pressures which exist under foundations. Tests by M. L. Enger, M. Am. Soc. C. E.,* and Messrs. H. E. Goldbeck,† and J. A. Moyer,‡ indicate that the pressures are far from uniform and may have values several times the average unit pressure.

CHARLES TERZAGHI,§ M. AM. SOC. C. E. (by letter).—This paper has called forth discussions from nineteen engineers in the United States, Russia, India, and China, representing a wide range of experience. While demonstrating the widespread interest in foundation problems, the discussion also disclosed the fact that few readers have had an opportunity to consult the publication from which the writer's Statement (*a*) was reproduced. For this reason, and on account of the condensed form of the statement, there was a tendency to misinterpret its meaning.

It has been previously emphasized that "cohesion" and "internal friction" are by no means simple properties. They depend not only on the character of the individual grains (shape, size, nature of their surface) but, to a variable degree, on the density, the water content, the pressure exerted by the surface tension of the water, and the hydrodynamic stresses which are associated with changes in load conditions. For very fine-grained soils, if the water content decreases due to evaporation, the cohesion increases rapidly. If friction tests are made with such soils so that during the test the water content of the specimen remains unaltered, results are obtained that are very different from those furnished by tests made on identical specimens enclosed between permeable plates.

Under these conditions it is self-evident that the terms, "cohesion" and "internal friction", represent abstractions and the validity of any statement which involves such abstractions necessarily depends on the validity of the simplifying assumptions on which the statement is based. This is obviously also true of the writer's Statements (*a*), (*b*), and (*c*). These refer to two different materials: (*a*) Those for which the bearing power depends essentially on cohesion, internal friction representing a negligible item; and (*b*) perfectly cohesionless materials. The validity of the statements is limited by the following assumptions:

(1) The shapes of the loaded areas are geometrically similar.
(2) The term, "settlement", refers strictly to the total downward movement measured after the structure has reached a state of complete rest.

* *Engineering Record*, Vol. 73, p. 106.
† *Proceedings*, Am. Soc. for Testing Materials, 1917.
‡ *Engineering Record*, May 30, 1914 and March 13, 1915.
§ Prof., Foundation Eng., Mass. Inst. Tech., Cambridge, Mass.

(3) The comparison between the settlement of loaded areas of different size should be confined to those produced by unit loads which are less than about one-half the ultimate bearing capacity for the smallest area.

(4) Hooke's law need not necessarily be accepted, but Poisson's ratio is assumed to be a constant.

Assumptions (1) to (4) apply to both Cases (*a*) and (*b*). The following additional assumptions apply to Case (*a*):

(5) The mechanical properties of the loaded material (relation between stress and strain and the compressive strength of the material) are practically independent of time and of the depth below the surface.

(6) At any point of the underground, failure occurs as soon as the difference between the greatest and the least principal stress exceeds the compressive strength of the material.

For Case (*b*), Assumptions (5) and (6) should be replaced by the following:

(7) The mechanical properties of the material (coefficient of internal friction) are practically independent of time and of the depth below the surface.

(8) The loaded material is incompressible; that is, the settlement of the load is merely due to the deformation, but not to the volume change of the loaded material. This condition combined with Assumption (4) leads to the following consequence: If all the principal stresses acting on a prismatic element of the material are increased by multiplying their intensity by equal amounts, the element changes neither in shape nor in volume, irrespective of the intensity of the stresses.

(9) At any point of the underground, failure occurs as soon as the ratio between the greatest and the least principal stress exceeds a definite limiting value. This condition represents the most important distinguishing feature between Cases (*a*) and (*b*); it also represents the fundamental assumption on which all earth pressure theories of perfectly cohesionless materials since Coulomb were based and may be considered almost strictly correct.

The subject content of Statement (*a*) is graphically illustrated in Fig. 50. Curve C represents the result of a loading test performed on an area (circular, square, or rectangular) with a width of 1 ft., supported by either one of the two ideal materials described by the writer. Curve C_1 shows the characteristic results of a loading test performed on an area with a geometrically similar shape, but with a width of 3 ft. supported by the first of the ideal materials; Curve C_2 applies to the second. The term, "ultimate bearing capacity", refers to the pressures, p_1 and p'_1, respectively, at which a very small increase in load produces a very important increase in settlement. The settlements produced by equal unit loads acting on areas of various sizes will be termed the "equivalent settlements" of those areas. Using these terms, the laws illustrated by Fig. 50 would be:

(*A*) If the ultimate bearing capacity of the loaded ideal material is essentially due to cohesion, the results of the loading tests performed on areas with a width, d, equal to 1 ft. and 3 ft., respectively, would be represented by Curves C and C_1 (Fig. 50). Under a load of p per unit of area, which is assumed to be

much smaller than p_1, the settlement, S_1, of the large area is approximately three times that of the smaller area, S; or, in other words, the equivalent settlement increases with increasing values of d. On the other hand, at a unit load of p_1, a small increase of the load produces for both areas a very large increase of the settlement, because both curves, C and C_1, bend steeply downward as soon as the load approaches p_1. Therefore, it is correct to state that the ultimate bearing capacity is independent of the size of the area.

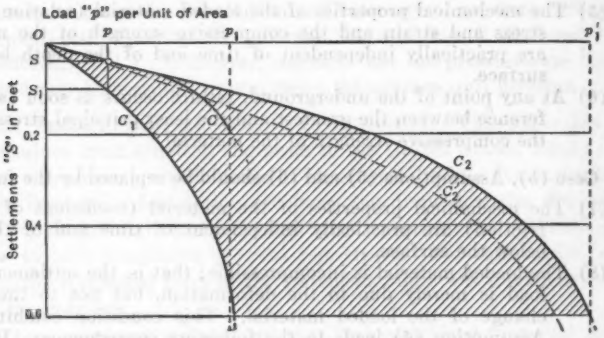

FIG. 50.—SETTLEMENT CURVES FOR LOADED AREAS.

(*B*) If the loaded ideal material is perfectly cohesionless, a similar pair of loading tests would be as plotted in Curves C and C_2 (Fig. 50). For a load of p per unit of area, the settlement, S, is practically independent of the size of the area, provided p is substantially smaller than p_1. On the other hand, the small area practically yields under a load of p_1 per unit of area, while the larger area must be loaded with $p'_1 = 3\,p_1$, in order to produce ultimate failure. Hence, it is claimed that the ultimate bearing capacity of the ideal, perfectly cohesionless materials (Law *B*) increases with the width of the area.

There was some doubt in the minds of most of the discussors as to whether Laws (*A*) and (*B*) were derived from theory or from experiments. To remove this doubt, it should be stated that the conclusions were obtained entirely by theory which was based on Assumptions (1) to (9), inclusive. As a matter of fact, if the validity of these assumptions is granted, Laws (*A*) and (*B*) need no proof, because they represent a simple consequence of the laws of similitude. Hence, any inconsistency between theory and practice must be ascribed to the properties of the material being at variance with those of the assumed, ideal materials.

If the properties of any soil conform reasonably well with the assumptions of theory, the laws represented by Fig. 50 must be valid. However, a comparison between the ideal materials and the actual soils leads to the conclusion that clean, cohesionless sands differ from the ideal cohesionless material inasmuch as they are not perfectly incompressible. If the intensity of all the stresses acting within the loaded material increases at the same rate, compression of the underground takes place which, in turn, causes a certain amount of

settlement in addition to that caused by distortion. Therefore, the empirical curve (C'_2 in Fig. 50) would be somewhat steeper than the theoretical curve, C_2; also, the ultimate bearing capacity of the loaded material may be slightly reduced for the same reason. However, since the compressibility of sands has already been thoroughly investigated, it is a simple matter of estimating roughly the discrepancies in every case that may come up in practice. For dense sands, the discrepancy between theory and practice is very small, while for loose sands it is apt to be important.

By comparing the ideal cohesive material represented by Curves C and C_1 (Fig. 50), with actual plastic uniform clays, the conclusion is reached that all assumptions are fairly accurate, except for a certain increase in the cohesion of the clay caused by progressive consolidation of the loaded material. Yet this increase could not possibly account for the striking discrepancy between the settlements which should be expected for clay foundations from the results of loading tests and the actual behavior of buildings standing on such materials. Among the fundamental assumptions of the theory, there is just one which could possibly be made responsible for the apparent defect of the theoretical results. According to Assumption (2), the term, "settlement", refers strictly to the total downward movement until the structure comes to rest. In practice, the settlement observations on buildings are made, at best, a few years after the buildings have been constructed, and when the settlement is still taking place.

The time which has to pass until the settlement of a fair-sized building resting on clay would approximately conform to Laws (A) and (B) obviously depends on the period required for the excess water to drain out of the clay beneath the building. This time, in turn, depends on the permeability of the clay and can be estimated by the theories previously published by the writer.* Suppose, for instance, that the settlement due to pure compression of the clay beneath an area 1 ft. wide was, after 5 days, 0.5 in. According to theory, for an area with a geometrically similar shape, 20 ft. wide, subjected to exactly the same load per unit of area, it would take $5 \times 20 = 100$ days to settle through the same distance of 0.5 in., provided the excess water could not escape except through the exposed surface of the clay, surrounding the loaded area; or, in other words, provided the bases of the loaded footings were water-tight. On the other hand, if the bases of the loaded footings were permeable, the settlement of both the small and the large areas, after 10 days, would be approximately identical. However, for the small area, the settlement would stop after it had reached during a period of several months a total of about 1.5 in., while for the larger one it would continue with decreasing speed until after several generations it would reach an ultimate value of $1.5 \times 20 = 30$ in.

Thus, it seems highly probable that the apparent contradiction between theory and practice for clay foundations is due not to a defect of the theory, but to the attempt to correlate the settlement of small loaded areas—measured almost as the footing comes to rest—with that of full-sized buildings in which the settlement has scarcely begun. As a matter of fact, in old cities with

* "Erdbaumechanik", Wien, 1925.

buildings resting on clay, or on very slightly permeable mud, such as parts of London or Constantinople, for example, there is ample evidence of progressive subsidence. The City of Chicago, Ill., too, despite its comparative youth, is crowded with instructive examples. A section of Cambridge, Mass., has subsided more than 2 ft. since 1880. If it were possible to compare the results of a loading test on clay with the settlement which a raft foundation, resting on the same clay, had undergone not 1 year but 200 years after the building was constructed, the agreement with theory would be much more satisfactory.

These statements are corroborated by the fact that the examples presented in the discussion as arguments against the validity of the writer's statement, referred entirely to clay foundations, on which the settlements are retarded by the enormous resistance of the material against the escape of the excess water. No contradiction was found to exist between theory and practice for foundations of friable limestone, muck soils, silt, and sand, and other fairly permeable materials (see, for instance, the discussions of Mr. White on limestone, Mr. Shaw on muck soils, and Mr. Wing on sand and gravel).

The bearing capacity of most of the more permeable soils commonly found in practice, for example, sands with traces of silt, or deposits of "muddy sands", is appreciably influenced by both cohesion and friction, the relative importance of cohesion depending on the composition and on the density of the material. For such soils, a loading test performed on an area 3 ft. wide should furnish a curve somewhere within the shaded area in Fig. 50, its shape and position depending on the degree to which cohesion participates in producing the bearing capacity.

Attention should also be called to the fact that Laws (*A*) and (*B*), or any rules for the interpretation of load test results, are based implicitly on the assumption that the soil is practically uniform and homogeneous to a depth at least equal to 1.5 times the width of the raft foundation, the settlements of which are to be predicted, or of the width of the area over which the footings are distributed.* Since in practice this condition seldom exists, the field for successful application of the load-test method for determining the admissible bearing value of the soil is far more limited than most engineers seem to realize.

In his paper the writer quoted the rules illustrated by Fig. 50 (Laws (*A*) and (*B*)), merely for the purpose of demonstrating that no real contradiction exists between the different settlement observations quoted in the paper (Chicago, San Francisco, or the test results of Goldbeck and of von Emperger), and that the apparent contradiction between these test results disappear if they are "examined in the light of applied mechanics". In all these cases, the properties of the loaded materials (hardpan in Chicago, succession of layers of clean or sticky sand in San Francisco), or the conditions under which the tests (by Goldbeck and von Emperger) were made, warranted the application of these principles (see Fig. 50). In contrast to this, no such application would be justified for correlating the results of a small-scale loading test on clay with the observations covering a period of a few months or years of the history

* According to Assumptions (5) and (7), p. 381, strict validity of the laws, requires uniformity of soil conditions to a depth equal to infinity.

of the settlements of a raft foundation resting on the same clay. In brief, the application of any rule to practical cases should be preceded by a careful investigation in order to determine to what extent, if any, the practical conditions agree with the fundamental assumptions of the rule. Due to the wide variation in soil properties no rules can be established that are valid for all soils.

The discussions deal essentially with two main topics—the *Engineering News* formula and the interpretation of the results of loading tests.

Among those who discussed the *Engineering News* formula, only one had anything to say in its favor. The others rejected it more or less emphatically, and without exception, on the basis of past experience. However, little attention was paid to what the writer considers by far the most important feature of the situation, namely, that the most general pile-driving formula (Equation (3)), is fundamentally rigorous, provided one grants the validity of the basic assumptions. The most important of these assumptions concerns the identity of the static and the dynamic pile-driving resistance. The failure of the formula to give satisfactory results for pile-driving through clay or saturated silts is due merely to the fact that, in these cases, the conditions existing in practice fail to conform with the theoretical assumptions.

These remarks lead to the attitude of the discussors and of engineers in general toward the writer's statements as illustrated in Fig. 50. Some experienced engineers have accepted these statements as not being in contradiction with their own observations. Others, also, backed by broad personal experience, have rejected them. This fact should arouse the suspicion that conditions are not simple enough so that solutions can be found in the shape of rough and ready half empirical formulas. In a third group of discussions, attempts have been made to disprove the statements by proposing formulas which are claimed to agree better with practice.

These reminded the writer of the many discussions he has read about pile-driving formulas in past years. The method of approaching the problem was always the same. As often as a new formula appeared it was found invariably that the results furnished by it did not agree with many of the observed facts; therefore, it was argued that the formula must be modified. Nobody seemed to suspect that its deficiency might be due to the nature of an assumption in common to both the criticized and the proposed formulas. Hence, the discussion of the pile-driving formula revolved for half a century in a vicious circle.

None of the discussors seemed to realize that the writer's statements stand as firmly "on their feet" as applied mechanics, provided the fundamental assumptions conform with the conditions existing in practice. The assumptions cover all the essential mechanical properties of the soils, except those which depend on time as, for instance, the compression of a clay or of a very fine saturated silt. In a similar manner, the assumptions on which Equation (3) is based consider all the essential elements of pile-driving, except the fact that, in many cases, the dynamic and static pile-driving resistance are not identical. Hence, it is justifiable to conclude that Laws (*A*) and (*B*) must be correct, except for cases in which the time factor partly or wholly upsets their validity for the brief period covered by the observations.

Instead of presenting this simple, but very important argument, the members of the third group of discussors merely tried to replace the laws, which have a limited but known range of validity, by others which are neither justified by rigorous analysis nor supported by a known range of validity. In doing so, this group repeated the mistake made by discussors who tried to replace the classical pile-driving Formula (3) by other more objectionable ones, instead of inquiring as to the fundamental cause of the observed disagreements.

These remarks also apply to discussors of the second group who attempted to question the soundness of the writer's statements solely on the ground of past experience. After realizing the limitations of theory, these engineers may ask: What then is the use for establishing rules at all? The answer to this question touches the most vital point of the science of foundations, and it cannot possibly be over-emphasized.

Settlements, as encountered in practice, depend as a rule on a number of circumstances, such as depth of foundation; presence of other structures in the vicinity of the new building; the occurrence of alternate layers of slightly permeable and markedly permeable strata; total thickness of the compressible deposits; relative position of the weakest spots of the underground with reference to the base of the foundation; and many others. In brief, the settlement of a structure is a function of so many variables that it would be hopeless to arrive even at crude and empirical conceptions of the causes of settlements unless systematic efforts are made to evaluate the relative importance of each one of the individual variables. This can be done merely by establishing a theory, not of the complex materials encountered in practice, but of a set of ideal materials with certain very simple properties, each one of which will serve as a means of studying one individual aspect of the real soils.

By such systematic analysis only can engineers gradually gain a deeper insight into the workings of actual soils. Since by necessity the very best analysis of that type falls far short of taking into account all the conditions that exist in practice, there always will be a certain gap between theory and practice, which can be bridged merely by experience. Considering the existence of this gap, the writer agrees heartily with Mr. Gow's warning against readily accepting common formulas for use in actual practice. The writer even doubts whether formulas with a fairly general degree of validity could be established at all. Theory in connection with foundation engineering should be regarded merely as an essential supplement to experience, to be used as a tool for acquiring a deeper insight into the causes of observed foundation defects and for evaluating the relative importance of the factors in existence.

Without a more profound analysis of phenomena encountered in practice, experience is doomed to remain the same accumulation of incoherent, meaningless facts which fill the space between the covers of many textbooks on foundation engineering. The time may come when a man with experience, but without a thorough theoretical training, will be considered almost as unfit to be trusted with a design of an important foundation as the theoretician who has had no experience. In structural engineering, this time came nearly a century ago.

The writer hesitates to accept Mr. Gow's advice concerning the *Engineering News* formula. If, as Mr. Gow states, it is a fallacy to rely too strongly on the results of individual pile tests, the application of the *Engineering News* formula seems to represent an even greater fallacy.

It is significant that Mr. Goodrich abandoned the formula long before the writer had even heard about its existence. The observations made by Mr. Goodrich concerning the stress distribution over a square bearing plate should be an incentive for similar investigations of raft foundations resting on clay soils by means of Goldbeck pressure cells or similar devices.

The experience reported by Mr. Endersby reminds the writer of a similar incident which occurred in Galveston, Tex. On the south side of the Island of Galveston, to a depth of about 50 ft., the underground consists of very fine sand mixed with powdered shells. Because of the very dense structure of this sand, it is considered impossible to drive piles to a depth of more than 15 or 20 ft. without smashing the pile-head. According to Colonel Schley, Government Engineer of Galveston, some piles driven with a steam hammer to refusal settled afterward several inches under a static load of less than 15 tons. This and the incident mentioned by Mr. Endersby are obviously decompression phenomena which can also be reproduced in the laboratory. If a layer of sand that is laterally confined is subjected to a rapidly applied pressure up to a certain value and then the pressure is kept constant (possibly by a testing machine), the counter-pressure of the sand against the piston first drops rapidly and then slowly to less than one-half the original reaction. In connection with this statement, it should be emphasized that there seem to be no records of conspicuous decompression phenomena except for cases in which the pile-driving was done with a steam hammer that could apply pressure very rapidly. The intensity of the decompression phenomena may be considerably increased by the presence of a layer or pocket of very loose sand a short distance beneath the point of the pile. Since the number of known conspicuous decompression phenomena on piles is exceedingly small compared to the number of cases in which the piles behaved normally, such a possibility could at least be considered.

Mr. Endersby's statement that the result of the tests with three different hammers was "a good test for consistency of the [*Engineering News*] formula as applied to various types of hammers", should be accepted with caution. The satisfactory agreement between the results appears to be mere chance; otherwise, it would always exist. To mention one example among several on record: When driving the piles for the Mariotis Lake Bridge, in Egypt, three different pile-drivers were used: A steam hammer (weight, $R = 4\,400$ lb.; drop, $h = 3.28$ ft.); a hand-operated drop hammer ($R = 1\,320$ lb.; $h = 6.56$ ft.); and a steam drop hammer ($R = 4\,400$ lb.; $h = 3.28$ ft.). The points of all the piles penetrated the same stratum of sand.* The *Engineering News* formula furnished for the safe bearing capacity of these piles the average values of 66 800, 16 800, and 27 600 lb., respectively. If the *Engineering News* formula would furnish consistent results for piles driven into the same stratum with

* According to Mr. W. Stross, in *Beton und Eisen*, 1908, p. 113.

different types of hammers, these three values would have been fairly identical. Mr. Endersby's statements show how a formula can acquire a good reputation by an act of Providence rather than by inherent merits. Since engineers very seldom have a chance to watch different types of pile-drivers operating simultaneously on a very homogeneous material, they are apt to base their opinions on an inadequately small amount of actual evidence.

Mr. Paaswell justly emphasizes the fact that the New York Subway "is unquestionably the world's best laboratory for the study and illustration of all types of foundation problems". The same was true for the Panama Canal in the field of stability of earth slopes. Unfortunately, very few results of lasting value were derived from the Panama experiment because of lack of funds available for purely scientific research. In New York, the unique opportunity for systematic research seems by no means to have been utilized to full advantage. The New York Subway remains a beautiful laboratory without equipment and without personnel. The profession should appreciate all the more the idealism of those few engineers engaged in subway construction who, by their own initiative, seriously endeavor to broaden technical knowledge on this subject by systematic experimentation.

Mr. Williams presents a theory based on three assumptions: (*a*) That settlement is merely due to compression of the underground; (*b*) that the total depth of soil compressed is limited by the depth at which the pressure intensity (per unit of area) drops below a certain limiting value; and (*c*), that the coefficient of compressibility, C, is independent of depth. Attention should be called to the fact that Assumption (*c*) could merely be considered approximately valid for materials with strong cohesion; for cohesionless materials, on conclusive, experimental evidence, it does not apply. Mr. Williams then computes the settlement of square areas with different widths, b. From Assumptions (*a*) to (*c*), it is evident that h (Fig. 18), increases in simple proportion with b. This fact is also expressed by Mr. Williams' formula, $h = \frac{b}{r}\left(\sqrt{\frac{w}{p}} - 1\right)$. By introducing the value of h into the terms preceding this formula, the same results are obtained as those expressed by Curve C_1, Fig 50. However, instead of retaining h, Mr. Williams ceases to consider it as a function of the width, b, without attempting to justify his step, thus transforming it into a constant. This operation leads to the formula, $W = A\,p + L\,f$, which contradicts his theory. Since his final formula does not represent the result of the theory, it could be accepted merely as an empirical equation and the writer considers that the empirical evidence is too fragmentary to warrant such a step.

The example quoted by Mr. Williams (the office building of the Michigan Central Railway Company in Detroit, Mich.) does not invalidate Curve C_1, Fig. 50. To conform with the assumptions of theory, the underground should be uniform to a depth equal to at least one and one-half times the width of the building. In contrast to this, from his own experience, the writer can state that the clay deposit of Detroit is far from being homogeneous. It consists of an irregular succession of layers of soft and stiff clay.

Furthermore, the observations quoted by Mr. Williams refer to a recently constructed building and settlements are not comparable as long as one of them still continues. For a building resting on clay foundations, the settlement twenty years after it was constructed is certainly not identical with that just after the building was completed. It may be many times more important. Thus, for instance, in Massachusetts, a short time after construction, the settlement of an important structure founded on plastic clay ranged between 0.1 and 1.1 in. One year later, the extreme settlements had increased to 0.6 and 2.8 in., respectively, and ten years later, they amounted to 1.0 in. and 7.6 in., respectively. In Chicago, conditions are not very much better.

Mr. Williams suggests reducing the discrepancy between the results of the loading test and the actual settlement by loading the soil around the test footing. To follow this procedure would mean an attempt to compensate for the effect of the time factor, which is absent, by adding a load factor. The importance of the time factor on the relation between settlements of small and large footings is exceedingly different even for the same clay, depending on the water content. Hence, it seems rather difficult to establish a reliable rule for computing the intensity of the compensating load which should be applied around the footing. Instead of trying to reduce the discrepancy between test results and the settlement of the proposed structure by introducing into his arguments one more element of uncertainty, the writer takes it for granted that this discrepancy (together with the possible effects of the lack of uniformity of the underground) represents inevitable defects of the load test method. Hence, when attempting to evaluate the probable settlement of a proposed structure, he bases his judgment not only on test results and his knowledge of soil physics, but also on past experience and on what the test borings show about the nature of the deeper strata. Test results and physical knowledge are used merely for establishing connection between past experience and the new situation. In no case would he dare to rely solely on a test result.

Mr. Williams states that the writer neglected the effect of the deflection of the foundation on the pressure distribution over the base of the foundation. For foundations on well compacted sand, the pressure-relieving effect of the deflections is very important indeed, but for soft soils, this is insignificant. This fact has been known for more than forty years. Since most raft foundations are supported by soft soils, designers do not often have an opportunity to take advantage of the pressure-relieving effect of deflection. The question concerning the distribution of pressures over the base of raft foundations is still in a controversial state, and the discussion by Mr. White of the same topic seems to indicate that engineers are by no means unanimous in assuming uniform pressure distribution to be safe.

Dr. Chatley calls attention to the slowness with which hydraulic fills, consisting of fine alluvium, expel their excess water. During 1928, under the writer's supervision, Glennon Gilboy, Jun. Am. Soc. C. E., made an exhaustive study of the process of consolidation of an hydraulic-fill dam. For this purpose, a shaft was sunk through the core of the dam and undisturbed samples were secured at various depths below the crest. The results

of these investigations represent an important contribution toward present knowledge of the consolidation process; they conform with Dr. Chatley's observations and with the conclusions previously drawn by the writer from theory.

Dr. Chatley's conception of the part that the molecular bond plays in the physics of granular masses is fundamentally sound, although it is still doubtful whether the molecules of two adjoining particles interact directly or whether the interaction merely takes place between the molecules of the skins of adsorped materials surrounding the particles.* The possibility undoubtedly exists that the degree of dispersion of a highly colloidal soil may gradually change. To date, very little is known about this process. The writer is inclined to believe that it is often associated with chemical changes and that it plays a very important part in Nature.

The most promising methods for the design of sheet-piling seem to be those based on the assumption of a circular sliding surface. These methods were developed by K. E. Petterson, Sven Hultin, and W. Fellenius, in Sweden.†

In 1920 the writer was at least as enthusiastic about colloids and about the possible benefits to be derived from colloidal chemistry for foundation and earth-work engineering as Mr. Holmes is to-day. However, during the succeeding years of struggle with the complex material called soil, this enthusiasm has dwindled to practically nothing. Some of the reasons of the progressive disappointment can be explained by means of Mr. Holmes' own data. He admits that "extracting the colloids from a soil to determine the amount of colloidal material is a long and laborious process". Therefore, he proposes a simplified method of his own. According to Fig. 20, an ignition loss of 3% may mean anything between 6% and 29% of colloid content.

Furthermore, since the physical properties of soils with equal "colloid content" are apt to be widely different, Fig. 20 is certainly not a very convincing argument. The following data from tests on a soil in Spanish Honduras may serve as an illustration. The soil had a clay content of 70% and, in its natural state, a water content of 33 per cent. The coefficient of permeability of this soil was found to be: (*a*) Undisturbed sample under primeval forest with 33% of water, $k = 2.6$ cm. per min.; (*b*) the same soil dried, powdered, and compacted, $k = 0.0024$ cm. per min.; (*c*) the same soil with the same water content as in Case (*a*), but after completely destroying its original structure by kneading, $k = 0.00000085$ cm. per min. In addition, by increasing the water content of Sample (*c*), from 20% to 40% the coefficient of permeability was increased from 0.00000010 to 0.00000250.

Hence, even if a rapid and reliable method should be found for determining the percentage of colloids, it may have but little practical value. The quality of a dam construction material depends essentially on its permeability, cohesion, and internal friction. No simple and universally valid relation exists between the colloid percentage and any one of these important physical properties. The situation becomes still more involved considering that

* "Mechanics of Adsorption and the Swelling of Gels," by Charles Terzaghi, M. Am. Soc. C. E., Fourth National Colloid Symposium, 1926.

† "Erdstatische Aufgaben," W. Fellenius, Berlin, 1927; "Erddruck, Erdwiderstand und Tragfähigkeit des Baugrundes," H. Krey, Berlin, 1926.

both the permeability and the cohesion of any soil may vary between extremely wide limits, depending only on the history and not on the substance of the soil deposit. Nothing except a refined chemical analysis could disclose the nature of the admixtures. Finally, some of the most excellent dam construction materials that the writer has ever encountered, which were splendidly fit for constructing earth dams without a core-wall, contained almost no colloids.

Considering these and many other facts, the writer cannot be blamed for his skeptical attitude toward those who hope to derive important practical benefits from colloidal research. He prefers to obtain data directly from the results of appropriate experiments. Nevertheless, any advance in the field of colloid chemistry is of outstanding interest to every one dealing with soils and with earthwork engineering. This interest, however, is at present of a purely scientific nature.

Mr. Feld thinks that the writer's effort to establish a more accurate interpretation of actual construction experience is a desire to "suddenly substitute a new 'science of foundations'." for precedent and experience. No such intention ever entered the writer's mind. The need is, not for a latent state of war, but a more intimate co-operation between field and laboratory. In establishing such co-operation, the absence of any authoritative nomenclature certainly is a serious handicap; but it is by no means the principal stumbling block. Far more detrimental is the widespread lack of training in abstract reasoning and the tendency to reject theory completely unless it leads, overnight, to conclusive results.

The reason the writer neglected to deal with the effect of the shape of the area on settlement is obvious. At the time when the paper was written, he did not know anything about it. Even in the case of the bearing of solid against solid within the elastic limits, the shape of the area has a very important effect, but all efforts made to solve the problem theoretically thus far have failed. However, since January, 1927, experiments have been conducted at the Massachusetts Institute of Technology, for the purpose of getting at least preliminary information on this controversial subject. The results obtained are interesting enough. They suggest that the effect of the shape of the area on both the equivalent settlement and on the ultimate bearing capacity may be very different, depending on the degree of cohesion.

For example, assume two loaded areas, one with a circular shape, of which the diameter is d, and the area, f; and the other one rectangular with the width, d, and a length several times larger than d, so that the area is F. For a material with dominating cohesion (Plasticine), the equivalent settlement for f was found to be smaller than that for F. On the other hand, the ultimate bearing capacity for f was found to be considerably greater than that for F. For perfectly cohesionless materials, the opposite relation was found to exist. The tests were repeated several times, and the results were remarkably consistent. Here, again, it seems a fact that the influence of the shape of the area may be very different, depending on whether the bearing capacity of the material is essentially due to cohesion or to internal friction.

The "sympathetic" settlement of adjoining footings may have very different causes. In the case illustrated by the writer's Fig. 11, a fence post

located at a distance of about 300 ft. from Building (*b*), had settled several inches. In this case, the sympathetic settlement was due to the presence of a layer of sand beneath a bed of unconsolidated clay. Another type of sympathetic settlement (settlement of the surface of the ground in the vicinity of a concentrated load) has been treated theoretically by the late Professor A. Föppl in "Vorlesungen über Technische Mechanik", which also contains the results of the tests performed in order to check the theory.

Mr. Housel presents a series of very interesting and valuable test results. However, from these results, he feels justified in concluding that the statements presented by the writer concerning the relation between the bearing capacity and the diameter of round plates, is false, and that they lead to absurd results. A similar opinion is known to be held by many other engineers.* The writer, therefore, may be justified in examining the arguments presented by Mr. Housel in somewhat greater detail.

At the outset of this closing discussion, the writer quoted the assumptions on which Fig. 50 was based. It also was shown that Laws (*A*) and (*B*), derived from these assumptions, are as unquestionable as the laws of applied mechanics, provided the assumptions agree with conditions existing in Nature. Therefore, if a discrepancy is found between theory and practice, it must be due to some factor not taken care of by theory. In the case of foundations resting on clay, an apparent discrepancy was found to be caused by the low permeability of the material which retards the settlement of a large footing much more than that of a small bearing-block. The advantages to be derived from such knowledge are manifold.

The first lesson learned is the intimate relationship that exists between the low permeability of the underground and the progressive settlement of the buildings which it supports. Furthermore, it is important to understand that a settlement of identical foundations on identical clays may be very different, depending on whether or not the clay contains streaks or layers of permeable sand through which part of the excess water of the clay may freely drain. It is also important to prevent the mistake of applying to a fairly permeable system of strata the experience previously obtained with foundations on very slightly permeable materials, such as plastic, homogeneous clays. That is what the writer calls a "scientific approach" to a soil problem; an attempt to uncover the responsible factors by isolating the variables and systematically determining their relative importance.

However, Mr. Housel selected another and apparently simpler method of dealing with his subject. Instead of attempting to investigate whether or not the statements quoted by the writer were consistent with the accepted laws of mechanics, he introduced into his discussion rather vaguely defined conceptions such as "shearing resistance" per unit per length of perimeter and "pressure bulb". These conceptions certainly are convenient for a general description of the conditions which exist in the underground of a loaded area; but, if it comes to rigorous analysis, they cease to exist. In applied mechanics, the term, "shearing resistance", refers exclusively to a unit of area, not to a unit

* *Engineering News-Record*, March 29, 1928, p. 520.

of length, and the pressure bulb is not referred to at all, except inasmuch as it indicates vaguely what is rigorously expressed by the formulas of Hertz and Boussinesq.

Considering these facts, it is very difficult to translate into terms of applied mechanics such statements as "the important consideration * * * is the effectiveness with which the different shaped plates adjust themselves to the pressure bulb."

Speaking of his test results, Mr. Housel admits that the results agree with conditions as defined by Curves C and C_1, Fig. 50. Yet, he rejects them because "* * * when the principle is applied to the much larger areas used in practice that the fallacy of this assumption becomes apparent". Then, without preceding analysis, Mr. Housel supersedes the term he rejects by a term of his own conception (Equation (11)), and simply claims that his term represents a satisfactory solution, valid for all soils irrespective of their physical properties. Nowhere in his discussion does he hint at the possibility that a difference in drainage conditions may have a far greater influence on settlements than a difference in compressibility or in internal friction.

Mr. Bailey touches the human side of foundation engineering by quoting two cases of failure which occurred in spite of thorough preliminary work. The question arises: Will it ever be possible to avoid entirely such tragic incidents? The writer does not believe so. At the same time, from his personal experience with foundation failures, he is convinced that more than 90% of the accidents which occur nowadays could be avoided by proper application of the results of soil research to the design of foundations. The others will remain inevitable, very likely forever, on account of the fragmentary character of the information furnished by test borings. By transforming this fragmentary information into complete geological profiles, the engineer automatically introduces into his forecast a personal element and with it an element of uncertainty. Thus, on construction work with which the writer was connected, careful test borings were made and all of them indicated the presence of a continuous bed of very stiff clay extending to a considerable depth below the base of the proposed raft foundation. Immediately before the reinforcement for the concrete slab was placed, water broke through the bottom of the pit, carrying large quantities of very fine sand. Subsequent investigation by supplementary boring showed that there was a narrow belt of quicksand enclosed within the clay bed at a very shallow depth below the bottom of the excavation pit and by mere chance the test borings missed it.

The risk caused by the fragmentary character of test-boring records will always continue to exist. In connection with dam foundations this inevitable risk is very much greater and very much more serious. The ultimate aim of the science of foundations merely consists in reducing the present intolerably wide margin between the factor of safety of the most and of the least solid foundations.

Mr. Condron describes an instructive case of foundation experience in connection with the Chicago blue clay. According to the test borings, the stiffness or the cohesion of this clay increased considerably with the depth.

Since the cohesion of the clay varied with the depth, and since, in addition, the clay represents a very slightly permeable material, Law (*A*) is not directly applicable to Mr. Condron's case, and the interpretation of the test results represents a rather complicated problem of soil physics.

Mr. Condron's method of handling the problem can be considered a typical example of a very conscientious and conservative approach along the lines of current practice. In order to determine wherein this practice may fall short of what is desirable, engineers may ask the question: What arguments led Mr. Condron to conclude that 3 000 lb. per sq. ft. is a safe load for the soil which he tested?

His most important argument undoubtedly was that the neighboring buildings, with foundations designed for a soil pressure of 4 000 lb. per sq. ft., showed no evidence of unequal settlement. After Mr. Condron had verified this fact, he made a loading test, with the soil around the loaded area remaining in place. From the favorable outcome of this test, plus the evidence furnished by the neighboring buildings, he reached his conclusion.

If the procedure for determining the admissible soil pressure is so simple, then why does the engineer need any of the more refined soil studies? To answer this rather vital question, suppose that an engineer has to construct a duplicate of Mr. Condron's building. Before preparing the plans for the foundation, he makes exactly the same test as Mr. Condron did, except to assume that there are no neighboring buildings the behavior of which would inform him about the quality of the underground. Furthermore, when making his test borings, suppose that the engineer discovers that, to a depth of 10 ft. below the base of the proposed footings, the underground is the same as that found by Mr. Condron. Below that depth conditions differ in one of three possible ways, as follows:

(*a*) Instead of homogeneous stiff blue clay, there is a homogeneous soft blue clay.

(*b*) Instead of homogeneous stiff blue clay, there is a stiff blue clay which contains several layers of dense but very permeable, water-bearing sand.

(*c*) Instead of homogeneous stiff blue clay, there is a "varved" clay, consisting of a succession of almost impermeable and fairly permeable layers about 1 in. thick.

Since, at a depth of 10 ft. below its base, the soil pressure exerted by the loaded 6-ft. square test footing is already negligible, the outcome of the loading test will be almost exactly identical with that obtained by Mr. Condron. Yet, the major part of the pressure bulbs of the full-sized footings will be in a material altogether different from those in the case cited by Mr. Condron. As a consequence, the ratio between the settlement of the test footing and of the full-sized footings will also be altogether different.

In Case (*a*), the settlement due to lateral yield of the soft clay will be much more important than it was when the deeper part of the stratum consisted of stiff material. In Case (*b*), the excess water in the clay beneath the full-sized footings can freely drain into the sand out of the clay, while

through the homogeneous stiff clay beneath Mr. Condron's building, it could not percolate except very slowly. In Case (*c*), the clay can discharge its excess water still more freely, and the settlements due to gradual consolidation are apt to be very important although the material gives the impression of being very stiff. Whenever, in practice, the writer encounters "varved clay", he knows there is trouble ahead, and experience has invariably confirmed his anticipation.

The engineer who pays little or no attention to the manifold characteristics of soils would be apt to trust the outcome of the loading test, and would consider Cases (*a*) to (*c*) to be identical with the one described by Mr. Condron. Hence, he would also consider 3 000 lb. per sq. ft. a safe load and to his surprise the result of his decision would be an excessive settlement of the structure. The task of developing a "science of foundations" consists in preventing such errors by painstaking analysis of the relative weight of each individual factor which could possibly influence the behavior of the proposed structure. Without such analysis, the profession would have always as many different rules for the interpretation of the results of loading tests as there are engineers who keep a record of their observations.

Mr. White's experience, derived mostly from construction work in New York, covers some of the most difficult fields of foundation engineering and, whenever he chooses to disagree with any of the writer's statements, the writer always feels compelled to "think it over twice" before he replies. The two points wherein Mr. White's opinions seem to differ from those of the writer are the value of loading tests and the relation between the bearing capacity and the density of soils.

The principal arguments against placing too much confidence in loading tests were explained in general at the beginning of this closing discussion and by means of an example in the writer's comment on Mr. Condron's discussion. The writer uses loading tests merely as a means of investigating the character of individual strata, but he never would dare to pass judgment on the probable settlements of a full-sized structure without careful consideration, not only of the results of the loading tests, but also of the influence of the characteristics of those strata between the elevation of the base of the pressure bulb of the test footing and that of the full-sized footing. The cases in which the soil is of a perfectly uniform character to a depth at least equal to the width of the building are very rare.

The relative density of a soil or of a rock is undoubtedly a factor of importance, but unfortunately the relation between the behavior of this soil and its density are by no means simple enough to furnish reliable information on the bearing capacity of the material. Thus, when experimenting with clays, the writer had an opportunity to compare two blue clays from two different localities. One of these clays, with a water content of 35% (volume of voids, 48%) was almost liquid, while the other with exactly the same water content and the same volume of voids was found to be stiff and had a very appreciable consistency. Similar although less conspicuous variations were found to exist when experimenting with sands.

This leads to a discussion of the effect of the shape of the grains. Mr. White is inclined to assume that the large voids ratio may have the same effect on the mechanical properties of a sand as the mica content. As a matter of fact, the compressibility of the same sand increases rapidly with its volume of voids. There is, however, one fundamental difference between pure sand and sand-mica mixtures which cannot be explained by Mr. White's assumption. This difference concerns the elasticity of the two materials as illustrated by the shape of the rebound curves. Thus, when experimenting with very fine quartz dust, it was found that the compression curve of this material was almost as steep as that of a sand-mica mixture, but the rebound curve was almost as flat as that of an ordinary sand, while the rebound curves of the equivalent sand-mica mixture rose very sharply. Since the rebound curves of the clays are as steep as those of sand-mica mixtures, the writer concluded that the clays and silts owe their mechanical properties essentially to the presence in the material of a high percentage of scale-like particles. At the time when this statement was published, it was presented as a hypothesis. Since then, Professor Goldschmidt, in Oslo, Norway, has succeeded in measuring the actual quantity of scale-like particles present in typical Norwegian clays,* and the data which he obtained checked so well with those derived from the sand-mica experiments performed at Massachusetts Institute of Technology that there is little doubt about the hypothesis being fundamentally sound.

From a practical point of view, the principal difference between very fine sand and an equally fine sand-mica mixture is that the volume of voids in the former is always very much smaller than that of the latter, provided both were deposited by identical geological processes. Sand-mica mixtures with macroscopic grains and with a high percentage of mica have not yet been found in Nature. The so-called "micaceous sands" as a rule contain only a very small fraction of mica by weight. The micaceous appearance is due to the fact that a single sand grain weighs twenty or more times that of a mica flake of equal size.

Mr. White is inclined to doubt the validity of the writer's statements concerning the effect of the depth of a foundation on the settlement for perfectly cohesionless material. His doubts are unquestionably based on what he has observed in actual practice where he has had almost no chance to study a material conforming with the condition of perfect lack of cohesion.

Mr. White's examples of the general character of the settlement of whole buildings (Fig. 31) leave little doubt that the centers of the outside walls settled more than the corners, but it is still an open question whether the centers of these buildings settled more than their perimeters. In order to insure uniform settlements, some engineers in Texas follow the practice of keeping the soil pressures for the outer footings 12 to 20% less than those for the inner footings, and their experience seems to confirm the soundness of their practice. It should also be considered that the relation between the amount of settlement of the center and of the perimeter of a building, at equal

* Abstract by Charles Terzaghi, M. Am. Soc. C. E., in "Economic Geology," 1928.

soil pressure per unit of area may be very different, depending on the degree to which the cohesion of the underground dominates over internal friction.

The introductory remarks of Mr. Simham's discussion describe exactly what the writer has been "driving at" for many years. The writer also concedes that no laws can be derived from uncorrelated sets of experiments; but, at the same time, he seriously doubts whether any formula can be derived to cover all the requirements of actual practice. In dealing with foundation problems, the writer confines himself to what Mr. Simham calls "a careful diagnosis of every factor that influences the behavior of a soil", and in doing so he has almost invariably found that he must be satisfied with finding out to what extent his previous experience applies to new cases. All the rules which he derived, and very likely all those which he will derive in the future, are merely intended to be tools for use in this fundamentally important diagnosis.

Equations (12) to (21), inclusive, represent one possible approach among many to a mathematical description of what engineers may observe. However, their value will depend on the degree to which Mr. Simham succeeds in taking care of the time factor, which is the stumbling block in the path of all similar attempts.

Mr. Marston describes an example for the application of soil physics to the study of materials for hydraulic-fill dams. Since this investigation was terminated, much progress has been made along similar lines by the work performed in the writer's laboratory. In pursuing this work, the thorough investigation of perfectly undisturbed materials extracted from the core of an existing hydraulic-fill dam proved to be of inestimable assistance and threw much light on the disputed problems. (See, also, the writer's comments on Dr. Chatley's discussion).

Mr. Shaw describes interesting experiences with New Orleans muck soils. Since the internal friction of under-drained muck soils is extremely low, their bearing capacity depends essentially on their cohesion. At the same time, that they are fairly permeable is proved by the fact that it is possible to drain them with open ditches. For soils of such a character the rule represented by Curves C and C_1, Fig. 50, has at least approximate validity. This statement agrees with Mr. Shaw's experiences.

Furthermore, previously published theoretical investigations of the writer have led to the following conclusions regarding the ultimate bearing capacity of medium permeable and saturated silts and muck soils. Select on the surface of such a soil two equal areas and load both of them at a different time rate until failure occurs by an "out-and-up" flow of the loaded soil. The more slowly the load is applied, the more chance the soil has to expel its excess water during load application. Therefore, ultimate failure of the area which was loaded very slowly will occur at a higher load per unit of area than that on which the load was rapidly applied. This theoretical conclusion is substantiated by the success of Mr. Shaw's method of levee construction by successive application of wide and thin layers. The compacting effect produced by load application is illustrated by the writer's Fig. 4.

Mr. Shaw's observations concerning the difference between the effect on soft soils of concentrated and of distributed loads call attention to an impor-

tant fact, closely related to the influence of the depth of foundation on the ultimate bearing capacity of the soil. Suppose the area, *a-a* (Fig. 51), is uniformly loaded, while on both sides of *a-a*, the load decreases from its value at *a* toward zero. For this case, both theory and experience lead to the conclusion that the wider the area over which the load spreads, the greater is the load, p, p_1, p_2, etc., at which failure occurs.

The effect of the flaring out of the load becomes still more conspicuous if the thickness of the soft layer is very much less than the width of the base of the fill (Fig. 52). In this case, the soft layer is "trapped" between the base of the load and the surface of the stiff layer. If the fill has no tensile strength, the limited depth of the soft layer and the friction along the top surface of the firmer ground introduce factors of resistance absent in deposits of greater depth; but if the fill has tensile strength, an arching effect, similar to that which takes place in grain bins, still further reduces the tendency of the soft material to flow. (See Fig. 52.) From his experiences with the construction of fills on peat deposits in Michigan, Mr. V. R. Burton* concluded that in placing a fill with a width ranging between 24 and 30 ft. on the surface of a peat deposit, the character of the resulting subsidence was very different, for varying thicknesses of the deposit. If the thickness was less than about 20 ft., the fill merely produced a trough-like depression in the peat deposit. On the other hand, if the thickness of the deposit exceeded about 26 ft., the fills penetrated as far as the bottom of the deposit, thus completely displacing the peat beneath the center line of the fill. Examples of the sudden subsidence of fills placed on soft muck soils can be found in the report of the Swedish Geo-Technical Commission.† The observations made by the Swedish engineers in connection with large-scale subsidence failures led them to base their stability computations for such soils on the assumption of circular sliding curves.

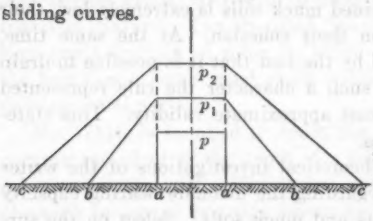

FIG. 51.—INCREASE IN BEARING CAPACITY OF UNDERGROUND DUE TO WIDENING FLARE OF TRAPEZOIDAL LOAD.

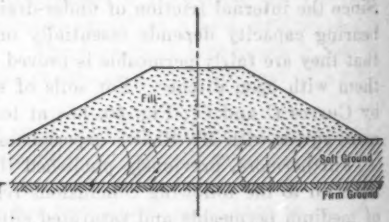

FIG. 52.—ARCHING EFFECT WITHIN A THIN, SOFT LAYER LOCATED BETWEEN BOTTOM OF FILL AND TOP SURFACE OF FIRM GROUND.

Mr. Shaw's experiences furnish instructive examples of the fact that the results obtained by theory can be depended upon, provided the assumptions conform reasonably well with the conditions existing in Nature.

It was a great pleasure to survey the valuable test results presented by Mr. Wing. In regard to the loading tests the writer would consider the tests

* "Fill Settlements in Peat Marshes," by V. R. Burton, *Proceedings*, Sixth Annual Meeting, Highway Research Board, 1926, pp. 93–113.

† Statens Jarnvägars Geotekniska Comm., 1914–22. An English abstract and comments on the report by Charles Terzaghi, M. Am. Soc. C. E., are filed in the Carnegie Library, Pittsburgh, Pa.

finished as soon as the settlement becomes equal to about one-fifth the diameter of the loaded area. Beyond this limit the process of settlement passes into one of penetration. When making the tests oil-jacks are always preferable to screw-jacks.

The writer uses as a criterion for the bearing quality of sand deposits the settlement under a load of 500 lb. per sq. ft., provided the loaded area is at least equal to 1 sq. ft. Under such a unit load, a well-compacted sand deposit does not settle more than about 0.001 ft. The loosest deposit that ever came under the writer's observation settled under the same load through a distance of $\frac{1}{4}$ in. From the character of the settlement curves for the sand (Fig. 44), the writer suspects that the sand was loosened by the upward current of water, as the pit was being pumped dry. On account of this possibility, the writer keeps the water out of a test pit by pumping, uncovers two opposite vertical sides of the pit, and makes the loading test in a horizontal direction, by inserting a hydraulic jack between two bearing plates, applied to the sides of the pit. The bearing plates should have a clearance, all around the rim, equal to at least twice the diameter of the plate. Experience has shown that the results of such tests differ but little from those made on horizontal plates, and one is sure that the loaded material is in an undisturbed state.

The results of mechanical analysis should preferably be presented in graphical form with the grain size plotted on a logarithmic scale.* The limits of consistency of the clay, quoted by Mr. Wing, remove any doubt concerning the type of clay that he encountered. Experience has shown that, for natural clay deposits, both the limits of consistency and the water content vary within rather wide limits. Therefore, it is advisable to perform these tests for each drill hole on several samples. Instead of determining the volume change associated with a change of the moisture content, it is preferable to determine the shrinkage limit (from dry weight and from the volume of the dried sample, assuming for the dried substance a specific gravity of 2.7).†

The settlement diagram (Fig. 45), for the clay indicates that the loaded area was too big for the size of the test pit. The abnormal shape of the curve seems essentially to be due to arching action within the clay, between the bearing plate and the walls of the pit. Similar phenomena were observed by the writer on a small scale, when loading clay specimens that were contained in a rigid box. The clay beneath the bearing plate undoubtedly compacted, but this fact alone does not account for the characteristics of the curve. The width of the pit should be equal at least to five times the diameter of the loaded area.

Loading tests on both sands and clays should always be made at least in duplicate on what appears to be the stiffest and the softest spot of the underground. The writer selects these spots after having passed over the ground with a sounding rod. The observations to be performed on the diversion dam are most promising, particularly if the settlement observations extend over a longer period and if, in addition, bench-marks are established on the unoccupied ground at a distance equal to one-half the width of the structure.

† "Present Status of Subgrade Testing," by C. A. Hogentogler, Charles Terzaghi, and A. M. Wintermayr, *Public Roads*, March, 1928.

In his very thorough and able discussion, Professor Krynine quotes certain statements made by Dr. Ing. Koegler concerning the relation between settlement and size of area, and finds them to be at variance with those of the writer, as far as soils with great cohesion are concerned. It should be emphasized that Dr. Koegler derived his conclusions exclusively from tests performed with cohesionless sand. For this reason they conform to Curves C and C_2, Fig. 50. For the same reason they certainly do not apply to soils in general, irrespective of their physical characteristics, and Dr. Koegler's generalized statements must be received with reserve until more convincing arguments are presented for substantiating their validity.

Professor Krynine's suggestion to consider, in the computation of a raft foundation, the presence in the ground of hard and soft spots is theoretically sound. However, in practice, it seems very difficult to follow the advice. First, loading tests would be required, not only all over the area, but also at different elevations below the ground surface. Furthermore, since engineers do not yet know the distribution of the soil reactions for perfectly homogeneous foundations, and the importance of the effect of the soil characteristics on this pressure distribution, there is little hope for successfully introducing further refinements into computations.

The doubts expressed regarding the writer's comment on the settlement of the hardpan caissons at the Chicago Union Terminal, were apparently due to the fact that Professor Krynine was not familiar with the details of the tests. The frictional resistance acting over the surface of the caissons was determined by undermining the caissons and loading them until they slipped. The unit loads quoted by the writer obviously represented the top load minus the relieving effect of side friction.

Another objection by Professor Krynine concerns the shape of the curve which represents the distribution of the soil reactions over the base of a loaded slab. When the writer stated that these curves have a parabolic shape, he obviously meant an approximately parabolic one. At the rudimentary state of present knowledge a more specific statement concerning this shape would be premature. In addition, the difference between the right and left sides of Fig. 40 is so slight compared with the importance of the errors associated with Professor Krynine's theoretical assumptions that it seems reasonable to disregard it. Very much more important is the question as to whether the parabolic law may not lose its validity altogether if applied to very cohesive soils. For such soils the pressure distribution is apt to be similar to that over the base of a piston which acts on the plane surface of a homogeneous, elastic solid. The writer doubts seriously whether this distribution has any resemblance at all with either one of the distributions represented by Fig. 40.

Professor Krynine's comments on Fig. 5 are fully justified. The writer agrees that the two lines will be neither straight nor parallel. The reason he failed to show their true shape in the diagram was simple enough. He does not yet know this shape.

The writer became interested in the subject of "entrapped air" for the first time when certain inconsistencies were found to exist between the results of compression tests on clays that were dried before testing and on others that

were used as they were taken from the drill hole. The inconsistencies were caused by the fact that those samples which were prepared by mixing the dried specimen with water contained an appreciable quantity of air, while the others contained practically none. In order to determine the importance of the influence of the air on the test results, Mr. A. Casagrande performed some tests in the writer's laboratory. Fig. 53 shows a typical test result. One of the two samples merely contained air and water. The other was prepared from dry powder and, in addition, air was injected into the specimen by a drop counter in such quantities that its voids ratio increased by almost 50 per cent.

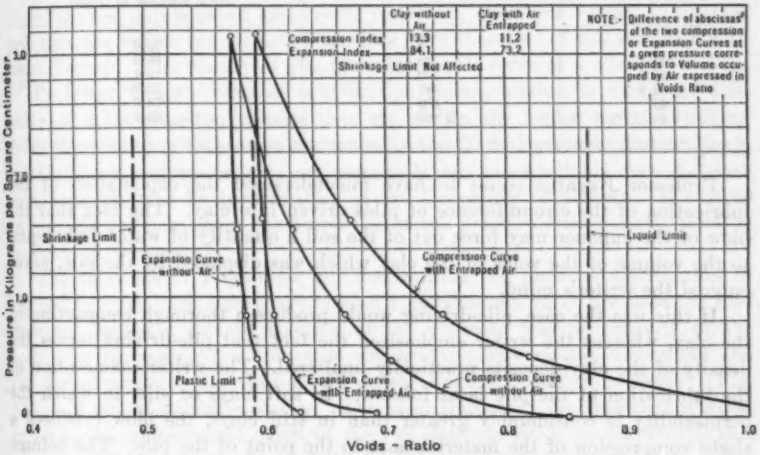

FIG. 53.—EFFECT OF AIR CONTENT ON ELASTIC PROPERTIES OF CLAY.

The most conspicuous effect of the air content was the difference in shape of the time-compression curves of the samples. This is caused by the fact that the compression of the air takes place almost instantaneously, similar to the compression under pressure of the air bubble in a spirit-level, while the compression of the clay occurs gradually, according to the laws of consolidation of compressible capillary systems. By this very reliable criterion, and by the results of numerous air-content determinations, the writer has learned that neither clays nor silts seem to contain in Nature a measurable amount of air, provided they are beneath the zone of temporary desiccation. For this reason the writer did not consider it necessary to mention the air factor in connection with a paper on foundations. It plays an important part merely in connection with sub-grade studies for roads. The intermittent wetting of the subgrade of hard surface roads occurs almost entirely by capillary action, whereby a considerable quantity of air remains in the soil.

Some experiments on the air content of fine sands and dust, wetted by capillary action, were conducted in 1926 by Mr. C. V. Arellano, under the supervision of the writer.* The test results seemed to indicate that the air

* "Relation between Permeability of Sands and Capillary Upward Movement of Water," by C. V. Arellano, Master's Thesis, Mass. Inst. Tech., 1926.

content decreases considerably with time. One of the samples tested was a fine, reddish, micaceous dust; effective size, 0.028; uniformity coefficient, 3.6; specific gravity of grains, 2.674; voids ratio, 0.698; and coefficient of permeability, 9.75×10^{-5} cm. per sec. The results are shown in Table 12.

TABLE 12.—AVERAGE DEGREE OF SATURATION OF FINE DUST WETTED BY CAPILLARY RISE.

Capillary rise, in centimeters.	Time elapsed since water started to rise, in minutes.	Percentage saturation, or the ratio between total volume of water and total volume of voids.
5	9	75.2

40	800	73.0
40	3 800	82.7

Professor Krynine seems to have misunderstood the explanation of the lubrication of the circumference of piles driven into clay. The idea that the blow of the hammer may force out of the soil a quantity of water fully equal to the volume of the voids of the clay which was displaced by the pile, never entered the writer's mind.

If this was the case, pile-driving would produce a thorough compacting of the clay, whereas the writer emphasized the fact that pile-driving leaves the density of the clay deposits practically unaltered. The writer's conception of the lubrication of the pile is as follows: In soft clays or silts in which the permeability is considerably greater than in stiff clays, the blow produces a slight compression of the material next to the point of the pile. The volume of water pressed out of the material represents a small fraction only of the volume displaced. Lubrication is caused by this small quantity escaping between the soil and the surface of the pile. The absorption of the film during the period between driving and re-driving is due to subsequent expansion of the slightly compressed clay which surrounds the pile. This process of absorption by no means requires (as Professor Krynine assumes) the presence of entrapped air, because it also occurs in the laboratory under test conditions which completely exclude the presence of air in the clay.

There is also another factor that is apt to cause a gradual increase of the "skin friction". If certain clays and organic muds are moulded into cylindrical shapes and tested at different times after moulding, one is apt to find that the shearing strength increases considerably as the time interval becomes greater. This increase seems to be due to the gradual development of a molecular bond between the individual particles across the layers of absorbed material. If piles are driven into such materials, the skin friction should also increase as time goes on.

Professor Krynine emphasizes the leaning of Russian engineers toward the "dry substance theory". On account of this leaning, Russian engineers seem to be inclined to speak of the "bearing capacity of soils" in general without due regard to their extremely manifold physical characteristics. This, at

least, is the impression the writer has obtained from some recent Russian publications on this subject.* More than a half century ago, a prominent French engineer expressed his experiences with earth slides in a single sentence which may be translated: "The fear of frost and of clay marks the beginning of wisdom". In a similar fashion the writer is inclined to summarize his experiences in dealing with the bearing-capacity problem in the sentence: "To recognize the full importance of the permeability factor marks the beginning of wisdom in foundation engineering". Since the permeability factor represents by far the most obstinate stumbling block in the path of any attempt to bridge the gap between small-scale tests with clays and actual foundation practice, the writer cannot help regarding "dry theories" of soil behavior with deep distrust. The history of pile formulas should serve as a solemn warning.

Professor Enger's valuable contribution calls attention to the great difficulty of measuring the stresses that act within the loaded earth. Judging from the results of measurements made by the U. S. Bureau of Public Roads the Goldbeck pressure cells do not seem to be any more reliable than the pressure capsules used by investigators at the University of Illinois. It will be interesting to learn about the properties of the pressure cells recently used by Koegler in Germany.†

The formulas of Boussinesq for determining the pressure distribution in the soil beneath loaded areas are at least approximately valid, provided the load does not exceed a certain fraction of the ultimate bearing capacity of the soil. For expressing the difference which exists between the theoretical and the actual pressure distribution, Professor Enger's "lines of pressure" (Fig. 48), will render valuable service. The most important problem that remains to be solved concerns the effect of the soil characteristics on the distribution of the pressures over the base of the loaded area.

The objection of Professor Enger against the use of remixed material does not seem to be quite justified. In the example which he cites, the compacting of the clay was performed by the capillary pressure at a time when the water-table was at a lower elevation. Once compacted, the clay takes up only a small fraction of the quantity of water which it previously lost. The process can be reproduced very easily in the laboratory by first compacting the clay under external or capillary pressure (applying the pressure under water or exposing the surface of the clay to the air) and then allowing it to expand very slowly under water.

In Nature one even encounters layers of very stiff clay beneath the bottom of lakes, between layers consisting of the same material in a very soft state. The history of these "fossil crusts" is as follows:‡ At a period when the surface of the older clay deposit was exposed to the air, the top layer of this deposit partly dried out (compression due to capillary pressure). At a later date, the surface of the older deposit was flooded, and a new soft clay deposit was formed on top of it. Due to the very imperfect volume elasticity of the

† "Ueber Tragfähigkeit von Sandschüttungen," *Bautechnik*, 1927.

‡ Statens Jarnvägars Geotekniska Comm., 1914–22, English abstract and comments by Charles Terzaghi, M. Am. Soc. C. E., filed in Carnegie Library, Pittsburgh, Pa.

clay, the former crust retained the greater part of its stiff consistency (see, for instance, the re-saturation or swelling curves in Fig. 53).

Since the paper was published, much headway has been made in developing methods for securing undisturbed samples of clay.* Tests are being planned to investigate the relative importance of the disturbance caused by different sampling tools. There seems also to be no difficulty in securing undisturbed clay samples from depths as great as 100 ft.

The effect of vibrations on the settlement of structures resting on clay was brought to the writer's attention under rather peculiar circumstances. Loading tests were made on a small scale on glacial clay, in his laboratory, and very sensitive instruments were used for measuring the settlements. All the settlement curves showed distinct breaks at points corresponding to 5:00 P. M. and 9:00 A. M., the 9:00 A. M. to 5:00 P. M. sections being considerably steeper than the 5:00 P. M. to 9:00 A. M. sections. The cause of this phenomenon was found to be that between 9:00 A. M. and 5:00 P. M. the different motors located in the Massachusetts Institute of Technology Laboratories are operating, while at 5:00 P. M., they are shut down.

The tests suggested by Mr. Jorgensen will be particularly valuable if they are made in triplicate, using identical bearing plates, resting on identical clay water mixtures, so that one of the bearing plates consists of cast iron (impermeable), one of concrete (medium permeable), and one of concrete separated from the clay by a sheet of filter paper and a thin layer of sand (permeable). The diameter of the bearing plates should not be more than one-fifth that of the container. The exposed surface of the clay should be covered with a paraffined rubber sheet in order to prevent evaporation, and the settlements should be measured with delicate instruments to detect the difference in the speed of settlement of the three plates. During the tests, the load should be kept constant, and should be equal to the pressure required to produce an initial settlement of the cast-iron bearing plate equal to about 0.05 or 0.1 times its diameter. In each of the three cases the load should be applied in equal increments and in equal time intervals. In order to obtain the maximum benefit from the tests, the base of the bearing plates should be equipped with annular oil-pressure cells, for investigating the distribution of the soil reaction over the case.

The procedure proposed by Mr. Jorgensen for load-moisture tests is practically identical with that of the writer. Since the shape of the re-compression curves, *c d* (Fig. 49), is only slightly influenced by the intensity of the pressure at which swelling was begun, no great care is necessary in performing the test.

In conclusion, the writer wishes to express his gratitude to the discussors for their valuable contributions. The gaps in the presentation of the subject are still numerous. Yet, the arguments brought forth offered a unique opportunity for expanding the paper on those points which were still in doubt in the minds of the readers.

* "Relation Between Permeability of Sands and Capillary Upward Movement of Water," by C. V. Arellano, Master's Thesis, Mass. Inst. Tech., Cambridge, Mass., 1926.

The results of the discussion may be summarized, as follows:

1.—The *Engineering News Formula* received all the comment it deserves and few engineers seem to be willing to defend it.

2.—The attitude of the different engineers toward the writer's theoretical statements represented by Fig. 50 was far less unanimous, yet it leads to very interesting conclusions because no obvious contradiction between theory and practice was found to exist by those who reported experiences with fairly permeable materials (Messrs. White, with friable limestone; Shaw, with muck; and Wing, with sand and gravel). Without exception, all the examples which were quoted as arguments against the validity of the writer's "rules" referred to clays. The reason thereof is obvious. The compression of clay under load proceeds very slowly. Large footings or raft foundations require decades or even hundreds of years for complete settlement, while the observations on which the arguments were based covered, at the very best, a period of a couple of years of the settlement records. In other words, the bill for the excessive loading of a sand or silt foundation should be paid without delay by the first generation, while that for treating the clay in a similar manner should be charged against the second or third generation.

It is amazing to realize that the Engineering Profession is facing the problem of progressive subsidence of clay foundations in almost every part of the globe, and yet is still completely ignoring the time element when it comes to approaching the settlement problem from the theoretical point of view. If the discussion had not brought forth anything but striking illustrations of this one fact, the labor involved could be considered as well invested.

Paper No. 1705

MAXIMUM FLOOD DISCHARGE IN SAN JOAQUIN VALLEY, CALIFORNIA*

By Oren Reed,† Jun. Am. Soc. C. E.‡

With Discussion by Messrs. Robert Follansbee, Harold K. Fox, Charles H. Lee, and Oren Reed.

Synopsis

Much has been written on the subject of floods in the last few years and many formulas have been presented for general or local application. Since the effect of similar storms on a given water-shed may vary widely, depending on temperature and storage conditions, formulas must be used with caution. In this paper an attempt has been made to estimate flood discharge for one river from the known discharges of rivers of the same meteorological province.

In each meteorological province there seems to be a type storm, the characteristics of which are relatively constant from time to time. Records of several streams in such a province, similar in storage, vegetation, soil, and other physical characteristics, can be combined, after the proper adjustments are made, to give an equivalent record for the stream under consideration.

When long-term records are available each drainage area may be considered by itself, but records of many years are required to estimate the extreme flood to be expected on a stream. The method may be used to estimate flood discharge of a stream, where no flow measurements have been made, by comparison with the known discharges of neighboring water-sheds.

Flood Characteristics

In many localities stream-flow records are few or entirely lacking; then the engineer must rely on a study of the evidences of former floods, and

* Published in November, 1927, *Proceedings*.

‡ Now Assoc. M. Am. Soc. C. E.

on the conflicting stories of inhabitants of the neighborhood. As an aid in flood study many different formulas have been proposed for computing probable flood run-off. Some are only applicable to the small area for which they were originally devised on account of local conditions of soil, soil cover, slope of drainage, storage, etc. The use of most flood formulas is dangerous unless due regard is given to their basic limitations.

Except for small areas, the great floods in the Pacific Coast section occur in the winter or early spring and are caused by heavy rainfall. On the larger streams, the drainage areas of which extend to high altitudes, the flood stage may be augmented, in some years, by the melting of snow.

In winter, an area of low barometric pressure exists over the North Pacific Ocean. As the great cyclonic storms sweep easterly or southeasterly from the Pacific, they yield gentle but persistent rainfall. After the storm center has passed and the wind swings from southeast to southwest, the rainfall increases in intensity for a short time; the winds then swing to the northwest and the storm has passed. In the early winter and late spring the storms follow each other in rapid succession, and heavy precipitation from these successive storms tends to cause extreme flood conditions. In the early part of winter, when a storm period that produces a considerable depth of snow is followed by a series of warm rains, a high flood is to be expected. If the snow becomes packed its water content is greatly increased, but high run-off will only result after several days of warm weather. With the rising temperature of spring, the dense snow cover starts to melt, augmented by short storms. This spring run-off seldom causes as high peaks as the mid-winter flood period, but gives a long-sustained stage of more moderate proportion.

Exceptions to these general rules are the spring-fed streams flowing from the lava country of Northern California, Eastern Oregon, and Southern Idaho, and small cloudburst areas, as in Oregon. Streams from the lava country are characterized by run-off of a marvelous constancy.

Flood Variation

While making an investigation to determine the probable maximum flood of the North Fork of Kings River, for the San Joaquin Light and Power Corporation, at Fresno, Calif., the writer was confronted with a maze of factors influencing the problem. The results of several formulas could not be reconciled, and it was decided to study previous floods on the Kings River at Sanger and on ten other major streams draining the west slope of the Sierra Nevada Mountains (Fig. 1), namely, the Cosumnes, Mokelumne, Stanislaus, Tuolumne, Merced, Fresno, San Joaquin, Kaweah, Tule, and Kern Rivers. Proper factors were determined to apply to a flood on one stream to make it applicable to Kings River.

To be strictly applicable to a particular drainage area, a formula for flood run-off must be modified to suit local conditions. General rainfall and run-off characteristics are relatively constant in each type province, but minor differences will be numerous. Small tributary streams may give widely different flood peaks on account of variable topographic conditions. Rancheria Creek, a tributary of the North Fork of Kings River, having a drainage area

of about 25 sq. miles, is an example of low flood variation. The average elevation of the area is about 8 000, and the total run-off per square mile is high. However, the stream is not flashy. It drains a northwest slope, and the forest cover of pine and spruce is heavy. Until the stream reaches the canyon of the North Fork of Kings River, the slope is moderate and the drainage is retarded by many lakes and meadows.

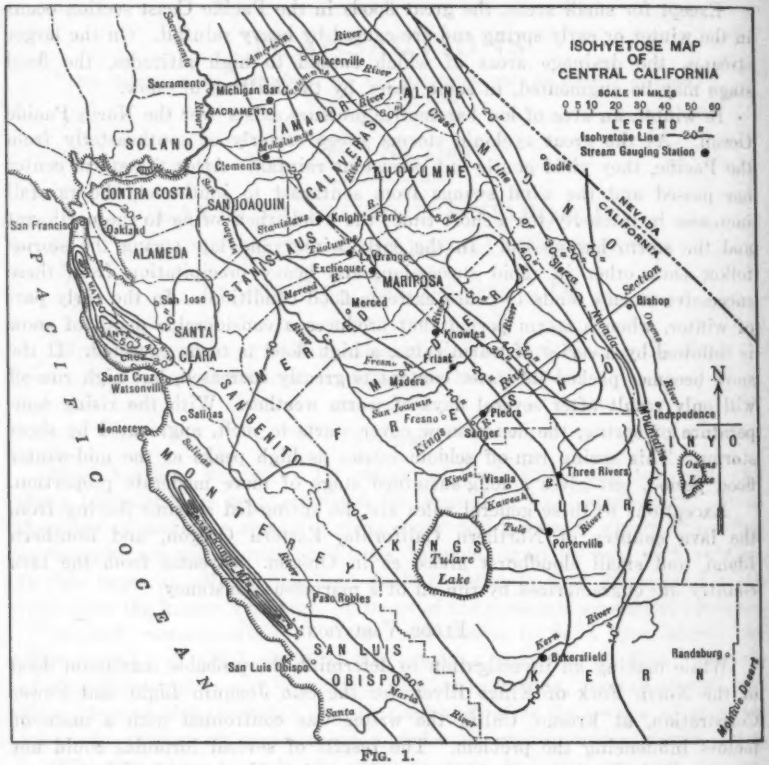

FIG. 1.

PHYSICAL FEATURES

General.—The streams chosen for this investigation are tributary to the San Joaquin River or discharge into the Tulare and Kern Lake Basins and, together, drain the west slope of the Sierra Nevada Mountains and discharge into the southern half of the Great Valley of California. The Central Valley is a deep structural trough filled with alluvial material derived principally from the débris brought down by those streams from the Sierra Nevadas. The Sierras are a granitic formation with small areas of volcanic material. The streams rise at or near the divide and flow by a rapid gradient and in deep canyons to the outwash plain. The rainfall decreases toward the south, but the precipitation characteristics are similar on all eleven streams considered (Fig. 1).

Kern River.—Kern River, the most southern of the great rivers that flow westward from the crest of the Sierras, has a long, narrow basin. The general trend of the basin is north and south, except at the lower end. At the head-waters is the Mt. Whitney region, the highest and roughest in the Sierras. The main or North Fork of the Kern River is very rugged, whereas the South Fork is more flat in its lower basin. In general, the forest cover is very poor.

Tule River.—The Tule River heads on the Great Western Divide, the secondary ridge west of the Kern River. Part of the upper basin is well forested, but a large part of the entire basin is densely covered with chaparral and scrub oak.

Kaweah River.—The head-water region of the Kaweah is very rugged, but does not reach to the main divide. The ridges of the lower country, especially on the Marble Fork, are well forested. The flow of short rivers, like the Kaweah and the Tule, is decidedly flashy, owing to the extremely steep gradients, the relatively small drainage areas, and the predominant granite formations.

Kings River.—The Kings River rises at the crest of the Sierras near the Mt. Whitney group. The South and Middle Forks have steep gradients near their sources and have carved out profound canyons. Their slopes in the lower courses are more moderate. In general, the forest cover is good, although it has been cut over in certain areas.

The head-waters of the North Fork drain the west side of Le Conte Divide, Mt. Reinstein (12 575 ft.) being the highest elevation. The upper part of the basin is an open plateau and the slope is moderate, but in the lower course the stream drops at a tremendous gradient to the main river. The lower basin is covered with scrub timber; above Elevation 4 000, there is an excellent stand of timber which extends to the timber-line near the head-waters.

San Joaquin River.—The mountain basin of the San Joaquin has the form of a rough isosceles triangle with a base fifty miles long, extending northwest and southeast along the crest of the Sierra Nevada Mountains. The course of the main stream is, in general, southwest, while the principal tributaries near its head-waters flow through troughs trending parallel to the main divide. The brush-covered foothills give place to well-forested ridges, extending up about 9 500 ft., above which the cover thins out and the upper basin is entirely bare. Some storage has been developed in the upper part of the basin: Crane Valley Reservoir, 45 000 acre-ft.; Huntington Lake, 88 000 acre-ft.; and Florence Lake, 60 000 acre-ft.

Fresno River.—The Fresno River does not reach the main divide, but heads on the secondary ridges west of the San Joaquin River.

Merced River.—The Merced River rises at an elevation of about 11 000 ft. on the west slope of the secondary ridges, west of the head-waters of the Tuolumne and San Joaquin Rivers, its basin touching the main divide of the Sierras at only one point, Mt. Lyell (13 090 ft.). The topography of the head-water region is extremely rugged, but below Yosemite Valley it becomes

more regular and the stream is shut in by two high brush-covered ridges. Much of the middle basin, especially on the South Fork, is well forested. Exchequer Reservoir, constructed near the foothills, has a capacity of 280 000 acre-ft.

Tuolumne River.—The topography of the head-waters of the Tuolumne is very rugged. The Hetch Hetchy Valley, which is in the upper basin, rivals the Yosemite Valley in grandeur. Below Hetch Hetchy Valley the water-shed is more open. Most of the drainage area is well covered with forest interspersed with bare granite ridges and mountain meadows. Two reservoirs have recently been completed on the Tuolumne—Don Pedro, near the foothills, 270 000 acre-ft., completed in 1923, and O'Shaughnessy Reservoir, 206 000 acre-ft., at the lower end of Hetch Hetchy Valley.

Stanislaus River.—The Upper Stanislaus Basin is typically Alpine, including tremendous domes and peaks of granite and very rugged topography. In the lower course the stream is shut in by two broad-topped ridges which are covered with heavy timber. Near the head-waters of the basin there are several small storage reservoirs; Relief Reservoir, 14 965 acre-ft., and Strawberry Reservoir, 17 900 acre-ft., are the largest.

Mokelumne River.—The Mokelumne Basin is long and comparatively narrow, and extends nearly due west from the crest of the Sierras to the eastern edge of the foothills. Round Top (10 430 ft.) is the highest peak. Except in the higher regions, the country presents a spacious and rolling, rather than rugged, appearance. The basin is well forested, except near the head-waters which is for the most part of bare granite.

Cosumnes River.—Like the Mokelumne River, the Cosumnes Basin is long and narrow; for a great part of their length the tributaries flow in nearly parallel canyons. The highest peak is Alder Hill (7 875 ft.).

Precipitation and Seasonal Run-Off

As an aid in interpreting flood data, a study was made of seasonal precipitation and run-off. An isohyetose map of the south-central part of the State was drawn (Fig. 1).* Records of mean precipitation of 114 stations were used. The number of years included in the record at each station varied from fifty-four at Stockton and Santa Barbara to only four for the stations established by the San Joaquin Light and Power Corporation on the North Fork of Kings River. Four, or even ten, years are too few to determine true averages, but some short-term records were used to show the general trend. The records of the stations on the North Fork of Kings River were adjusted somewhat by a comparison with the records of the corresponding years at Huntington Lake on the adjoining San Joaquin water-shed.

Except for thunder-storms, which occur in the mountains in the late summer and early fall, precipitation on the west slope of the Sierras results

* The base for this map is the General Land Office Map of California. Isohyetose lines are based on precipitation as given for various stations in *Bulletin No. 5*, California Department of Public Works, except those for the San Francisco Bay region, which are as given by C. E. Grunsky, Past-President, Am. Soc. C. E., in *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), p. 104.

from the movement of great cyclonic storms. The general track of these storms is from northwest to southeast. They enter the State from the Pacific Ocean near the northwest corner and, after crossing the Coast Range, follow a path roughly parallel to the trend of the Sierras. Drainage areas near the north end of the region considered—the Stanislaus and the Mokelumne—receive heavy precipitation. As the storm passes southward the atmosphere becomes dryer and beyond the Kings River Basin the decrease in precipitation is rapid. The southern water-sheds are rarely visited by cyclonic storms from the southwest. The variation in precipitation from north to south is shown by Fig. 2, which is based on three groups of stations, each group being in a definite elevation belt. During a wet winter, as in 1916, the storm center is shifted southward and the Kern and Tule Rivers receive much heavier precipitation.

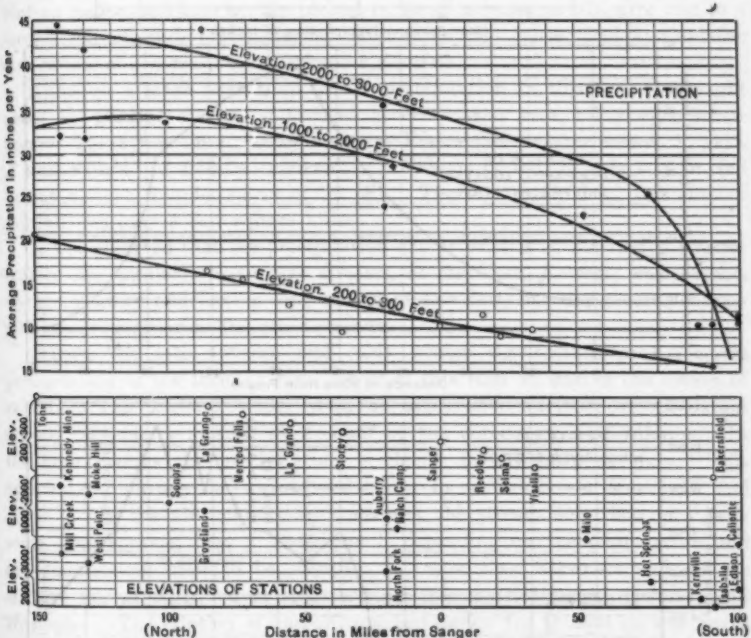

FIG. 2.—DISTRIBUTION OF PRECIPITATION FOR STATIONS AT VARIOUS ELEVATIONS IN SIERRA NEVADA MOUNTAINS, CALIFORNIA.

When precipitation records on a section at right angles to the trend of the Sierras are studied, it is seen that, to a certain elevation, precipitation increases with height. Beyond this, there is a slow decrease to the summit and a rapid decrease east of the mountains (Fig. 3). This Kings River Section is indicated on Fig. 1. The curves plotted for this section support the conclusions* of C. H. Lee, M. Am. Soc. C. E., that topography rather

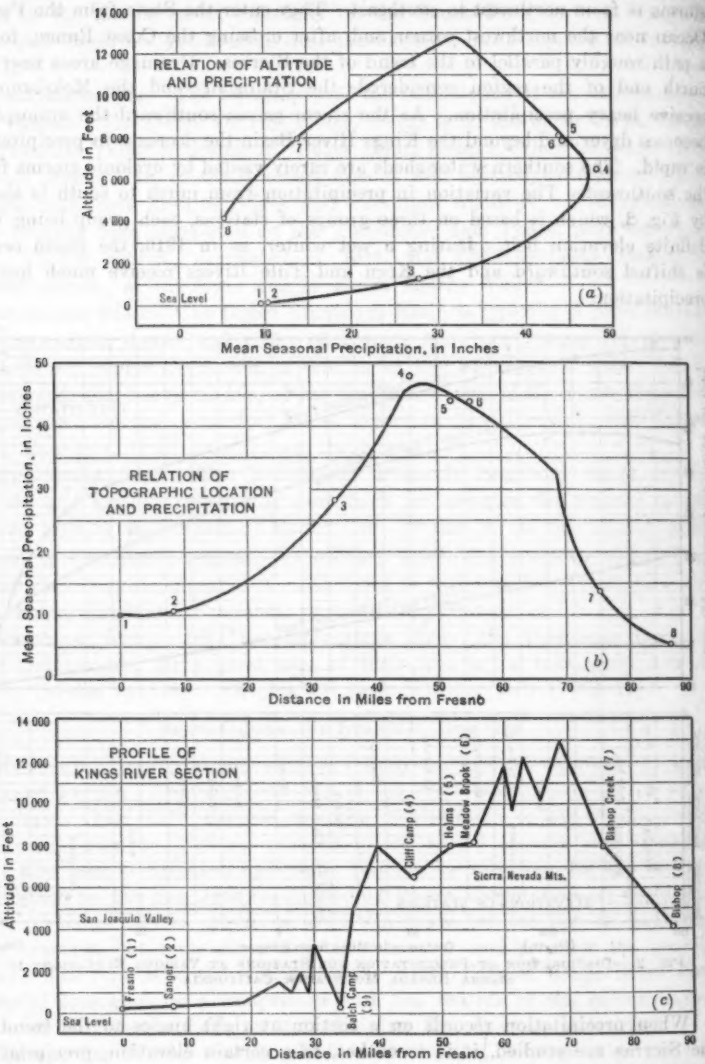

FIG. 3.—INFLUENCE OF ALTITUDE AND TOPOGRAPHIC LOCATION ON PRECIPITATION.

than elevation is the controlling factor in the distribution of total precipitation in the Sierra Nevada Mountains.

The greatest rainfall occurs at an elevation of 4 000 to 6 000 ft., differing with each storm, due to variation in relative humidity and temperature. The moisture-laden winds, which are blown against the mountain slope, are forced upward, giving rise to rapid cooling and precipitation. Heat is liberated with condensation and, as a result, the dew-point of the atmosphere is raised above this belt of maximum precipitation. The precipitation decreases gradually to the summit of the range, and as the winds pass over the divide, their absolute humidity having been decreased by the induced rainfall, they are compressed in their flow down the mountain with a further increase in temperature and, in consequence, become dry. If, after the winds pass through the lower area of maximum precipitation, they flow over a plateau region and lose heat, a second range of mountains will give rise to a second belt of high precipitation. Mountains also cause local atmospheric circulation and consequent orographic rainfall.

Although a large proportion of the precipitation in this area is brought about by general storms, sometimes severe storms resembling cloudbursts occur. There was an unusual storm at Fresno on October 4 and 5, 1925. A total rainfall of 1.56 in. occurred in a 36-hour period; of this 1.18 in. fell in one violent thunder-storm of 32 min. The area covered by this intense rainfall was only a few square miles.

It was observed that the precipitation characteristics of the twelve streams studied are similar. Secondary streams, as the Tule, Kaweah, and Fresno, are more flashy and have a long period of low flow, but the general characteristics are similar to the other streams.

During the late autumn and early winter the foothill area receives precipitation in the form of rain. Most of this runs off during the season of rainfall. The outwash slopes yield no appreciable surface run-off, except during very heavy storms, on account of the porous gravel formation. In the high Sierras the precipitation is chiefly in the form of snow. This accumulates during the winter and starts to melt between March 15 and April 1. As the air temperature increases, the stream flow rises to a peak some time between May 1 and June 1, depending on the temperature and the quantity of snow to be melted. The flow then decreases and all the streams are at their lowest stage during August, September, October, and November. The relation of run-off to precipitation for 1922-23 on the North Fork of Kings River above Balch Camp is shown in Fig. 4. This gives the true relation, although the distribution of precipitation is unusual.

When mean yearly run-off, in inches, on the drainage area was studied in relation to the location of the water-shed north or south of Sanger and to the average elevation of the drainage area, some interesting features of the drainage areas were observed. The "Distance from Sanger" curve (Fig. 5) was similar to Fig. 2, as was expected, but the low yield of the southern streams, the Kern and the Tule, was very apparent. Precipitation stations on many of the streams are in the foothills and their records are a

poor basis for determining the average precipitation on the drainage basins as a whole. The Fresno is a secondary stream with no tributary area of high elevation. The highest elevation of the water-shed is 6 350 ft. The relation of run-off to area of drainage (Fig. 6) showed more clearly the deficiency of run-off of the Kern, Tule, and Fresno.

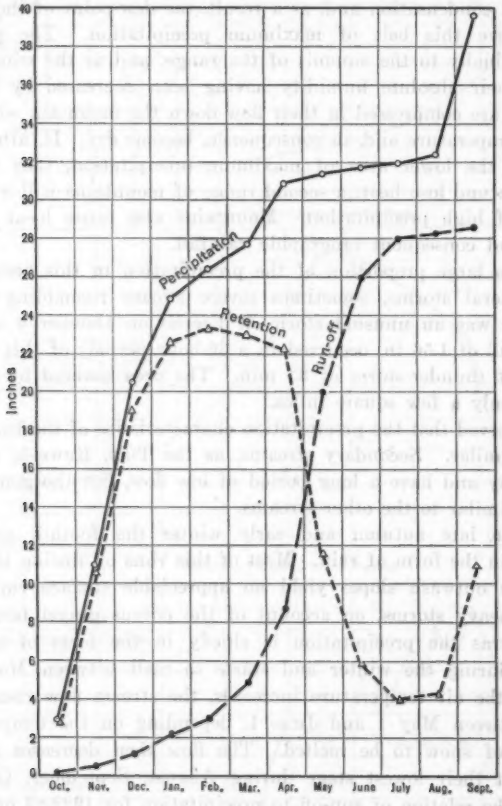

FIG. 4.—MASS DIAGRAMS OF RUN-OFF. PRECIPITATION RELATIONS ON NORTH FORK OF KINGS RIVER AT BALCH CAMP, 1922–23, SLIGHTLY BELOW NORMAL.

FLOOD DATA

The flood data used in this paper were taken from the *Water Supply Papers* of the U. S. Geological Survey. The primary data for the eleven California streams are given in Tables 1 and 2.

Gauging stations have been established by the U. S. Geological Survey on each of the rivers under consideration near the point where the stream leaves the foothills. The longest published record is for the Kings River near

Sanger, 26 years; the shortest record is for the Fresno, 8 years. The Kings River Gauging Station is at Piedra, a few miles northeast of Sanger. Until the seasonal year, 1913-14, only the maximum 24-hour flood was published.

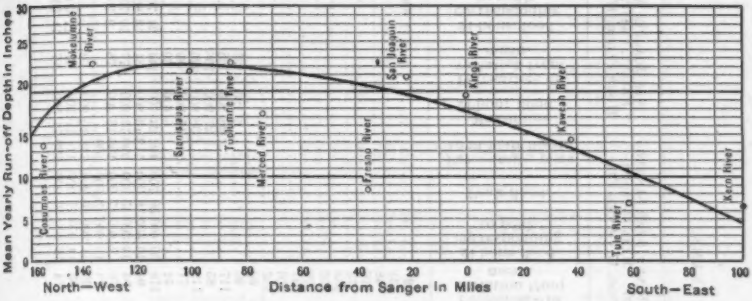

FIG. 5.—RELATION OF YEARLY RUN-OFF TO GEOGRAPHICAL LOCATION OF ELEVEN CALIFORNIA STREAMS.

In Table 1 the "24-hour flood corresponding to the peak flood" is given. In some years this peak flood did not occur on the same day as the maximum 24-hour flood, but came as a sudden and unsustained peak during the winter.

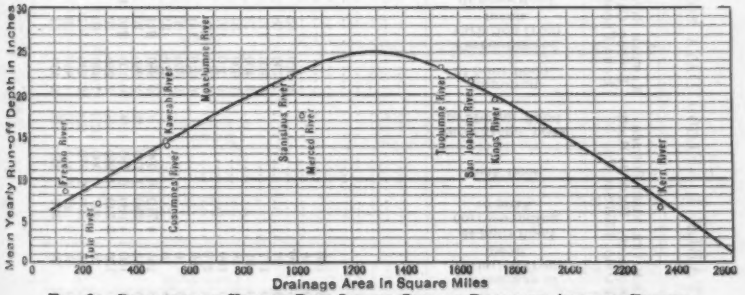

FIG. 6.—RELATION OF YEARLY RUN-OFF TO SIZE OF DRAINAGE AREA OF ELEVEN CALIFORNIA STREAMS.

FLOOD DETERMINATION

If sufficient data were available, the most accurate way of determining the maximum flood on any stream would be to consider each stream by itself. A record of at least 100 years on each stream would be necessary, in order to establish probable variations of flood run-off. Even that length of record might be inadequate, for maximum flows are often grouped close together with a long interval of medium, or low, flows. Flood records of the Danube River at Vienna, Austria, which cover 900 years, show that a record of 100 years is not sufficient to fix the maximum flood. Three extraordinary floods have occurred at Vienna with time intervals of 112 and 286 years. The greatest flood was one-third greater than the second record flood.

Keeping in mind the relation of mean run-off on the eleven streams, a maximum 24-hour flood was determined for the Kings River, at Sanger, which corresponded to the highest 24-hour flow on each stream in turn. The fact that the flood flow on each stream was the maximum for a period varying from 8 to 26 years had the effect of giving many comparable data for the Kings River at Sanger. Although the maximum rate of run-off is usually more important than the average for 24 hours, the 24-hour flood records were used because they were greater in number.

When the maximum 24-hour flood, in second-feet per square mile, for each stream was plotted according to its geographic location northwest or southeast of the Kings River (Fig. 7), a variation was shown similar to that for precipitation (Fig. 2). Flood flows decreased rapidly to the southward. The relative humidity of a storm, as it travels southward, becomes less, and the Kern Basin receives only slight precipitation from storms that cause intense run-offs on other streams farther north. The highest flows on the Kern River are usually caused by melting snow in May and June.

Geographic location is also of major importance in the other causes of flood variations that were considered. The average elevation receiving the heaviest precipitation is shown by Fig. 8. It is seen to be about 5 500 ft. The Cosumnes River has an average elevation of only 3 200 ft., but as it is at the north end of the area studied, it receives a high precipitation, which produces an extreme flood run-off. The Tule River, on the other hand, is of greater average elevation, but as it is near the south end of the valley the precipitation and flood yield is much smaller.

In relation to size of drainage area small floods were produced by the small secondary streams, the Fresno and the Tule, and by the Kern, a primary stream (Fig. 9).

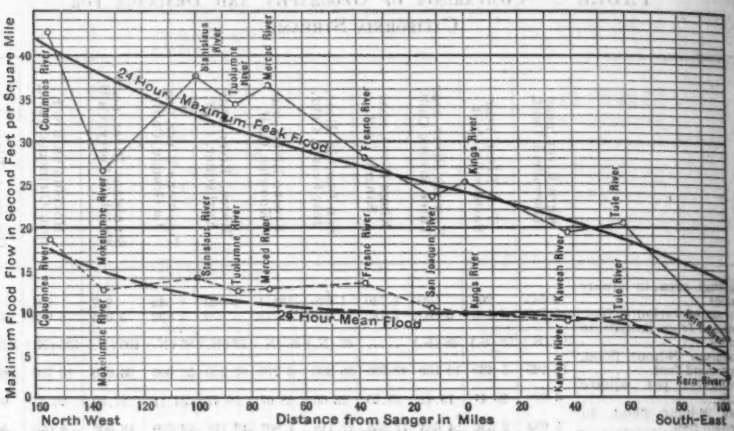

FIG. 7.—RELATION OF FLOOD RUN-OFF (24-HOUR) TO GEOGRAPHICAL LOCATION OF ELEVEN CALIFORNIA STREAMS.

In addition to the three factors of geographic location, average elevation, and drainage area, a fourth factor, the variation in proportion of the maximum 24-hour flood to the arithmetical mean, was used. This factor represents the susceptibility of a drainage area to floods or excessive rains. When a basin has a low variation factor the high stage will usually be caused by the sustained flows of melting snow in early summer; this is comparatively constant from year to year. High variations result from heavy storms during the early part of winter. Other factors, such as geologic formation, general topography, shape of the drainage basins, etc., are in this case of minor importance for, as has been pointed out, these physical features are similar among drainage basins in this area.

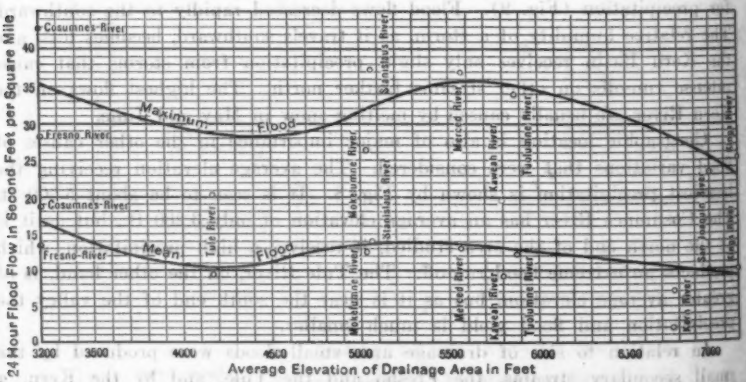

FIG. 8.—RELATION OF FLOOD RUN-OFF (24-HOUR) TO AVERAGE ELEVATION OF DRAINAGE AREA OF ELEVEN CALIFORNIA STREAMS.

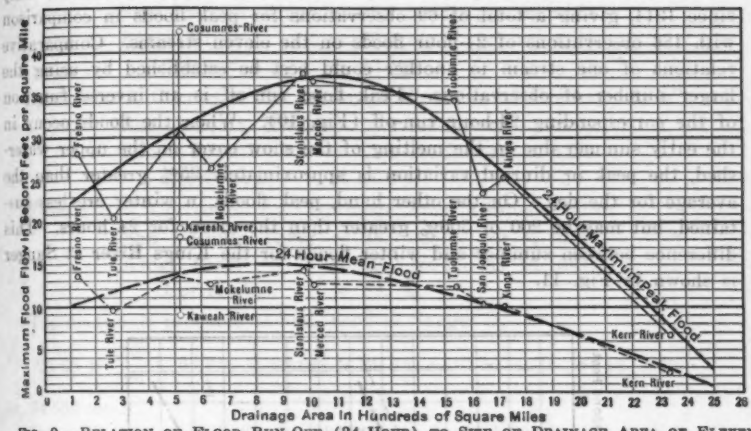

FIG. 9.—RELATION OF FLOOD RUN-OFF (24-HOUR) TO SIZE OF DRAINAGE AREA OF ELEVEN CALIFORNIA STREAMS.

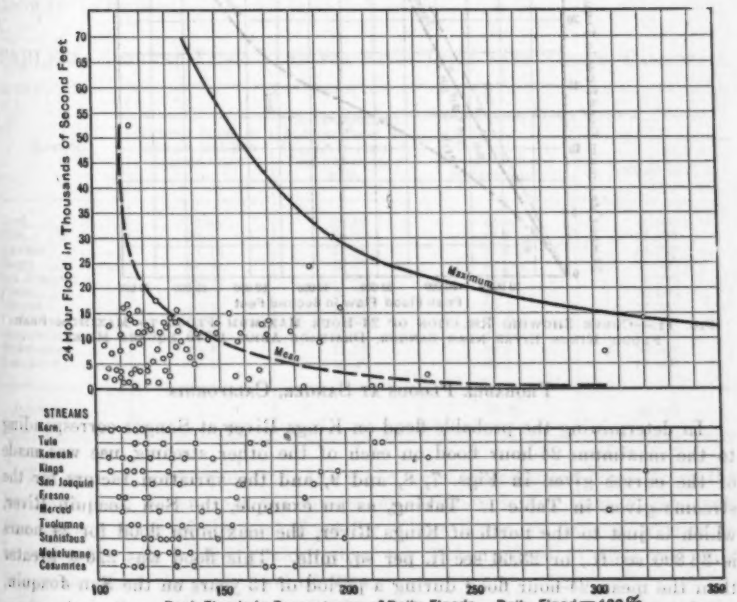

FIG. 10.—RELATION OF PEAK FLOOD TO 24-HOUR FLOOD FOR ELEVEN CALIFORNIA STREAMS.

Relation of Peak Flood to 24-Hour Flood

Peak floods have been published for the streams under consideration only since 1914, giving a total of 69 observations for peak floods in comparison with 186 observations of 24-hour floods on the eleven streams. Comparative relations of one stream to another could best be established by using the larger number of observations. Peak flood run-off is an inverse function of the corresponding 24-hour run-off (Fig. 10). When the floods occur in the early summer due to the melting of the snow cover on the upper watershed, the peak or diurnal variation is approximately 25% greater than the average for the day. On the other hand, peak floods in winter are less sustained, but may be 200 or 300% greater than the mean for 24 hours. This difference between summer and winter floods for the Kings River at Sanger is shown in Fig. 11.

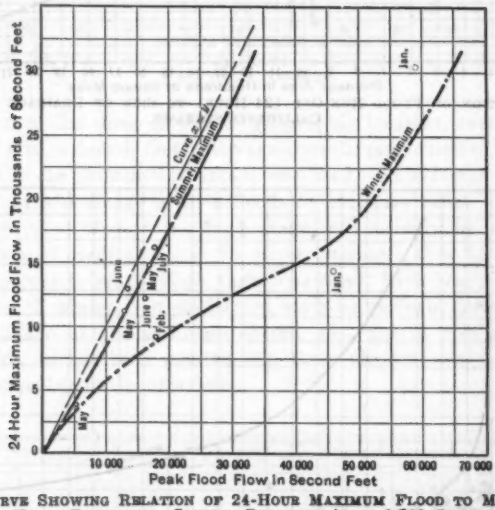

Fig. 11.—Curve Showing Relation of 24-Hour Maximum Flood to Maximum Peak Flood, Kings River near Sanger, Drainage Area, 1 740 Square Miles.

Probable Floods at Sanger, California

In determining the probable flood on Kings River at Sanger corresponding to the maximum 24-hour flood on each of the other streams, use was made of the curves given in Figs. 7, 8, and 9, and the variation factors for the streams given in Table 1. Taking, as an example, the San Joaquin River, which is just to the north of Kings River, the maximum flood for 24 hours is 38 800 sec-ft., or 23.66 sec-ft. per sq. mile. This flood was 226% greater than the mean 24-hour flood during a period of 13 years on the San Joaquin, while the maximum variation on Kings River was 253% greater than the mean.

In addition:

From Fig. 7, Correction for "Distance from Sanger":

San Joaquin River = 25.6 sec-ft. per sq. mile.
Kings River = 23.9 sec-ft. per sq. mile.
Correction = 93.3%

From Fig. 8, Correction for "Average Elevation of Drainage Area":

San Joaquin River = 25.8 sec-ft. per sq. mile.
Kings River = 23.2 sec-ft. per sq. mile.
Correction = 90.0%

From Fig. 9, Correction for "Drainage Area in Square Miles":

San Joaquin River = 28.0 sec-ft. per sq. mile.
Kings River = 25.0 sec-ft. per sq. mile.
Correction = 89.3%

The maximum probable 24-hour flood at Sanger is,

$$23.66 \times \frac{253}{226} \times 93.3\% \times 90.0\% \times 89.3\% = 19.85 \text{ sec-ft. per sq. mile}$$

or, 34 550 sec-ft.

From Fig. 10, a peak flood of 64 200 sec-ft., or 36.90 sec-ft. per sq. mile, would be possible from a 24-hour flood of 34 550 sec-ft.

The other ten streams were studied in a like manner and gave the results shown in Table 3.

TABLE 3.—Deduced Flood Flow for Kings River near Sanger, California.

Stream.	24-hour flood, in second-feet per square mile.	Corresponding 24-hour flood, at Sanger, in second-feet per square mile.	Peak Flood, Kings River at Sanger.	
			Second-feet per square mile.	Second-feet.
Kern	6.88	25.10	42.6	74 100
Tule	20.41	25.25	42.6	74 200
Kaweah	19.42	14.28	31.5	54 900
Kings	25.25	25.25	42.2	73 300
San Joaquin	28.66	19.85	36.9	64 200
Fresno	28.07	22.10	41.4	72 100
Merced	26.47	11.77	30.0	52 200
Tuolumne	34.11	13.58	32.0	55 500
Stanislaus	27.39	13.20	31.1	54 100
Mokelumne	26.47	11.83	30.2	52 500
Cosumnes	42.67	15.15	33.1	57 500
Average	.....	.....	35.78	62 240

The greatest variations from the mean were the adjusted floods from the Kern and Tule Rivers, but the maximum variation is less than 20 per cent. The average value of the peak flood for Kings River, at Sanger, appears to be reasonable. It is 42% greater than the 24-hour flood of 1901 and only 4% greater than the peak flood of 1914.

As a check, a maximum probable flood was computed for each of the other ten streams in the same manner as for the Kings River. In each case the computed flood was reasonable.

Probable Floods at Balch Camp, California

The original intention of this investigation being to determine the probable maximum flood on the North Fork of Kings River, studies were made to determine the probable flow at Balch Camp at the confluence of the North and West Forks of Kings River for a given flow at Sanger on the main river. The San Joaquin Light and Power Corporation has planned a series of developments on the North Fork of Kings River (Fig. 12). The first stage of the Balch Project has been constructed (1927). An arched diversion dam was built at Williams Crossing which will have an ultimate crest elevation of 4 110 ft. The water is then led by a 19 500-ft. tunnel along the north side of the stream to the penstock. Owing to the steepness of the canyon there was no feasible power-house site on the north side of the river, and the penstock was carried over the river to the station on the opposite side.

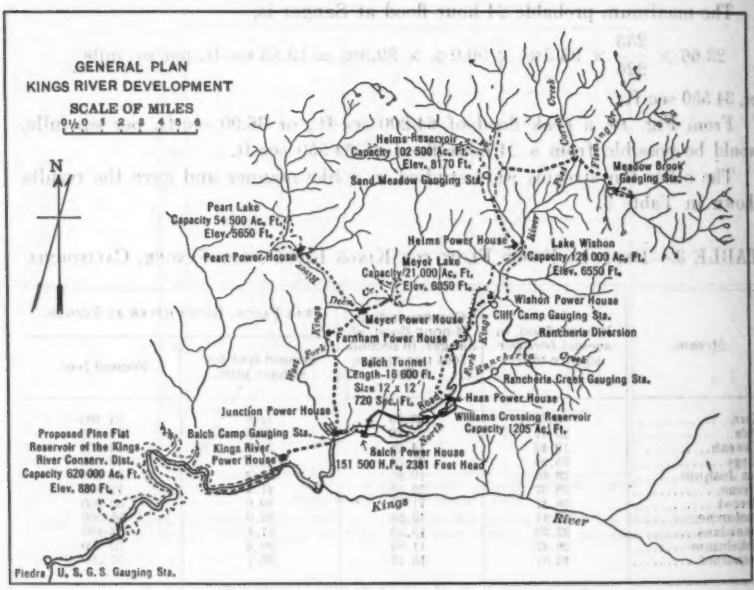

Fig. 12.

Four gauging stations (Fig. 12) were established on the North Fork water-shed in 1920: Balch Camp (1 240 ft.); Cliff Camp (6 150 ft.); Helms Creek (called Sand Meadow) (8 020 ft.); and Meadow Brook (8 140 ft.). In 1924 a fifth station was established on Rancheria Creek (6 400 ft.). On the West Fork there are two stations, near Balch Camp (1 310 ft.), and Dinkey Meadows (5 440 ft.). These stations have been maintained in co-operation with the U. S. Geological Survey. Flood run-off relations, which might be called secondary relations in contrast to the primary relations existing between the eleven different water-sheds, were deter-

mined for the main Kings River Station at Sanger and the North Fork Stations. These relations were expressed in second-feet per square mile for varying average elevations of water-shed (Fig. 13) and in square miles for drainage areas (Fig. 14). As there have been few floods on the North Fork since the stations were established, it was necessary to consider only the corresponding term of years at Sanger. Therefore, as more data are made available the run-off per square mile will be increased, but the relative value

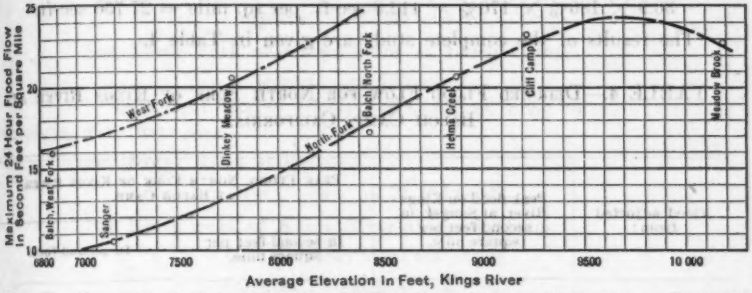

FIG. 13.—RELATION OF FLOOD RUN-OFF (24-HOUR) TO AVERAGE ELEVATION OF DRAINAGE AREA OF KINGS RIVER, CALIFORNIA.

from station to station should hold true. Insufficient data were at hand to determine variation factors for the North Fork Stations. As the relative difference in factors which determine run-off, such as slope, exposure to storm, forest and vegetable cover, etc., was small between Sanger and Balch Camp, the difference in variation factors should be slight. However, if the probable flood at an upper station, as Cliff Camp, were being estimated, it would be necessary to take the ratio of variation factors into consideration.

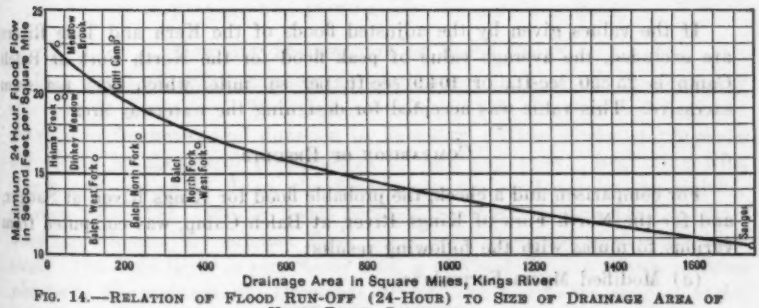

FIG. 14.—RELATION OF FLOOD RUN-OFF (24-HOUR) TO SIZE OF DRAINAGE AREA OF KINGS RIVER, CALIFORNIA.

The method followed in determining the maximum peak flood on the North Fork at Balch Camp was similar to that used in determining the primary floods at Sanger, as follows:

From Fig. 13, Correction for "Average Elevation of Drainage Area":

Kings River at Sanger	= 10.4 sec-ft. per sq. mile.
North Fork at Balch Camp	= 17.7 sec-ft. per sq. mile.
Correction	= 170%

From Fig. 14, Correction for "Drainage Area in Square Miles":

Kings River at Sanger	= 10.4 sec-ft. per sq. mile.
North Fork at Balch Camp	= 18.7 sec-ft. per sq. mile.
Correction	= 180%

The maximum 24-hour flood on the San Joaquin adjusted to suit Kings River conditions produced a peak flood of 36.9 sec-ft. per sq. mile at Sanger. The corresponding peak at Balch Camp would be:

$$36.9 \times 180\% \times 170\% = 112.8 \text{ sec-ft. per sq. mile} = 27\,750 \text{ sec-ft.}$$

The results of the complete study are given in Table 4.

TABLE 4.—DEDUCED FLOOD FLOW FOR NORTH FORK OF KINGS RIVER AT BALCH CAMP, CALIFORNIA.

Flood adjusted from:	Peak flood on Kings River, at Sanger, in second-feet per square mile.	PEAK FLOOD, NORTH FORK OF KINGS RIVER, AT BALCH CAMP.	
		In second-feet per square mile.	In second-feet.
Kern	42.6	130.0	32 000
Tule	42.6	130.0	32 000
Kaweah	31.5	96.5	23 800
Kings	42.2	129.0	31 800
San Joaquin	36.9	112.8	27 750
Fresno	41.4	126.8	31 200
Merced	30.0	91.9	22 700
Tuolumne	32.0	97.8	24 100
Stanislaus	31.1	95.2	23 500
Mokelumne	30.2	92.5	22 800
Cosumnes	33.1	101.2	25 000
Average	35.78	109.5	26 970

If the values given by the adjusted floods of the Kern and Tule Rivers are excluded, the average value of peak flood for the North Fork at Balch Camp is 25 850 sec-ft., or 104.9 sec-ft. per sq. mile, which does not seem excessive. This value was accepted for designing the waterway area.

COMPARISON OF RESULTS

For comparison and a check, the probable flood for Kings River, at Sanger, and for the North Fork of Kings River, at Balch Camp, was computed from various formulas with the following results:

(*a*) Modified Myers Formula*:

$$Q = C\sqrt{M}$$

in which, M is the drainage area, in square miles.

For interior drainage of California,

$$C = 1\,860$$

For Kings River at Sanger,

$$Q = 1\,860\sqrt{1\,740} = 77\,500 \text{ sec-ft.}$$

* "Flood Flow Characteristics," by C. S. Jarvis, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 985.

For North Fork of Kings River at Balch Camp,

$$Q = 1\,860\sqrt{246.4} = 29\,150 \text{ sec-ft.}$$

(*b*) Fuller Formula:*

$$Q(\text{ave.}) = C\,A^{0.8}$$

in which, $C = 70$.

For Kings River at Sanger,

$$Q(\text{ave.}) = 27\,400 \text{ sec-ft.}$$

For North Fork of Kings River at Balch Camp,

$$Q(\text{ave.}) = 5\,735 \text{ sec-ft.}$$

$$Q(\text{24-hour flood in } T\text{-years}) = C\,A^{0.8}\,(1 + 0.8 \log T)$$

in which, $T = 100$ years.

For Kings River at Sanger,

$$Q(\text{in } T\text{-years}) = 71\,300 \text{ sec-ft.}$$

For North Fork of Kings River at Balch Camp,

$$Q(\text{in } T\text{-years}) = 14\,920 \text{ sec-ft.}$$

$$Q(\text{max.}) = Q(1 + 2\,A^{-0.3})$$

in which Q = 24-hour flood in T-years.

For Kings River at Sanger,

$$Q(\text{max.}) = 86\,500 \text{ sec-ft.}$$

For North Fork of Kings River at Balch Camp,

$$Q(\text{max.}) = 20\,650 \text{ sec-ft.}$$

(*c*) *Bulletin No. 5*, "Flow in California Streams", Department of Public Works, California:

For Kings River, at Sanger,

($T = 100$ years) = 41 000 sec-ft. (for a 24-hour flood)

Monthly Distribution of Flood Peaks

Peak floods on California streams of the west slope of the Sierras never occur before December. They are most frequent in January and begin to decrease in frequency and duration in February. These winter storm peaks are caused by the direct precipitation of rain and snow. Beginning with March and ending in June, the flood peaks are produced by the melting of snow (Fig. 15). Winter floods produce a sudden extreme peak of short duration, whereas the summer flood has a long sustained moderately high stage. The Tule River is very flashy and, as is shown by Fig. 15(*a*), in three months of the peak season—December, March, and April—the greatest variation of the peak flood from the 24-hour flood occurred on the Tule. However, the greatest variation, 320%, which was produced by a winter storm in January, took place on the Kings River.

Expectancy of Flood Occurrence

The fact that flood run-off above the mean is more variable than flood flow below the mean has been long established. Rainfall follows the same

* "Flood Flows," by Weston E. Fuller, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXVII (1914), p. 564.

rule. Flood records for any stations covering a period of years will show a few great floods of high variation from the mean and several floods near or slightly below the average. The length of record on any of the California

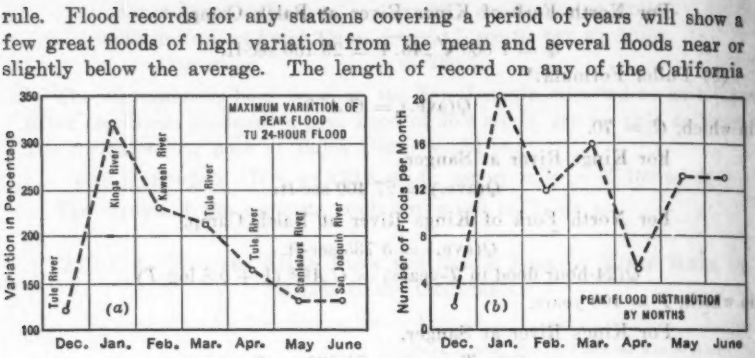

FIG. 15.—FREQUENCY AND INTENSITY OF PEAK FLOODS, ON ELEVEN CENTRAL CALIFORNIA STREAMS.

streams is too short to make an accurate forecast of the frequency of maximum floods. A graphical analysis of the frequency of Kings River floods at Sanger is given in Fig. 16, the data used being shown in Table 5. By

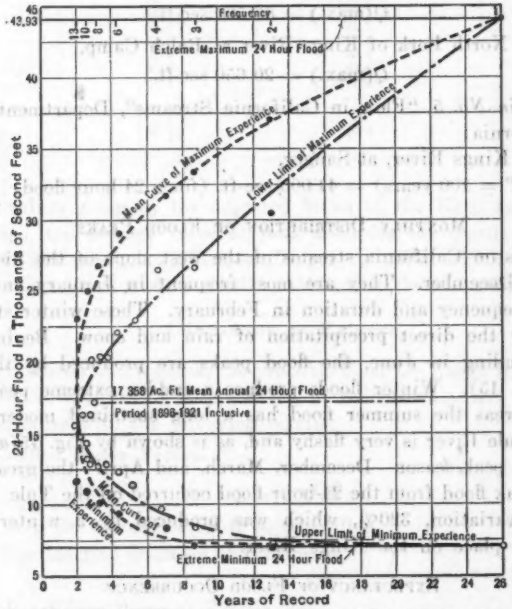

FIG. 16.—FLOOD FREQUENCY ON KINGS RIVER, NEAR SANGER, CALIFORNIA.

prolonging this curve in both directions it is seen that greater and lesser floods may be expected when a greater number of records are available. No

trustworthy estimate is possible by this method, however, for judgment would indicate that both maximum and minimum curves should become parallel with the base when the most extreme conditions are reached; but what those extreme conditions are, is problematic.

TABLE 5.—EXPERIENCE TABLE OF ANNUAL 24-HOUR FLOOD AT PIEDRA, CALIFORNIA.

Order of magnitude.	FLOODS IN ORDER OF MAGNITUDE, IN ACRE-FEET.		Number of annual floods averaged.	MEAN ANNUAL FLOODS, IN ACRE-FEET.	
	Maximum.	Minimum.		Maximum.	Minimum.
1	43 930	6 920	1	43 930	6 920

13	15 700	15 600	13	22 979	11 659

STORAGE

On a majority of the eleven streams considered, reservoirs of relatively large capacity have been constructed. These reservoirs are in the foothills and their primary use will be for irrigation. Supplemented by storage for power purposes near the head-waters, they will have some favorable effect on the flood flow on the tributary rivers. Being constructed principally for irrigation, a reservoir might be full when a great flood comes; nevertheless, to a certain extent, it would elongate the flood wave and thereby reduce the peak discharge. It would be a great community benefit if a certain proportion of the total capacity could be held for flood protection until the flood menace of a high year was past. This is practiced with a few of the larger U. S. Reclamation Service reservoirs. Although the principal effect of such reservoirs will be to reduce the flood peaks, they will probably have comparatively little effect on the maximum discharge of the extreme flood, which is expected only once or twice in a century.*

FLOOD ESTIMATES

Floods on any water-shed are caused by a storm of a certain type, which varies but little from year to year. If flood records of at least 100 years were available for each stream, it is evident, of course, that the best way to investigate the variations of flood discharge would be to treat each stream by itself. However, on many streams, few or no records are at hand. A fair estimate may be had by adjusting the recorded discharges of neighboring streams, similar to the stream in question in geologic, topographic, and meteorologic characteristics. The adjusting factors may not be the same in

* The relation of these foothill irrigation reservoirs to power development is discussed by William Kelly, M. Am. Soc. C. E., in his paper entitled "Co-Ordination of Irrigation and Power," *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 1429.

all cases, but size of drainage area will be a persistent influence. This comparison or adjustment of existing flood records should be supplemented by the solution of reliable flood formulas, by a study of rainfall records by the time-area-depth method, by reliable evidence of flood deposits, as drift and alluvial bars, and the experiences of observers. Precipitation records, especially if the precipitation is in the form of rain, will serve as a basis of flood prediction, under ideal conditions. Under actual conditions a given rainfall intensity will yield extreme variations of run-off.

Conclusions

In this paper, the writer does not assume to solve the wide problem of flood flows, but merely to describe one method of attack. The future can best be predicted by a study of the past. A rational study of past flood records should form the basis of estimating probable future floods on any stream. The full purpose will be accomplished when a better appreciation of flood danger is held by the Engineering Profession and by the general public. Only after this knowledge is general will the proper measures of flood control be taken.

In addition to the specific acknowledgments made in the paper, the writer has obtained valuable data from the published writings of many engineers, most of them members of this Society. This study was made for the San Joaquin Light and Power Corporation, under the general direction of Mr. J. W. Jourdan. H. K. Fox, M. Am. Soc. C. E., Construction Superintendent, was in charge of the Kings River Development.

DISCUSSION

ROBERT FOLLANSBEE,* M. AM. SOC. C. E. (by letter).—The author states that, up to a certain elevation, ranging from 4 000 to 6 000 ft., precipitation increases with height, but higher than that, it decreases slowly to the summit. That this statement concerning a zone of maximum precipitation below the summit is not applicable to the Rocky Mountain region is shown by precipitation records in Colorado, so situated as to be comparable.

TABLE 6.—PRECIPITATION RECORDS OF NORTHERN COLORADO.

Slope.	Station.	Elevation, in feet.	Mean precipitation, in inches.	Length of record, in years.
West	Fraser	8 560	19.12	8
East	Longs Peak (near)	8 600	20.99	9
West	Spruce Lodge	9 600	30.13	6
East	Silver Lake	10 500	37.03	10
Summit	Corona	11 600	45.99	6

The first set presented comprises stations located on a section through the Continental Divide in Northern Colorado, on both eastern and western slopes, with one station at the summit. These records are summarized in Table 6.

The second set is located near a section extending from Colorado Springs at the base of the mountains to the summit of Pike's Peak (Table 7).

TABLE 7.—PRECIPITATION RECORDS IN COLORADO.

Station.	Elevation, in feet.	Mean precipitation, in inches.	Length of record, in years.
Colorado Springs	6 098	14.37	33
Glen Eyre	6 500	16.15	18
Fremont Experiment Station	8 850	22.79	10
Lake Moraine	10 265	24.98	24
Pike's Peak	14 107	29.55	15

Even a casual comparison of the two sets will show that elevation is not the only factor in determining the amount of precipitation, since that on Pike's Peak at 14 107 ft. is less than the precipitation at 9 600 ft. on the Continental Divide. The writer has shown elsewhere† that the controlling factor appears to be the presence or absence of mountain masses to the westward.

HAROLD K. FOX,‡ M. AM. SOC. C. E. (by letter).—The water records of California streams do not cover long periods. The best and oldest records have been taken at points where the streams enter the valleys (usually above irrigation intakes), and were primarily established for purposes of irrigation. In investigating power resources, the several branches and tributaries in the high altitudes are the points of interest, and it is only recently that records

* Dist. Engr., U. S. Geological Survey, Denver, Colo.

† *Water Supply Paper 500-C*, U. S. Geological Survey, p. 69.

‡ Supt. of Constr., San Joaquin Light & Power Corporation, Fresno, Calif.

have been obtained on such streams. A large part of these records are for the period since about 1917 and, since the past ten years have been somewhat less than normal in precipitation, it is necessary to combine these records with those of longer duration on the main stream and to compare one river with another.

The rapid development of power has necessitated exhaustive studies of water resources and flood flow. The writer has a close personal knowledge of the vast amount of work that Mr. Reed has done in preparing this paper and hopes that it will be as beneficial to others who may have occasion to use it as it has been to those who developed the Kings River Project of the San Joaquin Light and Power Corporation. On this project it was necessary to locate the first power house in a very narrow and deep canyon, and one of the problems was that of protection against floods.

The writer has consulted the author on the matter of flood determination and finds that his method has been changed in certain details. The primary data are now used to determine one relation curve, which is called the "geographical location" curve. The location of a drainage area in relation to the path of cyclonic storms is of primary importance in this section of California.

The relation of average elevations and size of drainage area are, however, very important. Referring to Fig. 3, it will be noted that the elevation of maximum precipitation from the normal storm is about 6 000 ft. for Kings River. Storms which produce the highest run-off on the Kings River occur in January and February. At this season precipitation on the upper part of the water-shed is in the form of snow and contributes only a small run-off. Above Elevation 7 000 the mean monthly temperature is below 30° Fahr., in January and February. During some days of these months the temperature would be above freezing, but the contribution to the run-off would be slight. Thus, the effective area would be much reduced. The effective area of the Kings River above Sanger would be about 900 sq. miles instead of 1 740 sq. miles.

The mean elevation of the effective area is then determined. The various streams will then be compared with respect to the relative location of the mean elevation of their effective areas. If the mean elevation coincides with the point of maximum precipitation, it will have a factor of 1.0. On the other hand, if it falls above or below the elevation of peak precipitation, the factor will be suitably lowered. In this manner, factors will be obtained for evaluating the effect of average elevation.

The observation that a stream of small tributary area will have a higher run-off per square mile than a large stream from a storm of given intensity has been the basis of many flood formulas. The effective area at the time of maximum flood expectancy should again be used. In order to eliminate the effect of difference in precipitation, only four streams will be used in determining this curve—the Kings, Kaweah, San Joaquin, and Merced Rivers.

In February, 1927, a storm occurred on the Kings River which produced a run-off of high intensity. The locus of the storm was over a relatively small area about five miles west of the junction of the North Fork with the main stream, or about eight miles from Balch Camp. The area had been burned

over by a forest fire during the previous July. Periods of moderate rainfall preceded the main storm, which was of cloudburst intensity. Each small watercourse became a torrent and, since there was no grass or underbrush to hold the soil, erosion was very severe. Each watercourse became a gully, and boulders (many 10 ft. in diameter) were washed down, filling the channel of Kings River and forming pools of slack water. These dams sustained the flow very well.

The gauge at Piedra showed a peak discharge from this storm of about 22 000 cu. ft. per sec. This discharge from the upper reaches of the stream was not high; the discharge of the North Fork at Balch Camp was about 2 000 cu. ft. per sec. A conservative estimate of the run-off from the main storm area is 10 000 cu. ft. per sec. from approximately 100 sq. miles. This storm area was in the foothills, where there are moderate slopes.

It is not improbable that at some future date the locus of a similar storm will be over the North Fork area, where the run-off would be even more rapid, due to the steeper slopes and less cover. If that should happen, a run-off of 25 000 sec-ft. (or 101.5 cu. ft. per sec. per sq. mile) is entirely possible. A storm of this intensity will probably never occur before December, when the upper water-shed would contribute little to the flow. The run-off from the effective area might then be 150 cu. ft. per sec. per sq. mile.

CHARLES H. LEE,* M. AM. SOC. C. E. (by letter).—This paper describes a method of estimating maximum flood discharge which assumes that within the same meteorological province the records of several streams, similar in storage, vegetation, soil, and other physical characteristics, can be combined, after making certain adjustments, so as to give an equivalent record for one of the streams. The adjustments include corrections for geographic position, average elevation and size of drainage area, and relation of peak to 24-hour flood discharge. The author states that he adopts this method because of the inherent limitations of flood discharge formulas and the impracticability of extending their use to streams other than those for which they were originally devised.

The writer's experience in estimating flood discharges from formulas confirms these conclusions, but has led him to favor the rational method rather than the stream-group method. Drainage areas have individual characteristics. These are much more effective in producing differences in flood discharge than they are in the case of total run-off. With certain modifications, the author's method might be applied to the eleven streams which he studied, if his purpose was to determine long-time, mean, total run-off, but it is not logically applicable to the problem of determining flood discharge.

Throughout the paper the writer detects a confusion of thought regarding factors which influence total run-off and maximum flood run-off. It is believed that a rational analysis of these factors may be helpful.

* Cons. Hydr. Engr., San Francisco, Calif.

Total Run-Off.—The total run-off from a drainage area is usually considered for an annual cycle (or water-year) and depends on the total precipitation on the drainage area during the period, minus losses due to evaporation from water, snow, ice, and soil, and transpiration from plants. Cyclic surface, snow, or ground storage may be important if wide variation occurs in precipitation from year to year. Total run-off may be expressed for unit area by the formula, $r = P - L \pm S$, in which, r is the total run-off from a unit area; P, the depth of annual precipitation; L, the depth of annual losses; and S, the annual storage correction.

Water, snow, and ice evaporation depend on the extent and period of exposure of the respective surfaces, and the temperature, humidity, and other factors which influence the evaporation rate. Elevation and geographic location as they affect meteorological conditions play an important part in fixing these losses. Soil evaporation depends on slope, quantity, and time distribution of rainfall, vegetation, depth, and porosity of the soil, and the factors which influence the rate of water evaporation. Transpiration depends on the type and extent of vegetation, which, in turn, depends on soil, rainfall, and elevation and geographic location as they affect meteorological conditions. Cyclic storage ordinarily becomes important only when artificial surface storage of large capacity has been constructed, or large ground storage capacity exists in the form of gravel beds or volcanic débris.

Flood Discharge.—In contrast to total run-off, this factor depends on the intensity of rainfall and the amount of run-off finding its way immediately into drainage channels. It may be expressed for a unit area by the formula, $q = Ci$, in which, q is the discharge, in second-feet, for a unit area; i, the intensity of rainfall, in inches per hour; and C, the run-off coefficient representing the ratio of the rate of immediate run-off to rainfall intensity and expressing the physical characteristics of the drainage area.

As the automatic rainfall records obtained during the past 20 to 30 years have demonstrated, rainfall intensity at any point varies greatly with time, being greatest for periods of a few minutes, decreasing rapidly for longer periods, and approaching a more constant value for periods exceeding 12 hours. Maximum flow at any point on the stream results from a rainfall the duration of which equals or exceeds the time of concentration of water from the most remote point (in time) on the drainage area. It is greatest when the surface is frozen or saturated from a previous storm and may be augmented in special cases by the effect of warm rain in melting snow on the ground.

The maximum rainfall intensity to be considered for a given drainage area is not uniform within the same "meteorological province", but varies from place to place depending on local conditions and especially on the time of concentration. The latter differs for every point on the stream. It may also differ at the same point for different storms, depending on the extent of the area upon which precipitation falls in the form of rain. For example, precipitation might fall in the form of snow on the higher portion of the drainage area, or the maximum storm might not extend over the whole of the area.

The time of concentration is controlled by the following factors:

1.—The time of flow over the surface of the ground to the nearest stream channel. This is influenced by the average slope of the ground at the most distant point in the drainage area and the irregularities of the surface produced by vegetation and character and condition of the soil surface.

2.—The time of flow in stream channels. This is determined by the average slope and character of channel, as reflected in the value of n in Kutter's formula.

3.—The shape of the drainage area, whether long and narrow, fan-shaped, etc.

4.—The arrangement of branches and laterals.

5.—Surface storage.

The percentage of rainfall which finds its way immediately into the stream depends on:

(*a*) Losses, consisting of immediate evaporation (very small) and absorption. The latter is controlled by surface conditions, such as the extent of bare rock or frozen ground, the character of the soil, the slope, and the existence of a mat of vegetable material and humus.

(*b*) Temporary retention due to storage in irregularities of the surface and capillary action, the vegetation mat being an important factor in the matter.

(*c*) The degree of previous saturation, depending on the season of the year when the storm occurs and the relation of the time of the maximum storm to the storm period.

Table 8 summarizes these factors and serves to contrast the differences between those entering into total run-off and maximum flood run-off.

TABLE 8.—COMPARISON OF PRINCIPAL FACTORS CONTROLLING TOTAL RUN-OFF AND MAXIMUM FLOOD RUN-OFF FOR A GIVEN DRAINAGE BASIN OF AREA A.

Total run-off, $R = (P - L \pm S)\,A$.	Maximum flood run-off, $Q = C\,i\,A$.
A = superficial area of whole drainage basin.	A = portion of superficial drainage area covered by storm yielding rainfall of maximum intensity.
P = total depth of precipitation during complete run-off cycle (water-year).	i = maximum rate of rainfall of uniform intensity continuing throughout the period of concentration, or for the period of the storm if shorter than the period of concentration.
$L \pm S$ = depth of accumulated losses during the entire water-year by evaporation from water, snow, ice, and soil, and transpiration augmented or diminished by cyclic surface or ground storage.	$1 - C$ = percentage of rainfall at maximum rate lost by absorption and temporary storage in surface irregularities and capillary films.
	C = percentage of rainfall at maximum rate which runs off immediately and appears in the stream by the end of the period of concentration.

In the light of this analysis (see Table 8), the following conclusions are believed to be sound:

First.—The author's implied assumption that the rainfall intensity producing maximum flood discharge is uniform throughout a meteorological province, or for all points on a drainage system, is not justified.

Second.—Few, if any, drainage areas (including their drainage systems) are so similar that both the times of concentration and the run-off factors for maximum discharge correspond, as the author's second assumption would imply.

Third.—The items selected by the author for making adjustments between various drainage areas have no direct or apparent relation to the factors which control maximum flood run-off.

In comment on the third conclusion, the distance north or south of Sanger, Calif., has not been shown to be systematically related to the form of the rainfall intensity curve at different points, nor to any factor influencing flood discharge. Also, the average elevation of the drainage area, although indicating the percentage of precipitation falling as snow, is not so expressive of this relation as would be the proportion of the drainage area above the critical elevation. Fig. 8 shows no definite relation between flood run-off and average elevation. Then, again, the size of the drainage area, although it is an important factor for extremely large areas, or in regions of local storms where a given storm covers only a portion of the area, has little bearing on flood discharge from Sierra Nevada streams. The latter are normally visited by general storms the extent of which far exceeds the limits of the drainage area. Fig. 9 shows clearly the absence of any relation between drainage area and maximum flood flow for these streams.

The apparent conclusion illustrated in Table 3 is that the peak flood discharge to be expected on Kings River at Sanger is 62 240 sec-ft. The maximum 24-hour flood reported for this station by the U. S. Geological Survey is 43 930 sec-ft. on January 7, 1901. Correcting this to peak flood by use of Fig. 10, a value of 73 800 sec-ft. is obtained, which exceeds the author's value by 18 per cent. Table 9 is obtained by assembling the various values given in the paper. It appears from this table that the author's value for peak flood on Kings River, at Sanger, is from 12 to 19% less than that derived by any other method. It is believed that the author's paper is incomplete without a discussion of the reasons which underlie the assumptions on which his method is based. This is especially true in view of the fact that it departs somewhat from accepted practice.

* Obtained from 24-hour flow by use of Fig. 10.

The rational method of estimating flood discharge was originally used in estimating maximum run-off from urban and suburban areas in connection

with storm-sewer design. The same method is applicable to natural drainage areas of sizes exceeding those considered by the author, although for very large areas its use is impracticable because of the complexity.

The general application of the rational method is becoming more and more feasible as the appropriate basic data are accumulated. Automatic tipping-bucket rainfall records kept by the U. S. Weather Bureau and other public agencies, are now available at many points throughout the United States. At many of these stations records covering from 15 to 25 years are available for 5-min. periods, and up to 50 years for periods of 12, 24, 36, and 48 hours, etc. From such data rainfall intensity curves can be constructed, which indicate the range of rainfall rates for various periods of time and frequency of occurrence. The normal expected intensities of rainfall at Oakland, Calif., within 2, 5, 10, and 15-year periods are as shown in Fig. 17. These curves are based on automatic recording rain-gauge observations covering 18 complete years of a 23-year record (1904 to 1927) at the Chabot Observatory. They are typical of the San Francisco Bay region. The same storms upon which these curves are based, extend over the western slope of the Sierra Nevada Mountains, including the drainage areas of the San Joaquin Valley streams considered by the author. In the absence of automatic rainfall records on the drainage area of Kings River and adjacent streams, the writer believes that this curve could be modified and extended from local foothill and mountain records for 12, 24, 36, and 48-hour periods so as to give a generally representative curve for this region, which would include all times of concentration that would occur in practice.

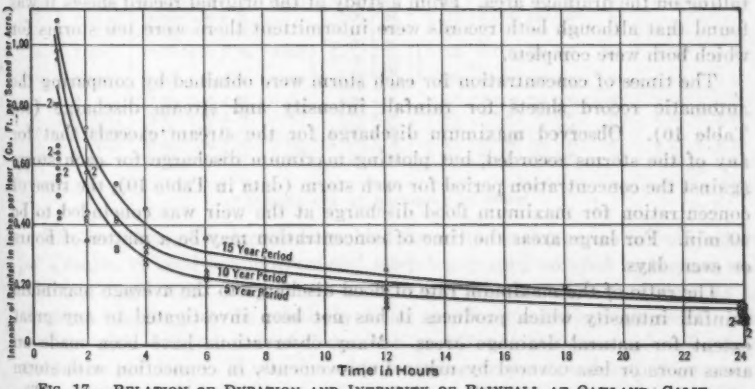

FIG. 17.—RELATION OF DURATION AND INTENSITY OF RAINFALL AT OAKLAND, CALIF.

The time of concentration at any point on a stream is readily estimated by observing the movement of flood waves down the channel, checked by velocity measurements during high water. It is to be recognized, however, that the water velocity usually indicates a more rapid rate of advance than the flood wave because the latter is modified by channel storage. The determination is most effectively made in conjunction with rainfall observations, but, on a long stream course, the observed rates of travel with proper modifications

may be extended back to stream head-waters. Time should also be allowed for the flow of water over the surface of the ground and down small tributaries before it reaches the larger channels.

The writer recently had an opportunity to determine the time of concentration for Strawberry Creek, a small stream flowing through the campus of the University of California at Berkeley and draining a canyon cut back into the hills on the east shore of San Francisco Bay. The area drained at the measuring weir is less than 1 sq. mile (509 acres) and has a range in elevation of from 1 200 to 1 500 ft. on the surrounding ridges to 500 ft. at the weir. The average distance from the ridge crests to definite stream channels is 0.25 mile, with a difference in elevation of from 400 to 600 ft. The greatest length of stream channel is 1.2 miles, with an average slope of 140 ft. per 1 000. The entire area supports a good growth of natural grass, with close-growing brush on the northern slopes and planting of young pines along the ridges at the head of the canyon.

Self-recording weir measurements of the flow were made by the University under the direction of Mr. H. B. Foster during the five seasons between 1910 and 1915. Automatically recorded rainfall records from a Friez tipping-bucket rain-gauge on the University Campus were also kept during the period by the College of Civil Engineering, under the direction of Charles Gilman Hyde, M. Am. Soc. C. E. During the season of 1914-15, comparative observations of rainfall on the University Campus and at thirteen rain-gauges placed at critical points on the Strawberry Creek drainage area indicated a practical agreement between the rainfall as measured at the campus and the average falling on the drainage area. From a study of the original record sheets it was found that although both records were intermittent there were ten storms for which both were complete.

The times of concentration for each storm were obtained by comparing the automatic record sheets for rainfall intensity and stream discharge (see Table 10). Observed maximum discharge for the stream exceeds that for any of the storms recorded, but plotting maximum discharge for each storm against the concentration period for each storm (data in Table 10), the time of concentration for maximum flood discharge at the weir was concluded to be 40 min. For large areas the time of concentration may be a matter of hours or even days.

The ratio of the maximum rate of flood discharge to the average maximum rainfall intensity which produces it has not been investigated to any great extent for natural drainage areas. Many observations have been made on areas more or less covered by urban improvements, in connection with storm sewer design; but run-off factors for such conditions do not apply. The factors generally used on such work for previous surfaces, such as parks, gardens, lawns, and meadows, vary from 0.05 to 0.25, depending on surface slope and character of subsoil.

Merrill M. Bernard, M. Am. Soc. C. E., states* that values for watersheds will vary from 0.11 to 0.15, but does not describe the types of drainage area to which such factors apply. It is probable that he has in mind the

* *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 1087.

milder climates and flat slopes. Other authorities quote values of from 0.50 to 0.75, probably for colder regions and steeper slopes.* Mr. George Chamier gives the following values:†

Frozen ground	0.66
Naked unfissured mountains, Very steep ground, Paved streets	0.80
Mountainous and rocky country or non-absorbent surfaces	0.55 to 0.65
Wooded hill slopes and compact or stony ground	0.45 to 0.55
Meadows and gentle declivities, absorbent ground	0.35 to 0.45
Flat country, sandy soil, or cultivated land	0.25 to 0.35

* Ground dry at beginning of storm.

The Strawberry Creek records enabled the writer to determine run-off factors for a region of mild temperature and steep topography covered with grass and close growing brush. The percentage of water running off during the peak of the flood was found to be relatively small and the stream was frequently still swollen with delayed run-off from one period of maximum rainfall when another would occur. It was desirable to segregate the flow due to the current storm from that derived from previous storms. This was readily accomplished graphically upon the hydrographs by extending the slope of the diminishing flood flow to a point beneath the succeeding peak. The results for the ten storms are summarized in Table 10, which indicate that for major storms (January 12, 1914) occurring when the ground was still wet from previous storms, the ratio of maximum flood discharge to the rate of rainfall that produces it

* "Public Water Supplies," by Turneaure and Russell, Third Edition, p. 74.
† *Minutes of Proceedings*, Inst. C. E., Vol. CXXXIV, 1897–98, Pt. IV, p. 313.

was 0.12. If delayed run-off from previous storms was added, the ratio became greater and reached 0.22 in one instance (afternoon, January 12, 1914). If it be assumed that the run-off from the preceding storm is still at peak flow when the peak from the succeeding storm arrives, the run-off ratio (in terms of rainfall) for the record storm might be 0.24, which represents a limiting value. For maximum conditions, a value of 0.25 was assumed.

It is thus apparent that the flood discharge run-off factor has a wide variation, depending on local conditions. This element in the application of the rational method is the weakest link. The writer regards the method as having real merit and believes that attention should be given by the profession to perfecting its application.

OREN REED,* ASSOC. M. AM. SOC. C. E. (by letter).—A review of recent engineering literature would indicate that flood intensity and frequency have not been given their due importance. Widespread interest has been manifested after each major disaster, but more studies should be made for preventative purposes. The year 1927 was a remarkable period for great floods claiming the attention of the engineer. In them, he finds a need for thorough study as a means of coping with repetitions.

When floods occur, men instinctively feel that they are helpless against such occurrences, and that they must continue to bear them even in the future. It is recognized by engineers, of course, that there have always been floods and that their frequency and intensity have not changed greatly. Loss of property and life have steadily increased because Man has encroached on the river banks.† When structures are erected on the bank of a river, engineers must design with reference to flood discharges and flood stages. Their only safe criteria in estimating floods of the future must be obtained from a study of floods of the past. At present, unfortunately, the knowledge of flood facts is quite inadequate.

The record of flood run-off from any California river is too short to estimate accurately its probable maximum flood. Since 1918 the precipitation has been sub-normal, and no major floods have occurred. The passage of years will make the record more complete, but in the meantime existing records must be used.

Further Flood Study.—As stated by Mr. Fox, the writer's methods of studying flood records have been changed in certain details. In Central California, as in other regions, the geographic location of an area in respect to the path of cyclonic storms determines to a great extent its flood run-off. The primary data are used to determine only one curve, such as Fig. 7, which was called the "geographical location curve".

The relation of average elevations and size of drainage areas is, however, of major importance. Storms which produce the maximum flood run-off on the Kings River occur in January and February. At this season precipitation on the upper part of the water-shed is in the form of snow and contributes only a small run-off. Due to this fact the productive or effective area would be a

* Asst. Designing Engr., San Joaquin Light & Power Corporation, Fresno, Calif.

† *Engineering News-Record*, November 10, 1927, p. 741.

relatively small part of the total. This extended study has been based on effective areas.

Temperature data are not published for many mountain stations in California. Reliable records are available for the Fresno-Auberry-Huntington Lake Section, on the San Joaquin River, and for the Sacramento-Auburn-Colfax-Norden Section, on the American River. (See Fig. 18.) The American River was not used for the run-off records, but may be used in the study of temperature variation without error. The American River is about 35 miles north of the Cosumnes River, the most northerly stream in the run-off study.

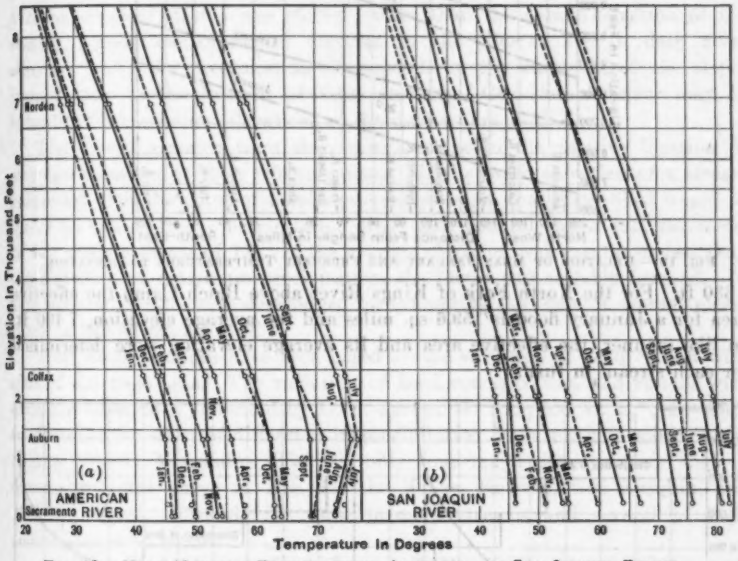

FIG. 18.—MEAN MONTHLY TEMPERATURES, AMERICAN AND SAN JOAQUIN RIVERS.

A study of meteorological data shows that the mean daily temperature during a storm period is from 4 to 8° higher than the mean monthly temperature. Based on that fact, the assumption has been made for this study that the run-off would be so slight that it could be neglected when the mean monthly temperature was below 22.5° Fahr. Fig. 19 has been drawn from the data given on Fig. 18 to show the relation of altitude to mean January and February temperature of 22.5° for the eleven streams. A curve for 25° is also given for reference. The curves are based on observations at only two stations and are plotted as straight lines. No doubt, there would be some variation from a straight line, but the deviation should not be great. This statement is substantiated by the temperature observations at the Upper Kings River meteorological stations. The Kings River stations have been maintained for six years.

The distribution of drainage area according to elevation was determined for each stream by planimeter and then plotted. Fig. 20 shows two of the

curves; one for the San Joaquin River at Friant (Fig. 20 (*a*)) and the other for the North Fork of Kings River above Balch Camp (Fig. 20(*b*)). Referring to Figs. 19 and 20(*a*), the effective area for the San Joaquin River, that would contribute to a January flood, was estimated to be 1 170 sq. miles, or 71.4% of the total area. The average elevation of the effective area was

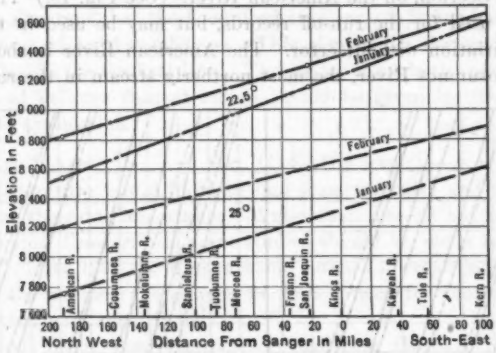

FIG. 19.—RELATION OF MEAN JANUARY AND FEBRUARY TEMPERATURES TO ELEVATION.

5 630 ft. For the North Fork of Kings River above Balch Camp the effective area for a January flood is 159.6 sq. miles and the average elevation, 7 490 ft. In like manner, the effective area and its average elevation were determined for each stream in turn.

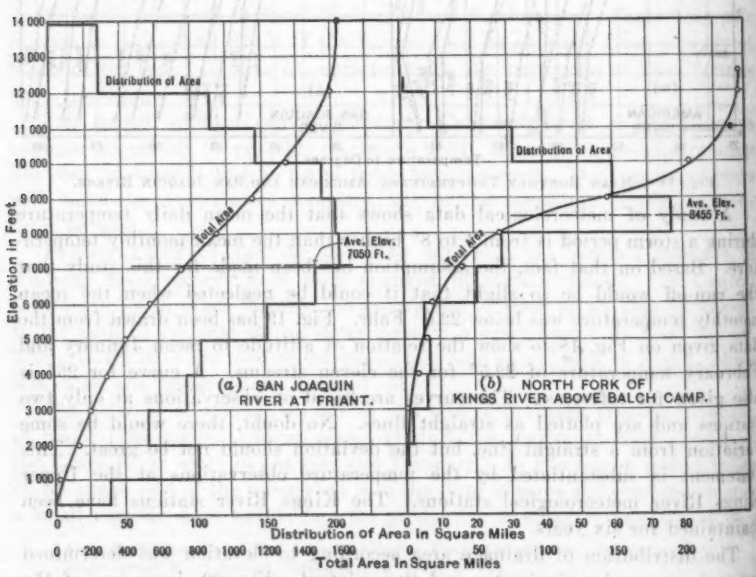

FIG. 20.—DISTRIBUTION OF DRAINAGE AREA.

It will be noted from Fig. 3, that the greatest precipitation from a normal storm on Kings River is about 6 000 ft. The locus of condensation on a mountain slope is usually at a lower level in winter than in summer, but this is offset to a certain extent by the low run-off of the upper part of the contributing area. Sufficient precipitation data were not available for each stream for plotting curves similar to Fig. 3 and only five curves were used, the Kern, Kings, San Joaquin, Mokelumne, and American Rivers. The San Joaquin River Section is indicated on Fig. 21. Each curve was used for two or three adjoining streams; the American River curve was used for the Cosumnes River only. In plotting these curves, the mean elevation of the slopes back of a meteorological station was plotted rather than the actual elevation of the station. Most meteorological stations in the Sierras are in deep river canyons while the precipitation corresponds to the elevation of the slopes immediately to the leeward of these stations. Considerable error may be introduced when actual elevations of the stations are used.

The eleven streams were then compared as to the relative location of average elevation of their effective areas. If the mean elevation of a stream coincided with the point of maximum precipitation, that water-shed would be likely to receive heavy precipitation from each general storm and, therefore, it was given a factor of 1.0. If the average elevation was greater or less than the elevation of maximum precipitation, the factor was suitably lowered. In this manner, factors were determined for evaluating the effect of average elevations of the eleven streams.

Most flood formulas have been based on the variation of flood run-off with size of drainage area. The variation of flood concentration and run-off with area has been ably presented by C. S. Jarvis, M. Am. Soc. C. E.* In order to decrease the effect of difference in precipitation from north to south in the Sierra Nevada Mountains (Fig. 2), only four major streams were used in determining the curve in Fig. 22—the Kings, Kaweah, San Joaquin, and Merced Rivers. Records for these primary streams and several of their tributaries were plotted.

Adjusted Probable Floods at Sanger, Calif.—Curves given in Figs. 7, 3, 21, and 22, and the variation factors for the streams given in Table 1 were used to determine the adjusted probable maximum flood on Kings River at Sanger, corresponding to the maximum 24-hour flood on each of the other streams. The San Joaquin River will be taken again as the example. The 24-hour maximum flood on the San Joaquin River was 38 800 sec-ft., or 33.16 sec-ft. per sq. mile of the effective area. This flood was 226% greater than the mean 24-hour flood during a period of 13 years on the San Joaquin, while the maximum variation on Kings River was 253% greater than the mean.

In addition:

From Fig. 7, Correction for "Distance from Sanger":

San Joaquin River = 25.6 sec-ft. per sq. mile
Kings River = 23.9 sec-ft. per sq. mile
Correction = 93.3%

* *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 985.

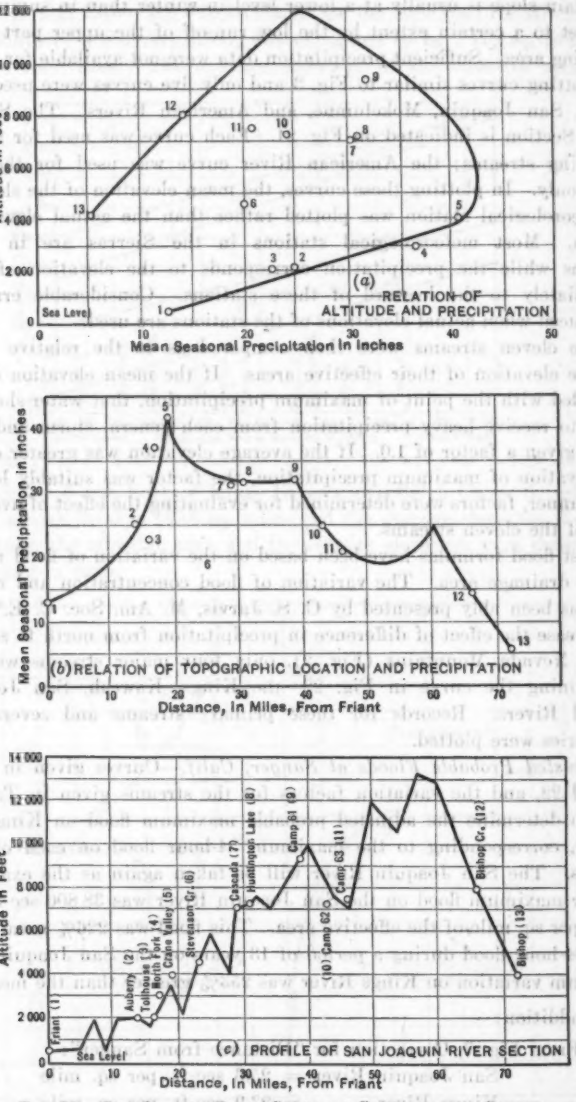

FIG. 21.—SAN JOAQUIN RIVER GROUP OF PRECIPITATION GAUGES.

From Figs. 21 and 3, Correction for "Average Elevation of Drainage Area":

San Joaquin River area above 9 100 ft. not productive:

Effective area = 1 169.4 sq. miles
Average elevation = 5 630 ft.

Kings River area above 9 200 ft. not productive:

Effective area = 1 191 sq. miles
Average elevation = 5 230 ft.

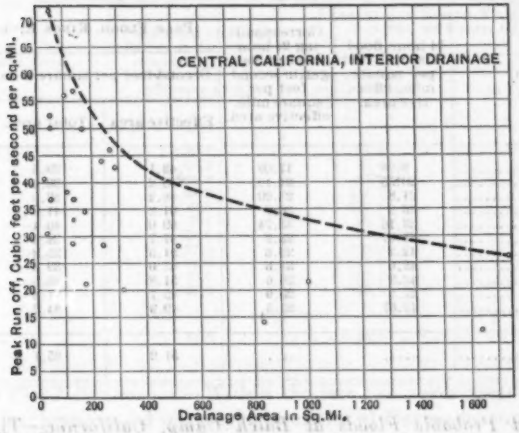

FIG. 22.—RELATION OF PEAK FLOOD TO SIZE OF DRAINAGE AREA.

San Joaquin River:

$$\text{Relative wetness} = \frac{43}{43} = 1.00$$

Kings River:

$$\text{Relative wetness} = \frac{46}{47.2} = 0.977$$

$$\text{Correction} = \frac{0.977}{1.00} = 97.7\%$$

From Fig. 22, Correction for "Drainage Area in Square Miles":

San Joaquin River... 1 169.4 sq. miles = 31.5 sec-ft. per sq. mile
Kings River..... 1 191 sq. miles = 31.4 sec-ft. per sq. mile
Correction..... = 99.7%

The maximum probable 24-hour flood at Sanger is,

$$33.16 \times \frac{253}{226} \times 93.3 \times 97.7 \times 99.7 = 33.74 \text{ sec-ft. per sq. mile}$$

or, 40 200 sec-ft. from the effective area.

From Fig. 10, a peak flood of 70 300 sec-ft., or 59.0 sec-ft. per sq. mile of contributing area, would be possible from a 24-hour flood of 40 200 sec-ft.

The other ten streams were studied in like manner and gave results as shown in Table 11.

The relation of the adjusted floods appears to be more reasonable than the values given in Table 3. The average value of the peak flood for Kings River, at Sanger, is only 2% greater than the peak flood of 1914. Peak flood intensity, as in 1914, is estimated from an extension of the rating curve and may be somewhat inaccurate.

Adjusted Probable Floods at Balch Camp, California.—The maximum peak flood on the North Fork at Balch Camp was determined by a similar method. The maximum 24-hour flood on the San Joaquin adjusted to suit Kings River conditions produced a peak flood of 59.0 sec-ft. per sq. mile of effective area at Sanger. The corresponding peak at Balch Camp was found to be:

$$59.0 \times 181.5 \times 100 = 107.1 \text{ sec-ft. per sq. mile of effective area}$$
$$= 17\,100 \text{ sec-ft.}$$

The results of the complete study are given in Table 12.

Effect of Storage Regulation.—Construction of a storage reservoir, Lake Wishon, is planned (1928) for a site near Cliff Camp, on the North Fork, at Elevation 6 550. When this dam is built, only that area between Lake Wishon and Balch Camp will contribute to a winter flood at Balch Camp, except in an extraordinary season. Usually, the storage reservoir would be drawn down by the beginning of winter and all of a winter flood could be stored. The drainage area between Lake Wishon and Balch Camp is 71.27 sq. miles and its average elevation is 6 450 ft. The peak flood at Balch Camp from this intermediate area, estimated by the method outlined for the total area, would be 7 990 sec-ft., or 112.2 sec-ft. per sq. mile of effective area.

However, in a very wet series of years, the reservoir might be practically full at the time of a late winter storm. Pondage above the spillway level

would reduce the flood peak, but the run-off from the drainage area above the storage dam would materially add to a flood at Balch Camp.

Flow for the Balch Tunnel is diverted from a small pond, which has a total capacity of 1 565 acre-ft. and a surface area of 37.75 acres at its maximum elevation. This pond will usually be kept full, and its effect on floods at Balch Camp will be negligible.

European Flood Experience.—Within the last few years great loss of life and property has been caused in various countries of Europe by storms of high intensity. In several cases the flood flow was greater than had been known possibly for centuries. In contrast to conditions in America where stream-flow records are limited to relatively short periods, most European countries have an unbroken record of river behavior for many centuries past. Recent experience there indicates that long-time contingencies must be reckoned with in providing protection against floods.

The following empirical data, Table 13, which are based on many years of past experience, are applicable to streams of Germany and Central Europe.*

TABLE 13.—PRECIPITATION AND RUN-OFF FOR GERMAN STREAMS.

Mountains	70.8 to 86.6	2.04 to 4.76	54.3 to 136.0

Discussions.—Mr. Follansbee gives some very interesting precipitation data for stations near the Continental Divide in Colorado. The writer thor-

* Hütte, Bd. III, 24th Edition, p. 634.

oughly agrees that the topography to the windward side of the region being studied is a controlling factor in determining variation in precipitation. General storms which produce heavy precipitation on the west slope of the Sierra Nevada Mountains travel in a southeasterly course from the Pacific Ocean. Before reaching the mountain slopes the storms pass over the Central Valley for a distance of 150 to 250 miles. The valley floor is relatively flat and ranges in elevation from sea level to about 400 ft. at Bakersfield, in the south end of the area.

As R. E. Horton, M. Am. Soc. C. E., has pointed out,* the winds approaching the Continental Divide from the west and southwest must blow for hundreds of miles over the Rocky Mountain plateau, for which the dominant elevation is about 7 000 ft. These winds lose nearly all the moisture derived from the ocean, which they originally contained, in ascending to this plateau, and the precipitation which they yield thereafter is apparently derived mainly from moisture picked up en route from evaporation. The general plateau extends at a more or less uniform elevation of about 7 000 ft., nearly to the Continental Divide, where a rise of 4 000 to 6 000 ft. occurs within a distance of a comparatively few miles.

The temperature and relative humidity of these winds govern the amount of precipitation. The records indicate a moderate increase of precipitation with elevation up to a certain height, after which the increase is more rapid to a maximum close to Elevation 11 000. The rate of increase at Corona on the Divide is less than at lower elevations. Pike's Peak is situated to the east of the Continental Divide and receives less precipitation than the corresponding elevation on the west slope. After the winds pass over the Continental Divide they are relatively dry, and precipitation at Pike's Peak is slight. If the distance between mountain chains is sufficient, the relative humidity of the winds will be increased, due to moisture derived from evaporation, as stated, and the second range of mountains will give rise to a second belt of high precipitation. This is illustrated by the heavy precipitation on the slopes of the Wasatch and Uinta Mountains in Utah. A case similar to that at Pike's Peak is shown by Fig. 21. The secondary ridge near Crane Valley receives high precipitation and robs the remainder of the San Joaquin drainage area of a considerable portion of its normal precipitation.

Many engineers have questioned the theory that precipitation decreases above a certain elevation. The contention is made that the records of precipitation for high elevations are insufficient in number and accuracy to warrant the general conclusion. It is true that the stations are few in number and that the accuracy of some of the records could be greatly improved. However, each case studied showed the same characteristics. Some of the stations, especially on the American River Section, have been established for many years and are well maintained.

The percentage of precipitation appearing as run-off increases up to an elevation of approximately 10 000 ft. in the Sierra Nevada Mountains (see Fig. 23). This is due primarily to a decrease in water losses (evaporation,

* *Engineering News-Record*, February 28, 1924, p. 355.

transpiration, etc.) above the timber belt, which thins out above 7 000 ft. The relation of run-off to precipitation for German rivers is given in Table 14.* A similar relation, no doubt, holds for the area studied and a relatively high run-off per square mile would be expected from the higher drainage areas.

TABLE 14.—PERCENTAGE OF PRECIPITATION APPEARING AS RUN-OFF FOR GERMAN RIVERS.

Location.	Ratio of run-off to precipitation, in percentage.
Plains	25 to 30
Foot-hills	50 to 70
Mountains	85

The points covered by Mr. Fox in his discussion have been previously enlarged upon by the writer. One fact might be further emphasized; that is, until many more records of precipitation and run-off are obtained, reliable estimates of probable future floods on any particular stream are difficult to make unless all the comparable data are used.

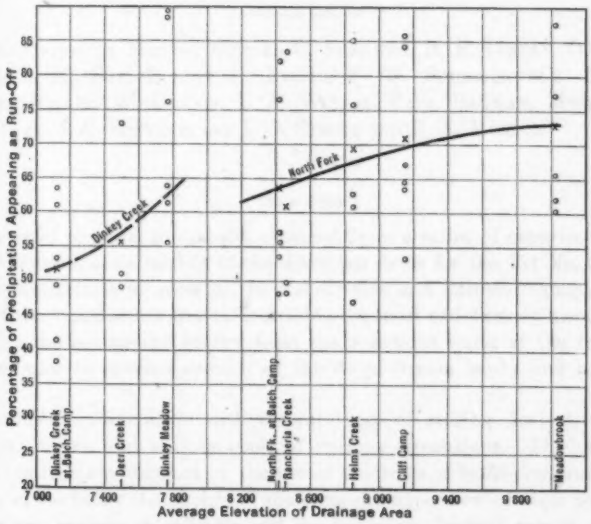

FIG. 23.—PERCENTAGE OF PRECIPITATION APPEARING AS RUN-OFF AT DIFFERENT ELEVATIONS, DINKEY CREEK AND NORTH FORK OF KINGS RIVER.

Mr. Lee's discussion is a valuable contribution to a study of flood discharge. When sufficient data are available, the rational method is the most reliable for studying flood behavior of a stream. Accurate records of precipitation intensity and amount must be collected for a considerable period for

* Hütte, Bd. III, 24th Edition, p. 634.

the area under consideration. The flood run-off factor can only be established by many observations. These data are largely lacking for drainage areas in the Sierra Nevada Mountains, and many years will be required to perfect the application of the rational method.

In the stream-group method, as used by the writer, the combination of intensity of rainfall and the percentage of resulting run-off make up the basic data. The record of maximum, 24-hour flood run-off for each primary stream, as determined by actual observation, was used in determining the equivalent record for the Kings River at Sanger.

BAFFLE-PIER EXPERIMENTS ON MODELS OF PIT RIVER DAMS*

By I. C. Steele† and R. A. Monroe,‡ Members, Am. Soc. C. E.

With Discussion by Messrs. Edward C. Sherman, B. E. Torpen, Oren Reed, Harold K. Fox, Robert F. Ewald, F. W. Scheidenhelm, Ralph L. Parshall, H. W. Dennis, I. A. Winter, Paul Bauman, Morrough P. O'Brien, J. C. Stevens, and I. C. Steele and R. A. Monroe.

Synopsis

This paper presents the results obtained from a series of experiments made on one-twentieth scale models of the diversion dams for the Pit No. 3 and Pit No. 4 hydro-electric projects of the Pacific Gas and Electric Company. The object of the experiments was to determine the most satisfactory means of controlling or destroying the energy from the over-pour water at the foot of the dams in order to prevent erosion of the down-stream banks and bed of the stream.

Experiments were made with several types of stilling devices, including baffle-piers, weirs, and stilling pools of various dimensions. The most satisfactory results were obtained by the use of two rows of baffle-piers resting on a concrete apron below the bucket of the dam, the upper row of piers being truncated prisms serving as splitters and the lower row having curved up-stream faces to act as deflectors and baffles.

Note.—The Special Committee on Irrigation Hydraulics selected the subject of "Scouring Below Dams" as one of ten for study and research. This paper was submitted to the Committee by its authors and the Committee has recommended its publication. (See Progress Report of the Committee, *Proceedings*, Am. Soc. C. E., March, 1927, Society Affairs, p. 124).

Pit No. 3 Dam

General Description.—Pit No. 3 diversion dam is a concrete structure of the ogee spillway type, 112 ft. high from foundation level to spill crest, with a spillway section, 18 ft. deep and 267 ft. long, designed to pass a flood of 70 000 sec-ft. The dam is arched in plan to a radius of 500 ft. Below the dam a concrete apron, with minimum thickness of 4 ft., supporting two lines of baffle-piers, extends a maximum distance of 160 ft. down stream from the toe of the dam. This apron is constructed at approximately river-bed level. (See Fig. 1.)

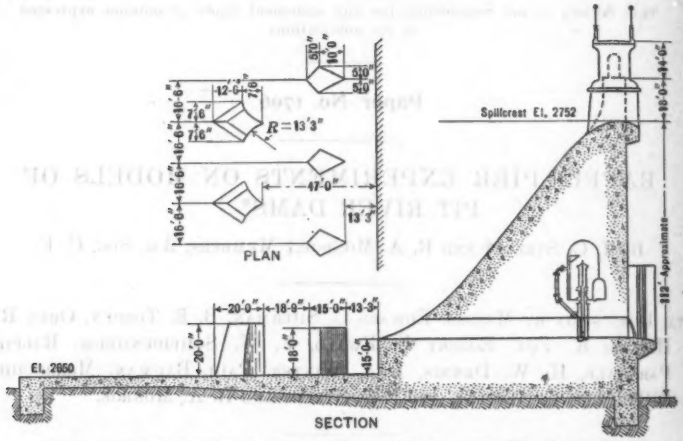

Fig. 1.—Arrangement of Baffle-Piers Adopted for Pit No. 3 Dam.

Unusual foundation conditions at the site of the dam influenced the adoption of concrete baffle-piers in conjunction with the lining of the river channel to guard against possible scouring and erosion at the toe of the dam. The prevailing rock formations in the Pit River Basin are either basaltic or andesitic lavas, lava agglomerate, or tuff, which vary from solid rocks capable of withstanding almost any load to soft friable masses. A thorough investigation of three miles of river channel by means of diamond-drill and drift work was made in order to determine the best possible site for the dam. Explorations at the site disclosed four alternating strata of basaltic lava rock and volcanic tuff lying in nearly horizontal position, but having a slight dip down stream. It was evident that the dam would be founded for the major part on the tuff with rock abutments. Tests of small laterally unsupported cubes of the tuff showed it to have an ultimate strength equivalent to from 50 to 75 tons per sq. ft. which was considered entirely safe as the foundation pressures under the dam are only about 8 tons per sq. ft. This material is firm, dense, and impervious, and very resistant to erosion, as was evidenced by the fact that although the river had cut through the upper rock formation, it had cut into the tuff only to a small extent.

It was felt, however, that during the alternate periods of wetness and dryness some weathering would take place and also that the tremendous

energy from the over-pour in times of flood might erode the tuff if left unprotected. It was not deemed advisable to attempt construction of any form of stilling pool because of the limited thickness of the tuff strata and because it was desired to leave intact as much of this impervious material as possible. Further, the banks immediately below the dam required protection, consequently it was decided to line the river channel with concrete for approximately 150 ft. down stream from the dam and to construct two rows of baffle-piers placed on, and incorporated with, the apron. The toe of the dam is designed with a 15-ft. vertical face, or jump-off, which extends the full width between the concrete wing-walls. As will be noted in Fig. 1, the tangent to the curve of the down-stream face of the dam at this jump-off is downward rather than horizontal. This was so designed to reduce the base width of the dam and to direct the spill water at this point so that the stream would strike well down on the up-stream or splitter piers and downward into any high back-water. If the tangent to the curve were horizontal at this point there would be a greater tendency for the water to jump over the piers, thus making them more or less ineffective at the very time they were most needed.

Tests on Model of Pit No. 3 Dam.—As there was little precedent for the use of baffle-piers, it was decided to construct a model of the dam and conduct a series of experiments to determine the proper shapes, sizes, and location of the piers. These experiments proved to be exceedingly interesting and enlightening and led to the selection of piers and layout considerably at variance with those first proposed.

Advantage was taken, in the design and construction of a small concrete diversion dam in Rock Creek, the waters of which are diverted into Pit No. 3 Tunnel, to carry out a series of experiments to determine a suitable system of baffles. This dam was designed and built as a one-twentieth scale model of the main structure in so far as features were concerned, which related to the problem at hand. A simple removable flash-board arrangement was installed to store water behind the dam in order to secure a maximum head equivalent to one-twentieth of that for which the main dam was designed.

While there is some question as to the action with any given depth of flow over such a model, as compared with that for the full-scale structure and its corresponding overflow, it is believed that the results obtained clearly indicated the relative efficiency of the several layouts and that the baffle arrangement as actually constructed will give excellent results.

During the early experiments an attempt was made to measure with a Pitot tube the velocity of the water flowing over the apron. No reliable information, however, was obtained owing principally to the strong eddy currents and the foamy condition of the water. An attempt also was made to take measurements of the trajectory of the stream below the apron in order to determine by calculation the velocity of the water as it left the apron. An inclined gauge was set up for this purpose, but it was found that, due to the commotion of the water, readings could not be taken with any degree of accuracy.

It was finally decided that close observation and notation of the action of the water during the various experiments and photographic study were the

best means of obtaining results. The experiments, therefore, were carried on in this manner and the notes and photographs carefully compared. Additional check experiments were then made to determine the plan that appeared to give the best results.

The experiments were made with various arrangements using three main groups of piers, as follows:

(1) Truncated pyramid-shaped piers.
(2) Prisms, or diamond-shaped piers.
(3) Combination of triangular prism piers and piers with curved up-stream faces approximating an impulse-wheel bucket in horizontal cross-section.

The spacing and types of piers, the gauge height or depth of overflow, the control height, and remarks relating to the observed results are given in Figs. 2, 3, and 4, and Tables 1, 2, and 3, for each of the eighteen experiments. Views of the action of the various piers are shown in Figs. 5 to 10, inclusive.

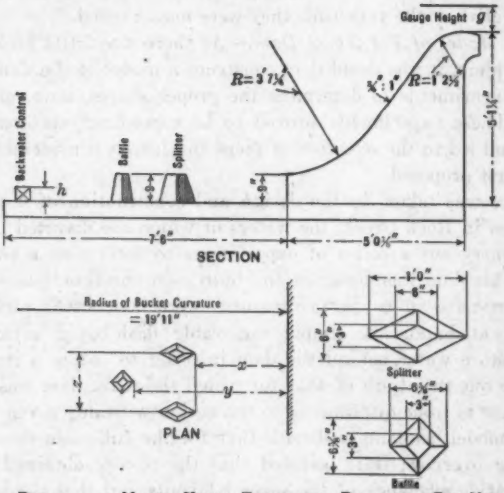

FIG. 2.—DETAILS OF MODEL USING TRUNCATED PYRAMIDS, PIT NO. 3 DAM.

All experiments, with the exception of Experiment No. 17, were made with two rows of piers set on arcs parallel to the curve of the front face of the dam and the bucket jump-off, the piers in the two rows being staggered. The up-stream piers were termed splitter-piers and those in the down-stream row, baffle-piers. Experiment No. 17 was made with only one row of curved baffle-piers.

The results may be summarized as follows:

1.—The first group of experiments using truncated pyramids gave very unsatisfactory results, the water leaping very high into the air as it left the splitter-piers.

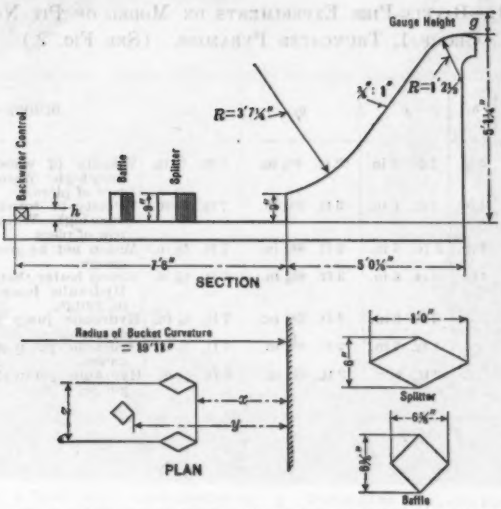

FIG. 3.—DETAILS OF MODEL USING PRISMS, PIT NO. 3 DAM.

7	3 ft. ¾ in.	0	2 ft. 6 in.	3 ft. 8¾ in.	7 ft. ½ in.	Action very satisfactory at this gauge and below.
8	.....	....	2 ft. 6 in.	3 ft. 8¾ in.	9 ft. ⅝ in.	Water jumped vertically at up-stream piers. Hydraulic jump started at 3¼-in. gauge.
9	4 ft. ½ in.	....	2 ft. 6 in.	3 ft. 8¾ in.	1 ft. 4¾ in.	Height to which water jumped less than in Experiment No. 8, but velocity below piers was greater. Hydraulic jump started at 3-in. gauge.
10	.....	....	1 ft. 0 in.	3 ft. 8¾ in.	9 ft. ⅝ in.	Water hurdled from up-stream piers over down-stream piers at high gauges, but did not rise higher than in Experiment No. 8. Action unsatisfactory.

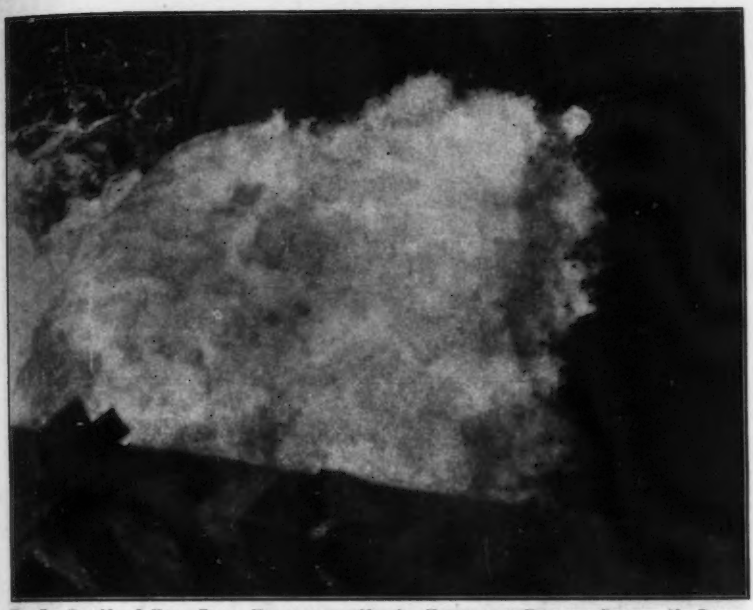

FIG. 5.—PIT NO. 3 TEST DAM: EXPERIMENT NO. 1. TRUNCATED PYRAMID PIERS. NO BACK-WATER CONTROL. GAUGE HEIGHT PROPORTIONAL TO 15 FEET ON ACTUAL DAM.

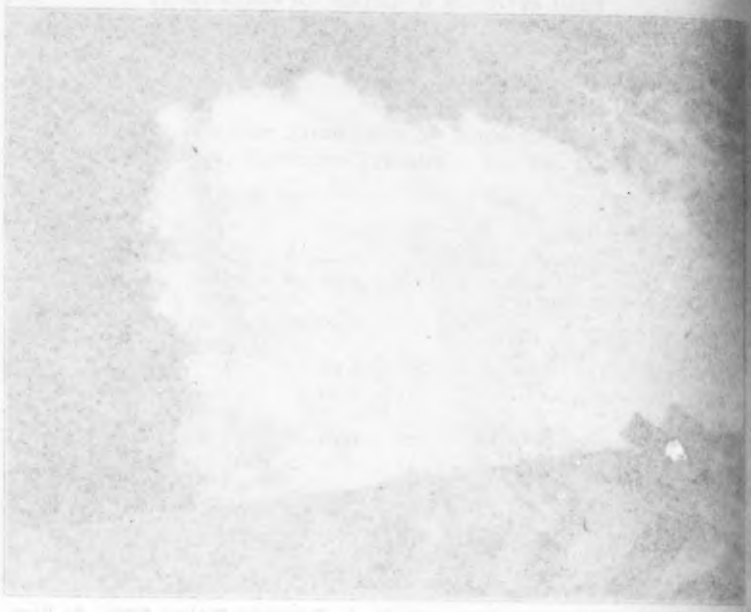
FIG. 6.—PIT NO. 3 TEST DAM: EXPERIMENT NO. 2. SAME AS FIG. 5, WITH BACK-WATER CONTROL PROPORTIONAL TO 6 FEET 8 INCHES ON ACTUAL DAM.



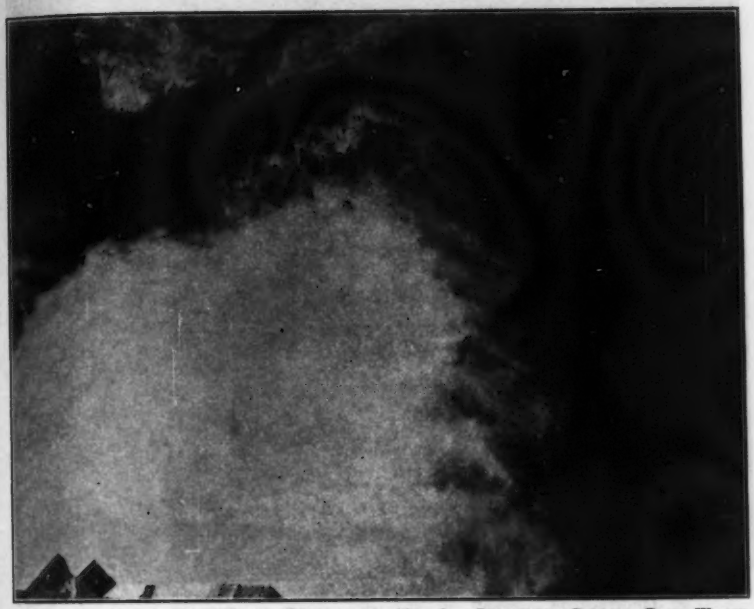


FIG. 7.—PIT NO. 3 TEST DAM: EXPERIMENT NO. 6. PRISMATIC PIERS. BACK-WATER CONTROL PROPORTIONAL TO 6 FEET 8 INCHES AND GAUGE HEIGHT TO 15 FEET ON ACTUAL DAM.

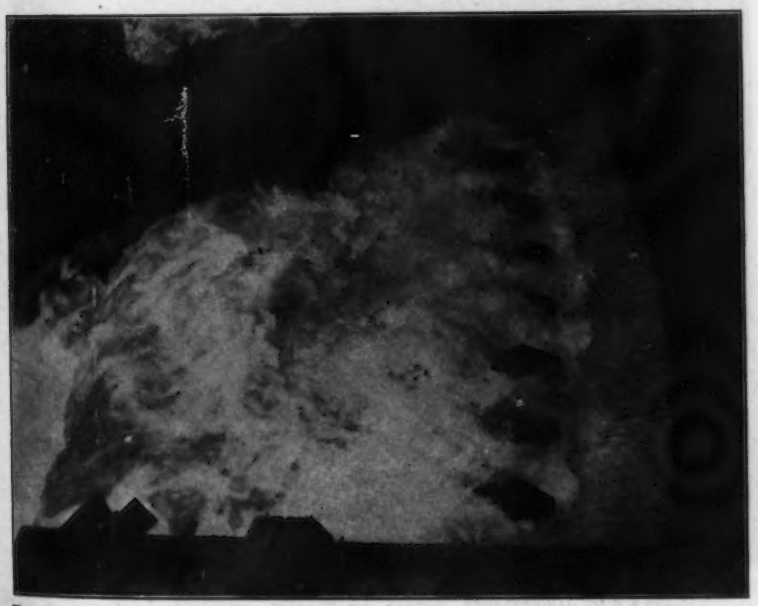

FIG. 8.—PIT NO. 3 TEST DAM: EXPERIMENT NO. 6. SAME AS FIG. 7, BUT WITH GAUGE HEIGHT PROPORTIONAL TO 10 FEET ON ACTUAL DAM.

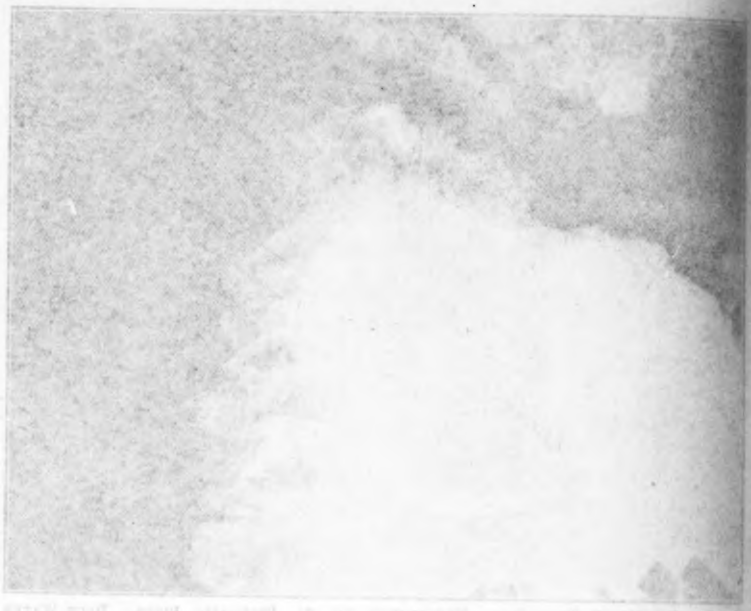

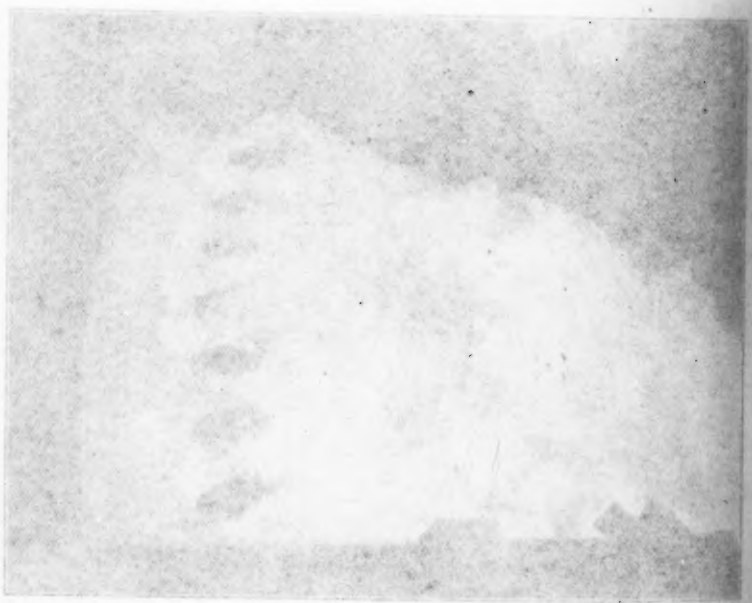

FIG. 9.—PIT NO. 3 TEST DAM: EXPERIMENT NO. 11. SPLITTER-PIERS ON TOE OF DAM. CURVED BAFFLE-PIERS ON APRON. BACK-WATER CONTROL PROPORTIONAL TO 6 FEET 8 INCHES AND GAUGE HEIGHT TO 15 FEET ON ACTUAL DAM.

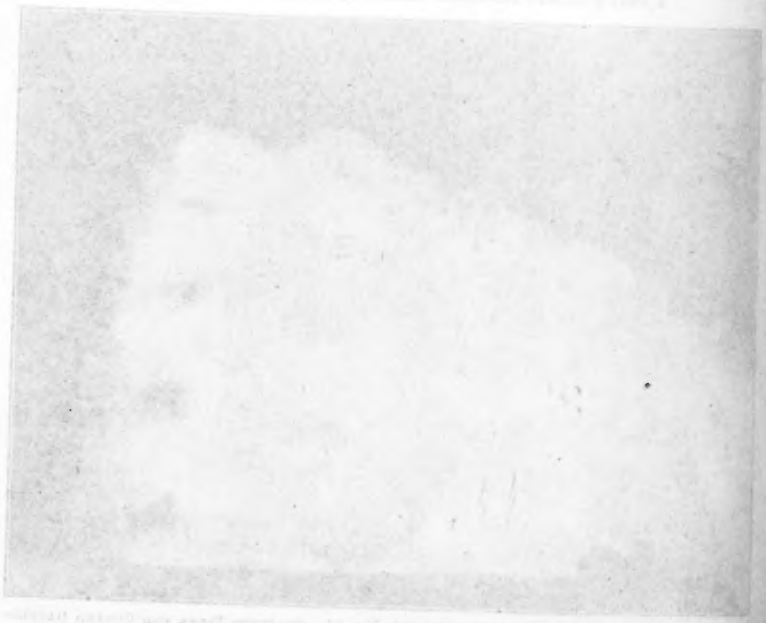
FIG. 10.—PIT NO. 3 TEST DAM: EXPERIMENT NO. 13. SPLITTER-PIERS AND CURVED BAFFLE-PIERS ON APRON. BACK-WATER CONTROL PROPORTIONAL TO 6 FEET 8 INCHES AND GAUGE HEIGHT TO 10 FEET ON ACTUAL DAM.



2.—The second group of experiments using prism piers gave better results, but were still unsatisfactory.

3.—The third group of experiments using curved baffle-piers showed a marked improvement in stilling action. The best results were obtained by locating the splitter-piers close to the jump-off. Experiment No. 11, made to determine the effect of placing the splitter-piers on top of the jump-off, gave poor results. The water striking against these piers splashed very high on either side and in a manner very similar to the sidewash at the bow of a fast moving boat.

TABLE 3.—BAFFLE-PIER EXPERIMENTS ON MODEL OF PIT NO. 3 DAM. GROUP 3, CURVED BAFFLE-PIERS. (SEE FIG. 4.)

14	.....	....	1 ft. 6 in.	2 ft. 6 in.	1 ft. 0½ in.	C	9 in.	At high gauges, water washed over tops of front piers and hurdled curved piers. Action good at lower stages.
15	.....	....	1 ft. 6 in.	2 ft. 6 in.	1 ft. 0½ in.	C	1 ft. 0 in.	Did not wash over piers, but jumped 3 ft. 9 in. vertically from them at gauge heights of 13 ft. 0 in., or more. Very good hydraulic jump occurred up stream from piers and between rows below 5½-in. gauges.
16	.....	....	1 ft. 6 in.	4 ft. 6 in.	1 ft. 1 in.	C	1 ft. 0 in.	Good. Curved piers caused good stilling action.
17	9 in.	4 in.	2 ft. 4 in.	.....	1 ft. 9 in.	....	.....	Action good. Did not compare with Experiment No. 13.
18	.....	....	1 ft. 0 in.	2 ft. 0 in.	1 ft. 9 in.	C and E	1 ft. 0 in.	Additional piers 3 in. from jump-off. Action good. Splashed to 2 ft. 3-in. height.

The layout finally adopted in the design and construction of the Pit No. 3 diversion dam gave excellent results. This was approximately that used in Experiment No. 13. The water flowing over the lower edge of the apron was comparatively quiet for all gauge heights and from all appearances no more harmful than the natural stream would be in time of high water.

Behavior of Completed Structure.—The Pit No. 3 Dam was completed in the summer of 1925 and, consequently, has passed through only two seasons of high flow. No floods were experienced in the spring of 1926 or 1927, the maximum flow of the river amounting to less than 8 000 sec-ft. The stilling action of the piers proved to be excellent. Continued observation during periods of high water will be maintained and eventually this structure will

afford valuable evidence of the success or failure of this method of preventing scour below dams.

Pit No. 4 Diversion Dam

General Description.—Pit No. 4 diversion dam is situated on Pit River approximately 9 miles down stream from Pit No. 3 diversion dam. On account of the peculiar foundation conditions at the site, the dam is designed as a composite structure. The foundation on the right bank and under the main channel of the stream is solid rock, whereas the left bank consists of a compact soil, gravel, and boulder formation. The design adopted for this site comprised a concrete ogee overflow spillway section from the right bank across the main stream channel, flanked by a flat-slab and buttress non-overflow structure on the left bank.

This dam is a relatively low structure, its function being to raise the water surface of the stream about 40 ft. The spill section of the dam is 136 ft. long, controlled by two drum-gates, each 68 ft. long by 14½ ft. high. Provision is made in the design for a maximum overflow depth of 27½ ft., which it is estimated will discharge a flood of 70 000 sec-ft.

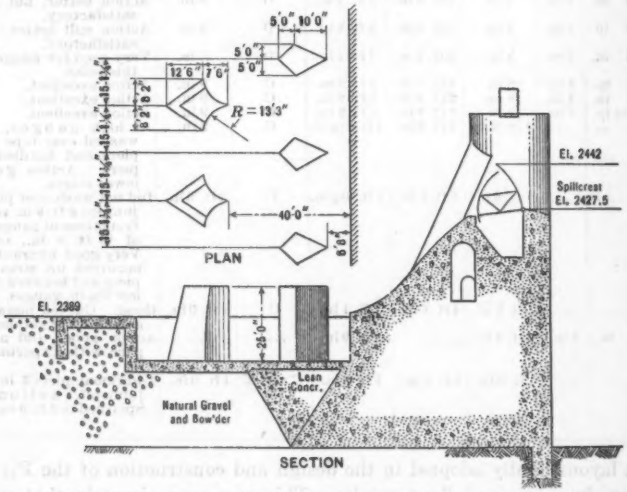

Fig. 11.—Arrangement of Baffle-Piers Adopted for Pit No. 4 Dam.

Below the dam a two-level concrete apron supporting two lines of baffle-piers extends a distance of 100 ft. down stream. The apron at the lower level has incorporated in its design a stilling pool, but this was incidental and was adopted as a measure of economy on account of the slope of the rock foundation and also to accommodate more conveniently the discharge openings through the dam. Fig. 11 shows a cross-section of the dam through the maximum or stilling-pool section and also indicates in plan the arrangement adopted for the baffle-piers.

Tests on Model of Pit No. 4 Dam.—The Rock Creek diversion dam which was constructed as a one-twentieth scale model of Pit No. 3 Dam, was reshaped with a wooden overflow and apron section to correspond to a one-twentieth scale model of the proposed Pit No. 4 Dam. A length of channel representing 100 ft. of river channel down stream from Pit No. 4 was also constructed to the shape of the actual river with loose rocks on a false wooden bottom. The general arrangement of the test model is shown by Fig. 19.

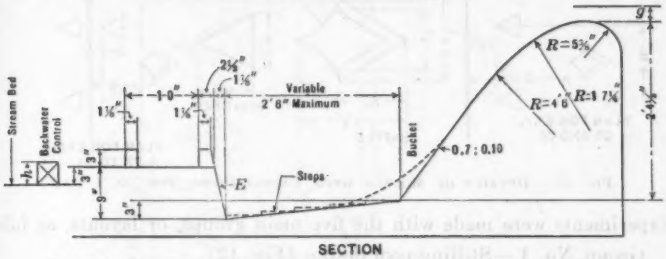

FIG. 12.—DETAILS OF MODELS WITH STILLING POOL, PIT NO. 4 DAM.

Various test runs were made by placing flash-boards across the overflow section of the dam and allowing the water in the reservoir above to rise to a gauge height corresponding to 28 ft. on the proposed Pit No. 4 Dam. This

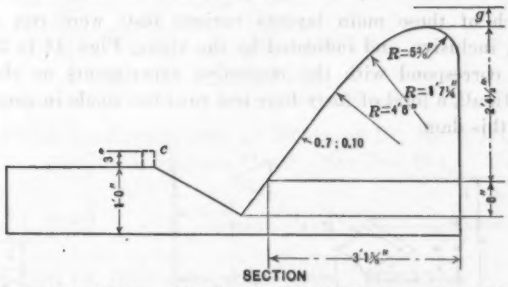

FIG. 13.—DETAILS OF MODEL WITH FRENCH DESIGN SETTLING POOL, PIT NO. 4 DAM.

allowed the overflow water, when the flash-boards were lifted, to come to a steady condition of flow at 27½ ft. representing the maximum expected flood.

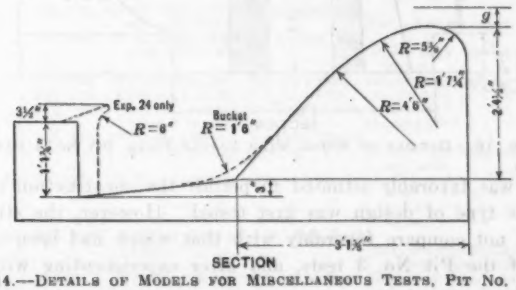

FIG. 14.—DETAILS OF MODELS FOR MISCELLANEOUS TESTS, PIT NO. 4 DAM.

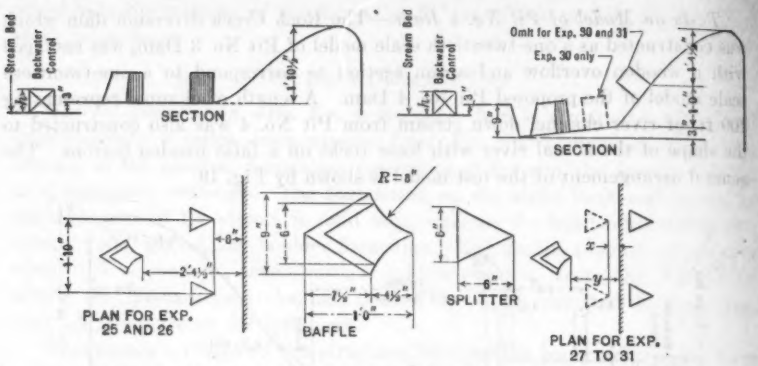

FIG. 15.—DETAILS OF MODELS WITH BAFFLE-PIERS, PIT NO. 4 DAM.

Experiments were made with the five main groups, or layouts, as follows:

Group No. 1.—Stilling-pool design (Fig. 12).
Group No. 2.—The French stilling pool with upward sloping bottom (Fig. 13).
Group No. 3.—Miscellaneous layouts (Fig. 14).
Group No. 4.—Baffle-pier designs (Figs. 15 and 16).
Group No. 5.—Baffle-pier designs, with two-level apron (Fig. 17).

Under each of these main layouts various tests were run as given in Tables 4 to 9, inclusive, and indicated by the views, Figs. 18 to 27, inclusive, numbered to correspond with the respective experiments as shown on the photographs. In all, a total of forty-four test runs was made in connection with the design of this dam.

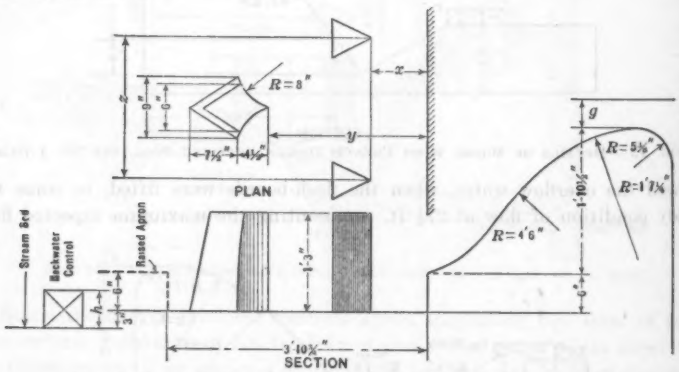

FIG. 16.—DETAILS OF MODEL WITH BAFFLE-PIERS, PIT NO. 4 DAM.

The site was favorably situated to permit the construction of a stilling pool and this type of design was first tested. However, the stilling action observed did not compare favorably with that which had been observed for baffle-piers of the Pit No. 3 tests, and after experimenting with the plain

stilling pool, the French stilling pool, and some miscellaneous layouts, it was decided to experiment with baffle-piers. The piers were duplicates of those at Pit No. 3 and spaced similarly. Splitter-piers, that is, the up-stream piers, were half spaced from the wing-walls, and the end pier in the line of curved piers was one-half the regular pier fastened against the wing-wall on one side.

35	9 in.	4 in.	2 ft. 0¼ in.	River channel extended up stream to within 2 in. of baffle-piers.	Action very good. Water below apron quiet.
36	5¼ in.	4 in.	2 ft. 0¼ in.	Raised apron.	Action very good. Water rose from 1 ft. 3 in. to 1 ft. 6 in.
37	11⅜ in.	4 in.	2 ft. 0¼ in.	Raised apron.	Action very good.

TABLE 9.—EXPERIMENTS ON MODEL OF PIT NO. 4 DAM.
GROUP 5, TWO-LEVEL APRONS. (SEE FIG. 17.)

Experiment No.	*h*.	Remarks.	Stilling action.
38	11⅜ in.	.....	Action good. Water thrown up by flat face of right splitter.
39	11⅜ in.	Right splitter reduced to half width.	Same as Experiment No. 38, except right splitter only threw thin sheet of water.
40	11⅜ in.	Right splitter removed.	Action very good except for water which washes up right wing-wall at bucket, as in all tests of this group.
41	11⅜ in.	Right splitter cut to fit against wing-wall.	Action same, except slightly more splash on right side.
42	5 in.	Right splitter as in Experiment No. 41. Splitter at step between apron levels increased to height of piers on high portions.	Reduced control did not effect action. Raising center pier caused better action.
43	5 in.	Same as Experiment No. 42, except piers spaced at 2 ft. 1¾ in.	Action not as good as previous experiments.
44	11⅜ in.	Same as Experiment No. 42.	Action better. Not as good as with closer pier spacing.

The experiments showed that the baffle-piers were by far the most effective destroyers of energy for such a deep over-pour as that proposed for Pit No. 4 Dam. In fact, none of the other layouts was satisfactory.

Of the arrangements of piers, the best was with a jump-off from the bucket of the dam, thus making the jet of water strike the piers at about mid-height With no jump-off, that is, with the overflow jet striking at the base of the piers, the water passes into the air in vertical sheets, unless there is considerable back-water from the channel below. With the jump-off the back-water, or lack of back-water, has little affect on the baffle-piers.

After a series of tests on a one-level apron a second series was undertaken with a two-level apron similar to that actually used in the design of the Pit No. 4 Dam. The model was accordingly altered to represent the two-level apron type. Results of tests of this layout and with slight modifications are shown in Fig. 11. The stilling action was not affected by the two-level feature. The action was just as satisfactory on the high apron side as if the whole apron was at that elevation. The "killing" of velocity was accomplished with less commotion on the deep side than on the shallow, but the difference in the final result, as indicated by the velocity in the river channel below, was, as nearly as could be judged, uniform across the width.

The flat up-stream face of the splitter-pier near the right wing-wall seemed to throw considerable water into the air. Even with a sharp cutting-edge, this pier seemed to do more harm than good.

Incidentally, it was noted that the edge of the over-pour water at the right end of the dam maintained a vertical face until reaching the bucket curve where it flattened out with a resulting component of velocity along the length of the dam. This water impinged against the sloping right-bank wing-wall and washed up this wall to a height corresponding to 40 ft. on the actual structure. It is thought that this action could be eliminated either by a training wall on the down-stream face of the dam, or by moving the wing-wall out so as to be in line with the end of the spill section of the dam.

Observations on Completed Structure—Pit No. 4 Dam was completed after the high-water season of 1927. It will not be possible to observe the action of the piers in destroying the energy of the over-pour water under actual flood conditions until the spring of 1928.

DISCUSSION

EDWARD C. SHERMAN,* M. AM. SOC. C. E. (by letter).—It is fortunate that such a complete series of experiments was possible on the models of Pit River dams. The writer concurs in the opinion that there is a question as to the flow over a model being entirely comparable with the corresponding flow over the full-sized structure. However, there can be no doubt that useful information may be obtained from such investigations.

From 1909 to 1911, the writer was Designing Engineer on the Panama Canal, and had charge of the preparation of plans for the spillway dams at Gatun and Miraflores. The larger is at Gatun, and for that location, consideration was given to two types: One with a straight crest and stepped section; the other curved in plan and of ogee section. Models of both were made, primarily to aid in determining the better type to use, but incidentally the opportunity afforded was utilized to test the action of baffle-piers in checking the velocity at the toe of the dam.

The lake formed by the great earth dam at Gatun, with its surface 87 ft. above sea level, has an area of 168 sq. miles, and receives the drainage from a water-shed of 1 320 sq. miles. The heavy precipitation of the rainy season frequently causes a high rate of run-off, and as records had been kept for many years, it was possible to determine that the probable maximum momentary rate of discharge at Gatun would be 183 000 sec-ft. The area of the lake is so great, however, that spillway capacity of this amount is not necessary, and the design was made to provide a discharge of 140 000 sec-ft. with the lake at its normal level of 85 ft. About midway in the length of Gatun Dam, there was a rock outcrop which afforded a suitable foundation for the spillway. The extent of this foundation determined the possible length of the crest and, consequently, its elevation. The total distance between abutments is 760 ft., giving a clear crest length of 630 ft., which is divided into fourteen 45-ft. openings. The canal locks were designed on the assumption that the summit level in Gatun Lake would not rise above Elevation 87, and to secure the required capacity without allowing the lake to rise higher, the spillway crest was placed at Elevation 69, with gates of the Stoney type for control.

Tests made with the model of the straight crest dam (Fig. 29) indicated that, with all gates open, the stepped section was effective in destroying the energy of the fall and that uniform flow could be expected below the standing wave at the toe of the dam if the down-stream edge of each step were provided with a strip which would form a pocket or pool. Gatun Lake is frequently regulated by opening a few gates, or only one. It rarely requires full spillway capacity. A test of the model, with only one gate open, gave unexpected results. It was noted that the stream, after striking the first step, turned upward to approximately lake level, without apparent loss of head, and shot forward with sufficient velocity to miss the other steps; so that most of the water fell directly on the floor at the toe of the dam without any check to its force. Similar action on a dam of full size would quickly

* Project Mgr., Bureau of Yards and Docks, U. S. Navy Dept., Washington, D. C.

destroy it; therefore, the results of the test influenced the decision to adopt a dam of ogee section, the model of which is shown in Fig. 30.

The crest of the dam is of a form which facilitates the flow while providing seats for the Stoney gates and the caisson required to permit repairs. The upper part of the down-stream face is parabolic, and shaped so that the nappe adheres to the masonry, and the lower part of the face is a circular curve of long radius. The general plan and sections of the spillway dam are shown in Fig. 28.

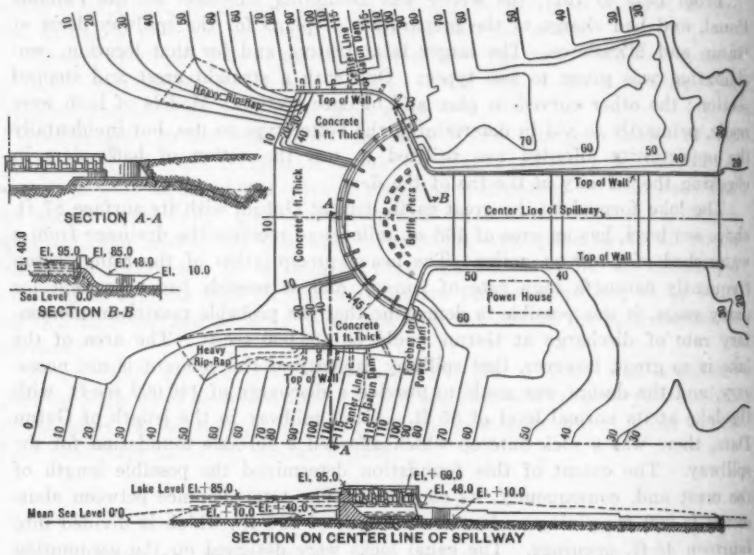

FIG. 28.—GENERAL PLAN OF GATUN SPILLWAY ON PANAMA CANAL.

The floor of the spillway channel below the dam is 10 ft. above sea level, and the overflowing water, having fallen 75 ft., reaches it with a velocity of about 60 ft. per sec. Some stilling devices other than the effect of the convergence due to the curved crest appeared to be necessary to destroy the energy created by the fall, and a system of baffles was laid out in the floor immediately below the toe of the ogee.

While the model was available, it was possible to make tests to determine whether the proposed arrangement of baffles might be expected to accomplish the desired result. The model was on a scale of $\frac{3}{8}$ in. to 1 ft., the dam being made of concrete placed between wooden baffles cut to the proper section. The crest piers were of wood, grooved for wooden gates, so that the discharge could be regulated. The baffles were made of wood and fastened to the floor with screws to permit trials in different positions. A water supply was temporarily available from the drainage of the hydraulic fill then being placed in Gatun Dam, and a by-pass permitted the regulation of the flow so as to obtain any desired depth on the crest of the model dam.

FIG. 30.—MODEL DAM WITH OGEE SECTION.

FIG. 29.—MODEL OF STRAIGHT CREST DAM.

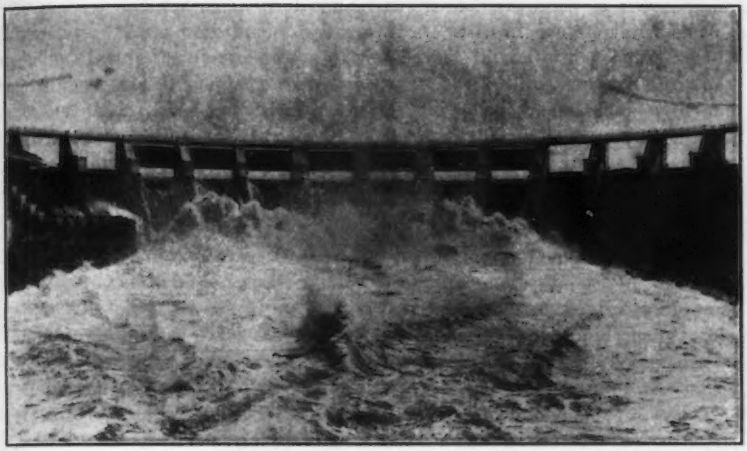

FIG. 31.—VIEW OF COMPLETED DAM.

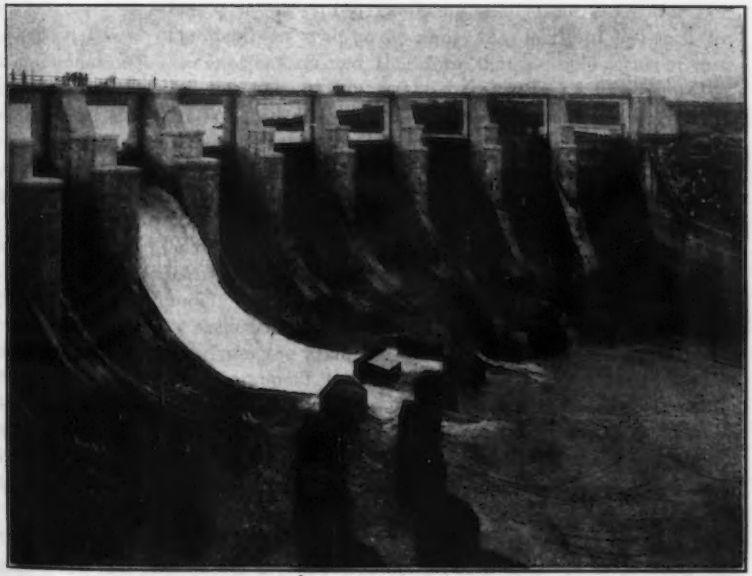

FIG. 32.—ARRANGEMENT OF BAFFLES, GATUN SPILLWAY DAM.

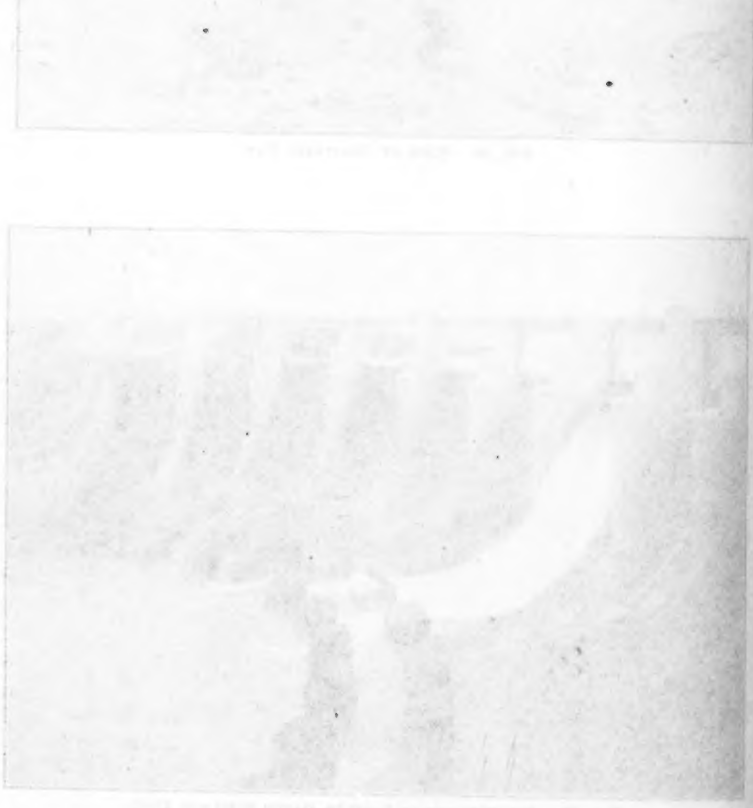

The time allowed for experiments was limited, because the water was very muddy, and the small pool behind the model was entirely silted up in a few days. Tests were made, however, first, with all contemplated baffles; second, with only the up-stream row of baffles; and, third, without baffles. Only approximate measurements were recorded, but the stilling effect of two rows of baffles, placed as shown in Fig. 28, was obviously greater than with any other arrangement that was tried. The effect of the baffles in establishing a standing wave and uniform flow in the channel is shown in Fig. 30, and a view of the completed dam in Fig. 31. The arrangement of the baffles in the actual structure is shown in Fig. 32.

B. E. TORPEN,* M. AM. SOC. C. E. (by letter).—The subject of scour below overflow dams or spillways is becoming more important as more and higher dams are built, and is of especial interest to hydraulic and designing engineers. The scour below the Wilson Dam,† and many other similar experiences with service dams, show the necessity of better design of spillway aprons. The type of spillway, and the treatment of the apron best suited to any special site are dependent on many factors, such as (1) safety, the factor of prime importance in all structures; (2) economy, a factor second only to safety in many cases; (3) type of dam, whether gravity, arch, earth, etc.; (4) architectural treatment; (5) hydraulic gradient of the stream; (6) geology; (7) topography; (8) climate; (9) proximity of power house or other structures; (10) percentage of time curve for certain flood flows; (11) depth of over-pour; and (12) depth to bed-rock for dam foundation. It cannot be expected, therefore, that a single series of tests on a special phase of this subject can establish the type of treatment best suited to all sites. It is hoped, however, that observed discharges during the next few years will demonstrate the similarity of actual conditions to the results of the tests, and prove beyond doubt the utility of models in illustrating new features for design.

In the Pit River tests the feature of causing the falling sheet of water to strike the mid-height of the splitter-piers and in a downward direction, seems especially effective. This was secured by placing a 15-ft. jump-off at the bucket of the dam.

The Pit dams are arched in plan, but of such long radius that no stability can be depended upon from the arch, the dam being of the full gravity section. The bottom of the jump-off, therefore, must be outside the full gravity section and all concrete in the bucket and jump-off is chargeable to the spillway, in addition to the massive piers. The total of this concrete is no small item and can not be overlooked when comparing types from the standpoint of economy.

In selecting the type of spillway for the Pit dams the authors have stated their reasons clearly. Their tests indicated the type best suited to meet those conditions, and now actual overflow will be the final test. It is believed that other unpublished data on tests of spillway models may add to the value of

* Hydr. Dept., Elec. Bond & Share Co., New York, N. Y.
† *Engineering News-Record*, February 3, 1927.

these discussions and with this in mind the writer presents, as briefly as possible, the results of a series of such tests for the Bull Run Dam constructed for the water supply of Portland, Ore.

The dam is 200 ft. high, of the concrete gravity type, and curved in plan as is common practice at sites slightly too wide for pure arches. The maximum flood may be 21 000 sec-ft., the free over-fall is 176 ft., and the minimum flow of the stream is about 160 sec-ft. The water-shed is only 75 sq. miles, but due to winter rains from 500 to 5 000 sec-ft. will spill over the dam half the time.

The topography is favorable for a spillway around the left end of the dam with a concrete apron to the edge of the bluff, 150 ft. above the river. The country rock is basaltic, in horizontal layers varying from 5 to 50 ft., and some flows are considerably altered. Some fear was entertained that the constant over-pour would erode this basalt and eventually require the spillway channel to be concreted to the water's edge, which made this location of the spillway rather costly. The alternate plan chosen was to carry the spillway over the central part of the dam to an apron, which extends down stream 150 ft. to protect the toe.

Toe Protection.—The question of further protecting the toe was next considered. Special treatment must be given the down-stream end of the apron also unless the velocity is reduced at this point. This has recently been illustrated at the Wilson Dam. To build heavy baffle-piers at the toe of the dam and concentrate the destruction of energy up to 350 000 h. p. directly over the toe (the most dangerous part of the dam foundation) seemed undesirable. This type of treatment also requires a "bucket" 15 ft. deep, and much extra concrete is necessary.

Baffle-piers at the bucket cause considerable spray at the toe of the dam and this was objectionable because the outlet-valve house is located immediately adjoining the spillway on one side and a future power-house setting is on the other. The spill water may at times carry large logs (in spite of boom protection) with enormous striking effect when hitting the nose of a baffle-pier. The conditions for destroying energy at the toe of the dam by a standing wave were unfavorable since the river gradient is so steep that water at all stages flows at a depth below the critical. A subsidiary dam below the main dam would have been required to create a deep pool. This, in turn, would have had to be protected from down-stream erosion.

The best plan seemed to be to carry the spillway sheet at a high velocity across the apron to a point 150 ft. down stream from the dam and there deflect the sheet upward so as to secure the maximum distance and spread of the striking area of the water mass and the river bed-rock. This plan was tested experimentally.

Model.—A 1 to 20 scale model of the spillway sections of the dam was constructed in the empty Reservoir No. 2 in the City of Portland, where adequate facilities for flow and control of water, head, etc., were possible. (See Fig. 33.) Flow over the model spillway was regulated by valves and gates and was accurately read on gauges to simulate certain discharges over the dam. Tests of various types and combinations of upward deflectors (see Fig. 34), were then

conducted for flows representing approximately 1 000, 3 500, 5 000, 10 000, 15 000, and 21 000 sec-ft.; measurements were recorded and characteristics of flow noted. (See Table 10.) An illustration of typical cases is shown in Fig. 35.

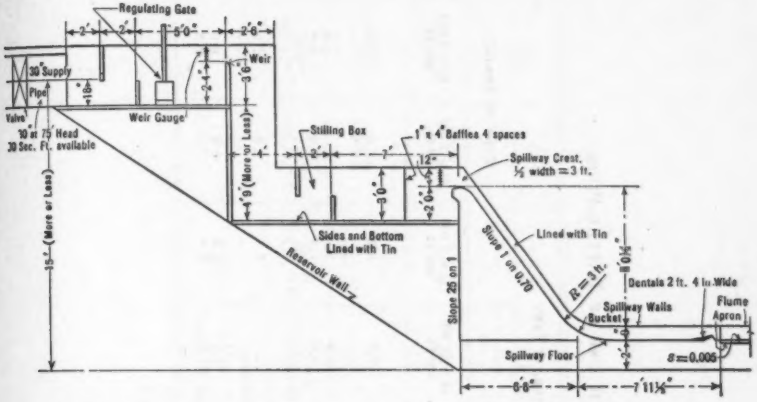

FIG. 33.—ONE-TWENTIETH SIZE MODEL OF SPILLWAY SECTION, BULL RUN DAM.

At first, curved throw-back baffle-piers, spaced alternately with deflectors (Fig. 34(*a*) and (*b*)), were tried in an attempt to destroy the energy, but the result was disappointing for the large flows because the water was thrown violently upward over the dentals to a height equivalent to 90 ft. (See Fig. 35.)

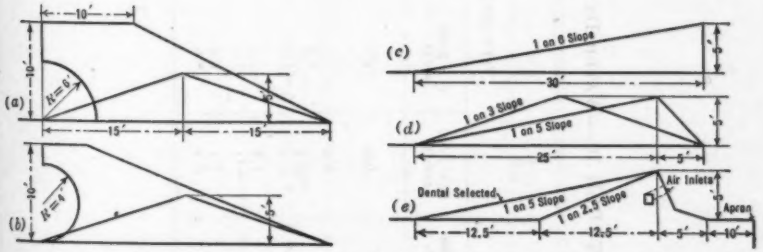

FIG. 34.—TYPICAL DENTALS TESTED WITH MODEL SPILLWAY, BULL RUN DAM.

Next a simple uptilt in the apron was tried. The end of the apron was raised 5 ft. in 30 ft. (Fig. 34 (*c*)), in the direction of flow. This served the purpose of lifting the fast traveling sheet into the air and preventing the rock from scouring close to the end of the apron. The disadvantage was that the attack of the falling sheet was concentrated and was still powerful although at a safe distance from the dam. To split this attack the apron was divided into dentals of different slopes (Fig. 34(*d*) and (*e*)), which spread the attack over a wide range by creating two separate parabolas. (See Fig. 36.) By varying

these slopes the point of a falling jet may be regulated at will, within the limiting velocities of the overfalling sheet, which passes over the spillway floor and over the dentals without any appreciable loss of energy, and dissipates

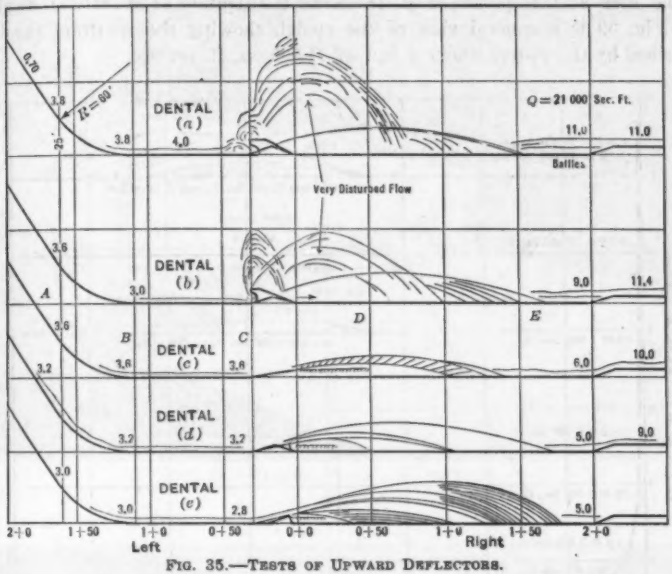

FIG. 35.—TESTS OF UPWARD DEFLECTORS.

itself in a well-scattered attack on the river channel far beyond the apron. Types (*d*) and (*e*) (Fig. 34), were both considered good. Type (*e*) was selected because of the ease of providing air inlets, although the necessity of these inlets was not apparent from the experiments.

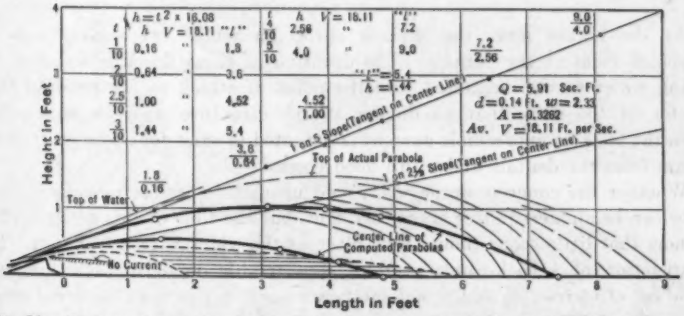

FIG. 36.—COMPARISON OF COMPUTED PARABOLAS AND FIELD MEASUREMENT OF ACTUAL PARABOLAS, SPILLWAY DENTAL TESTS FOR BULL RUN DAM.

From the "Percentage of Time Curve" (Fig. 37), it is evident that for 98% of the time the discharge over the spillway will be less than 3 500 sec-ft. which is required to sweep the apron at high velocity. During this long period the

discharge down the ogee slope will enter the pool on the spillway floor and form a small standing wave there. Over the dentals the over-pour will be steady and a 10-ft. apron is provided in Type (*e*) (Fig. 34) to prevent erosion of the rock at this point. Fig. 38 shows the dentals (Fig. 34(*d*)) in place and Fig. 39 is a general view of the model, showing the resultant parabola described by the waters under a flow of 21 000 cu. ft. per sec.

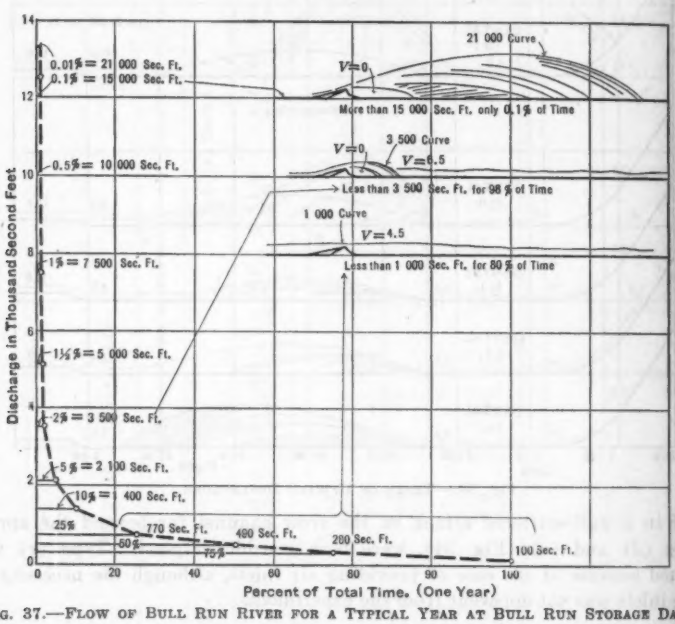

FIG. 37.—FLOW OF BULL RUN RIVER FOR A TYPICAL YEAR AT BULL RUN STORAGE DAM.

At the higher flows the shallow apron bucket is swept clear and the parabolas form at the dentals. The duration of these floods is so short, the falling water so well scattered, and the point of attack so far removed from the toe of the dam, that no danger to the structure need be anticipated. From the tests no appreciable current is expected to exist for about 40 ft. down stream from the dentals under full flood flows.

Whether the concrete apron will stand up under the fast moving sheet of water can be answered after actual overflow, but the time of this action will be so short that little scour should take place as the water is free from silt. The construction of a back-water pond of considerable depth for a stilling-pool would be, of course, an additional safety measure, but is not considered necessary. The falling parabolas may excavate a pool, in time, which will serve the same purpose. The dental piers, as constructed, are practically identical with Model (*e*) (Fig. 34), except that the down-stream portion is excavated 10 ft. into the solid rock and poured as one piece with the piers and the whole anchored into the rock with steel rods. The advantages of this type of spill-

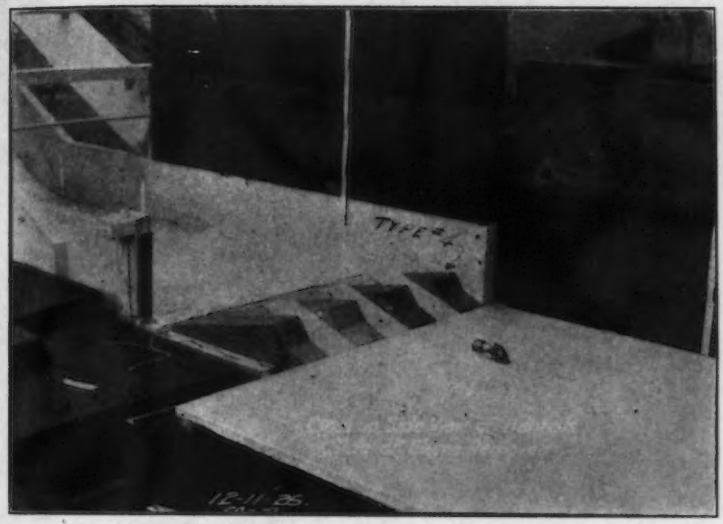

FIG. 38.—BAFFLES, TYPE (*d*), IN PLACE.

FIG. 39.—SHAPE OF PARABOLA, AS SEEN BY REMOVING THE SIDE OF THE FLUME.

way are simplicity, economy, and safety. For greater economy the fore-apron could be shortened considerably. The cost of the dentals is very low as compared to deep buckets, jump-offs, depressed aprons, or stilling-pools.

The curve at the bucket was first tested for a short radius of 10 ft., but the rebound of the overfalling sheet was very pronounced at the larger flows. A radius of 100 ft. was next tried and gave very smooth delivery, but at quite an expense in extra concrete over a short radius. A radius of 50 ft. was next tried, and this gave fairly good results. For additional safety, a radius of 60 ft. was chosen.

These tests were carried out under the personal direction of D. C. Henny, M. Am. Soc. C. E., Consulting Engineer, and Ben S. Morrow, Assoc. M. Am. Soc. C. E., Chief Engineer, of the Bull Run Dam.

OREN REED,* ASSOC. M. AM. SOC. C. E. (by letter).—Although a great number of problems, such as those presented by the author, are difficult, or impossible, to solve by mathematics, opportunity is seldom given to attempt their solution by experimental observation. In Europe, on the other hand, extensive laboratory and field experiments are run on models of many important projects, before the final designs are made.† This is particularly true of hydraulic problems.

Difficult foundation conditions introduce a special problem which, unless properly taken care of, forms a great hazard for a dam. The experiments described by the authors have made it possible to insure that the over-pour will leave the concrete apron at a low velocity under the most unfavorable conditions.

The design adopted is very similar to the energy-controlling device at the Gatun Dam. However, the baffle-piers at the Gatun Dam are probably secondary in importance for destroying the energy of the spill. The spillway is in the form of a circular arc, 808 ft. in length along the crest. The discharge converges to a concrete channel, 285 ft. wide. The energy of the converging stream will partly neutralize itself, while the baffle-piers will aid materially. The Gatun Spillway has proved its effectiveness to pass high flood flows.

Before the flood control dams for the Miami Conservancy District were built in the Miami Valley, Ohio, many experiments were made to determine the best form for several features, including the outlet and spillway structures.‡ The outflow from certain of these dams may become large and the banks of the channels below the outlets are of soil, which is easily eroded. After thorough trial the use of stilling-pools was adopted as the most practicable method of controlling the energy of the outflow. The pool was constructed so that a hydraulic jump occurred through a wide range of discharge and tail-water conditions. The position of the jump was controlled within narrow limits by sloping the floor downward from the outlets. For the conditions below the Miami Valley dams, the use of baffle-piers was found to give

* Asst. Designing Engr., San Joaquin Light & Power Corporation, Fresno, Calif.

poor results. The flow on the models was not stable under moderate changes of discharge and tail-water level, or in changes of the form of the structures. It was considered that the analogy between the models and the full-sized structures was inconclusive.

Model experiments may often be carried out on complete plants. This was done in 1919 on a 1 to 25 scale model of the Solbergfos Power Project in Norway. At Solbergfos, the Glommen River is controlled by a gravity dam with three roller-gates for flood regulation. The power house is parallel to the stream, and the up-stream end forms part of the dam. The reaction units, thirteen in number, take water from an open forebay and discharge into the river just below the dam. By these experiments an arrangement was determined which gave the least interference of the spillway over-flow with the discharge from the power house.

The conclusions from model experiments should be mainly qualitative because, even under the most favorable conditions, the water is in a very turbulent state, and any quantitative measurements will be inconclusive. Caution must be observed because slight peculiarities in the model might correspond to great irregularities in the complete structure. The observation of tendencies is, however, of great importance. More problems should be attacked by this method, and it is hoped that the future will see a marked change in attitude toward such research.

HAROLD K. FOX,* M. AM. SOC. C. E. (by letter)—A real experiment such as the authors have conducted and have so ably presented, always adds something worth while to engineering knowledge. The writer visited the project during construction and, therefore, can fully realize the problems encountered.

A description of an emergency job which, at the same time was an experiment, is prompted by this paper. The problem is not in connection with a dam, but is one of the same nature, namely, destroying the energy of water to prevent erosion.

A concrete lined ditch, 3½ miles long, with a capacity of 100 sec-ft., was constructed to divert water into a reservoir. The discharge end terminated above the lake level and about ½ mile from the shore. Water was discharged into a ravine leading to the lake, and the problem was to prevent undercutting at the end of the ditch, as the material was a deep deposit of red clay and decomposed granite which eroded very easily. After some study, it was finally decided to connect the end of the ditch to a steel pipe in order that the water might be conveyed down the steepest part of the ravine and then be made to flow in the channel. At the end of the pipe where the velocity was 35 ft. per sec., a very crude wooden structure was built for the purpose of destroying energy and transferring the water to the ground surface at a low velocity. Fig. 40 shows the method of splitting the water as it left the pipe and creating a "boil" within a chamber. It was found necessary to build a roof over this chamber and weight it down with rocks as the spray got behind the retaining walls on the sides and started to cut. From this chamber, the water flowed over a pile of rock which further reduced the velocity and then, finally, over

* Supt. of Constr., San Joaquin Light & Power Corporation, Fresno, Calif.

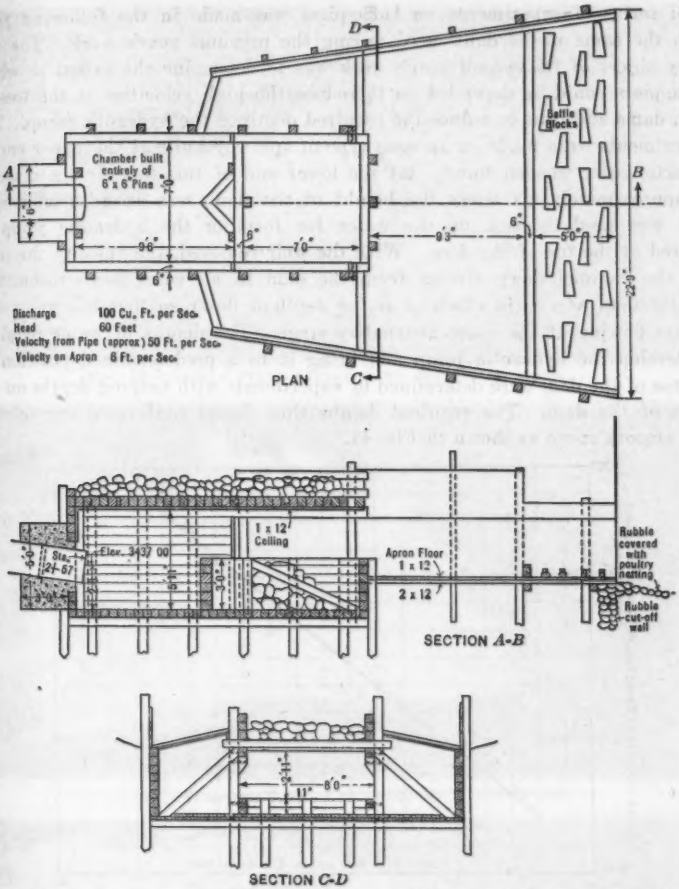

FIG. 40.—PLAN AND SECTIONS, ENERGY DISSIPATING CHAMBER, BROWN'S CREEK DITCH.

a series of baffles, and left the platform with a velocity of about 6 ft. per sec. The structure has stood for several years without repairs and apparently will give service for several more years.

ROBERT F. EWALD,* ASSOC. M. AM. SOC. C. E. (by letter).—In 1915 the writer obtained some data relative to baffle-piers at the toe of high over-fall dams. This information is presented herewith in the hope that it will prove to be a worth-while addition to the general store of knowledge on the subject to which the authors have contributed so much.

The data were obtained as part of a rather elaborate series of experiments, begun in 1914, on the hydraulic jump in relation to high over-fall dams. A

* Asst. Engr., The Aluminum Co. of America, Pittsburgh, Pa.

brief series of experiments on baffle-piers was made in the following year, with the same model dams used during the previous year's work. The primary object of the second year's work was to determine the extent to which baffle-piers could be depended on to reduce the high velocities at the toes of high dams and thus to reduce the required depth of the hydraulic jump. The experiments were made on an ogee type of spillway built at the upper end of a rectangular wooden flume. At the lower end of this flume, at a distance of approximately six times the height of the dam, was an adjustable weir that was used to back up the water for forming the hydraulic jump as desired at the toe of the dam. With the weir removed, the velocity throughout the channel down stream from the dam in all cases was considerably greater than $\sqrt{g\,d}$ (in which, d is the depth of flow), so that the water was always flowing at the lower alternative stage. The depths of water required to develop the hydraulic jump and bring it to a predetermined position at the toe of the dam were determined by experiments with varying depths on the crest of the dam. The required depths thus found conformed very closely to a smooth curve as shown in Fig. 41.

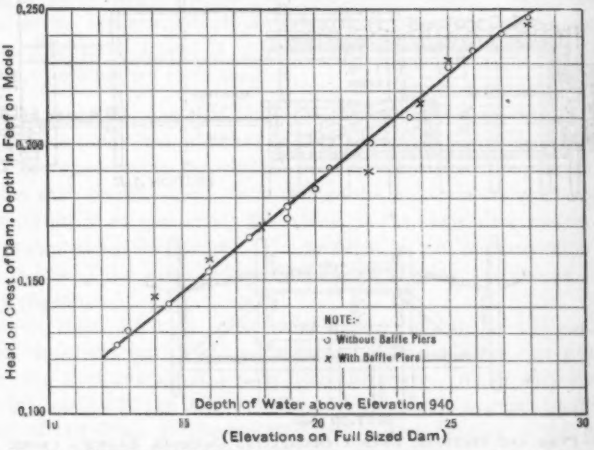

FIG. 41.—DEPTHS OF WATER REQUIRED TO BRING JUMP TO TOE OF DAM WITH AND WITHOUT BAFFLE-PIERS.

The problem arose as to reducing the velocities sufficiently to form the jump and one of the suggestions was the use of baffle-piers. It seemed that if they possessed any pronounced efficiency in absorbing the high over-fall velocities, such efficiency could be determined by noting the reduced depth of water required to develop the hydraulic jump. In following out this idea, a line of baffle-piers was attached to the bucket of the dam, as shown in Fig. 42. These baffles were of the same height as the estimated maximum depth of water at the point where the velocity was greatest, and were staggered so that the deflected jets presumably would "interfere" with each other to the greatest possible degree.

FIG. 42.—BAFFLE-PIERS ATTACHED TO BUCKET OF MODEL.

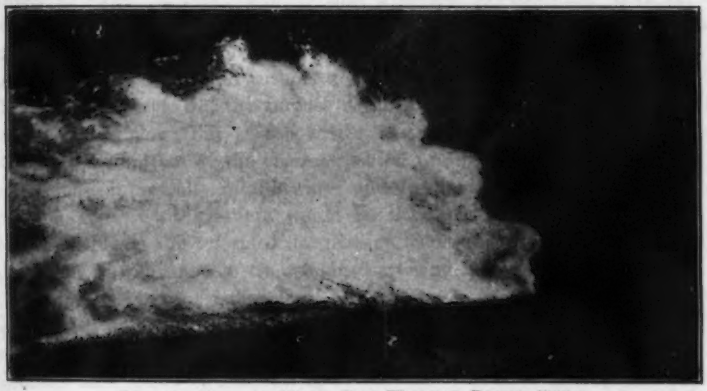

FIG. 43.—VIEW OF MODEL DAM WITHOUT BAFFLE-PIERS.

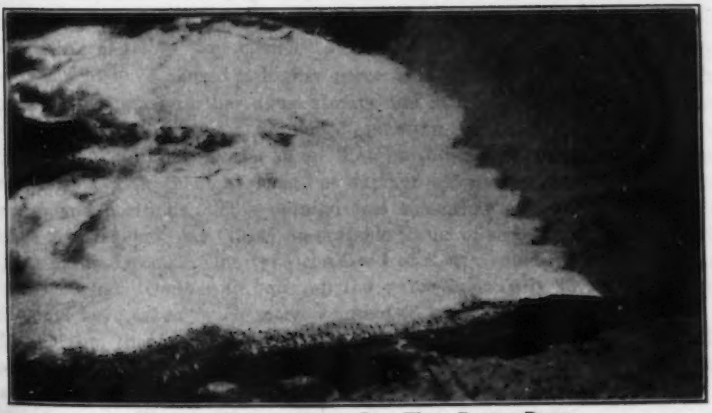

FIG. 44.—VIEW OF MODEL DAM WITH BAFFLE-PIERS.

Another series of experiments was run, and, as before, the head on the crest of the dam was obtained as well as the depth of water (in the down-stream channel), that was required to bring the beginning of the jump to the predetermined position at the toe of the dam. It was a rather difficult matter to establish the beginning of the jump with any degree of accuracy and a somewhat indirect method was required. The procedure was to establish the jump clearly at the extreme down-stream end, then to build up the pool depth, watching the movement of the jump up stream, until its beginning was lost in the disturbed flow around the piers. By relating the increment of movement to the increment in depth, it was possible to make a fair estimate of the depth required to bring the beginning of the required jump to position. These estimated depths were plotted on the curve, previously developed (see Fig. 41) and since they fell indiscriminately above and below, it appeared to the experimenters that the energy dispelled by the piers was relatively so small in proportion to that absorbed by the jump that further experiments along this line would not prove of particular profit. Comparative photographs were taken, similar to those shown in Figs. 43 and 44, to record conditions with and without the baffles. There was little question but that, with the baffles in, the surface action of the water was much smoother than with them out, but as the writer was primarily interested in the conditions at the bottom of the channel, which presumably were reflected by the net decrease in velocity of the water and freedom from its up-stream movement, it appeared that there would be little practical gain in the use of baffles. In fact, they seemed to possess a practical disadvantage in that they would be subjected to tremendous battering action and must be repaired from time to time. Furthermore, unless they were very skillfully designed and placed, and the gates on the dam correctly operated, water would be sprayed everywhere. This was a positive detriment with the power-house locations then under consideration.

It is apparent from Figs. 42, 43 and 44, that the internal interference caused by these baffles is less than that obtained in the Pit River experiments; yet having had the "first chance" at the high velocities, these baffles apparently should have caused a higher percentage of reduction in velocity than piers located much farther down stream and nearer the middle of the jump. Unfortunately, the writer developed such an unfavorable opinion of the baffles as an adjunct to the jump that he did not attempt any systematic experiments with them at locations farther down stream or with different shapes and positions. This opinion was somewhat affected by experiments made the previous year (1914) on suitable forms of secondary dams for developing cushion pools. One type consisted of heavy square-nosed piers spaced closely enough together to back up the water sufficiently to form the jump. It would have taken much more concrete to build piers of sufficient size for this purpose than for a dam of the straight ogee type. Having tried piers at both ends of the jump, the middle did not appear very promising and was completely neglected.

The principal requisites for good action in the hydraulic jump were clearly established during the experiments. These principles, with some additions, have been clearly expressed* once more by Sherman M. Woodward, M. Am. Soc. C. E. One of the requisites stated by Professor Woodward is:

"That if the slope of the jump off be made greater than one in three, experiments indicate that the certainty and effectiveness of the jump in destroying energy are perceptibly reduced. If the slope is made as steep as 45°, the usefulness of the jump is mostly lost".

It appears to the writer that the steep slope of the down-stream end of the bucket used on the Pit River dams must interfere very seriously with the development of the jump in its desired form. In the Pit River experiments, the inability to secure satisfactory action of the jump without the piers may have been due in large measure to the steep slope of the bucket and the failure to place the control weir far enough down stream. Dam No. 3 was built with an apron extending 150 ft. down stream from the bucket. It would have been interesting to know the results that would have been obtained by lowering the bucket until its lower edge was nearly tangent to the apron, and then placing a single line of piers about 100 ft. from the edge of the bucket instead of 47 ft. to the more distant pier. The baffles then would act as a control weir. The end results probably would have been nearly the same as those secured by the authors, but the baffle-piers would then have been saved from the tremendous battering to which they are now subject.

Any one who has watched and experimented with the hydraulic jump as developed under suitable conditions cannot avoid marveling at its efficiency in absorbing high velocities without effect on the channel, and the conviction grows that in its action lies the secret of the success of most over-fall dams, otherwise many structures standing to-day would have disappeared as the result of erosive action. Whether or not artificial construction is really necessary to develop the jump in its most efficient form, depends entirely on local conditions. Usually, there is no serious objection to permitting scour, providing the down-stream channel conditions and the design of the bucket are such as to prevent eddies scouring backward toward the toe of the dam. Eventually, Nature will scour a pool sufficiently deep to permit the development of the jump in its most efficient form and the scouring action will then cease.

Where scour in the immediate vicinity of the toe is undesirable, it appears entirely logical to construct a smooth apron in front of the dam just as was done at Pit River, carrying it far enough down stream so that the hole that will be scoured at the end of the apron will not be too close to the dam; then "letting it go at that". It is true that some of the apron may be lost in the hole that will be formed at its end, but it is equally certain that eventually a natural cushion pool will develop and further scouring will cease. It is only a question of determining the size of pool required and making the apron long enough so that, assuming the rock to have been cut backward

* In a letter to *Engineering News-Record*, December 15, 1927, entitled "Toe Erosion Below Overfall Dams."

under the apron, the final pool will be of the required dimensions and far enough away from the dam to avoid trouble. Of course, where eroded material may land in tail-races, such procedure is not permissible, and provision must be made for an artificial pool. Very high over-fall dams are generally founded on exceptionally good rock and long aprons usually are not necessary. The very hardest rock will be eroded, and at a surprisingly fast rate in many cases, but such erosive action through proper design of the bucket can be forced to take place at a considerable distance from the dam and dangerous "back lash" eliminated.

Just what constitutes "proper design" has not yet been clearly established, but that it is attainable is illustrated by two high dams located on Little Tennessee and Yadkin Rivers in North Carolina, designated as the Cheoah and Narrows Dams. At Cheoah Dam, in which the drop from the spillway crest to normal water level is 175 ft., the lip of the bucket is about 5 ft. below the normal water level, and there is a natural pool about 30 ft. deep at low water, the depth rapidly increasing with higher stages. This dam has had many floods over its crest with 19 ft. of water passing through some gates. Ever since the last and most severe flood in 1920, which caused considerable scour at some distance from the dam, gravel and loose stone have actually been piled against the toe of the dam below the lip of the bucket, indicating complete absence of erosive eddies at the toe. At the Narrows Dam, the drop from the crest of the dam to normal water level is 170 ft.; the lip of the bucket is at normal tail-water level, and the stream in front of the dam is relatively shallow. Considerable scour has taken place much closer to the dam and in a few spots the rock has been taken out directly in front of the bucket for a depth of 6 ft. In no place has loose material remained against the toe of the dam below the lip of the bucket. The rock at the Narrows Dam is considerably more friable than that at the Cheoah Dam, but this does not explain why loose material will pile against the bucket at one dam and not at the other.

The differences in conditions must be explained by (1) differences in natural pool depth; (2) differences in position of lip of bucket (designated "jump off" by Professor Woodward) relative to bottom of pool; and (3) whether or not the water is permitted to flow directly away from the dam or is forced by obstructions into major eddies in the cushion pool. (By obstructions is meant large masses of rock or heavy structures projecting into the thread of the current.) Major eddies may also be caused by jets of water directed into the pool at large angles to the main flow down the dam. At the Cheoah Dam the natural pool is three times as deep as at the Narrows Dam, and the relative position of the lip of the bucket to the bottom of the pool is much lower than in the second. At Cheoah, it has been possible to turn water into the pool in a fairly uniform direction, and the pool is relatively free from major obstructions, whereas at Narrows some water has been turned into the pool at a fairly large angle to the main flow and rock obstructions also develop large eddies.

To the writer it appears that the ideal method of absorbing kinetic energy of water at over-fall dams is to take the water through the entire drop over perfectly smooth surfaces into cushion pools, functioning in accordance with the laws governing the formation of the jump, and avoiding all obstacles to the free and direct flow of the water away from the dam, with the exception of those primarily designed to increase the depth of water at the toe of the dam, providing they are far enough away from the dam to permit the formation of the jump. For economic reasons scouring usually can be permitted, care being taken to predetermine the probable ultimate dimension of the pool and to see that it is eroded at a reasonably safe distance from the dam. Ultimately, by the formation of the jump under ideal conditions, the erosive action will cease, and no further trouble may be expected so long as the bucket is maintained in its proper condition.

F. W. SCHEIDENHELM,* M. AM. SOC. C. E. (by letter).—The authors' statements and their description of the tests indicate that observation of the surface of the water and photographic study were largely relied upon as a basis for comparing the various experiments. The importance attached by the authors to surface appearance is further emphasized by their characterization of the results of Experiment No. 13 which, in model form, approximated the final construction. However, the writer's experience in experimentation by means of models, as to energy destruction and scour at the foot of spillways of dams, indicates strongly that the appearance of the surface of the water flowing from the foot of the spillway is not a reliable criterion regarding the effect on the stream bed. After all, the most reliable criterion for comparison of the various means of preventing scour is the action on the stream bed itself.

Experiments made under the writer's direction at the hydraulic laboratory of Cornell University indicated that the relative height of tail-water is of great, even of controlling, importance. In the model dam tests for determining the design of Pit River Dam No. 3, there was provided a "back-water control", as shown in Figs. 2, 3, and 4. Apparently, this control or block (perhaps of wood in the model), was not embodied in the final or full-sized structure (see Fig. 1). However, the writer's experiments indicate that the omission, in the full-sized structure, of a control located so close to the foot of the spillway would result in a performance differing from that in the model. In particular, he suspects that there would result somewhat greater scour of the stream bed than if the equivalent of such a block or control were embodied in the final construction.

In the case of the model experiments for the dam of lesser height (No. 4 Dam) a so-called "two-level" apron was tested and a similar apron was embodied in the final construction. The writer is inclined to the belief that the "back-water control" (again, apparently, a block in the model), would be of greater significance in the case of the higher apron, which is shown at the far side of the model in Figs. 17, 26, and 27. The near, or lower, side of the apron would seem, in effect, to involve a stilling-pool, terminating in the

* Cons. Engr. (Mead & Scheidenhelm), New York, N. Y.

equivalent of a solid transverse baffle-wall nearly 14 ft. high and located about 70 ft. down stream from the vertical face of the spillway bucket (both dimensions are in terms of the full-sized structure). The writer has not overlooked the authors' statement that "the difference in the final result, as indicated by the velocity in the river channel below, was, as nearly as could be judged, uniform across the width." However, here, too, one may infer that judgment was based primarily on surface appearance, which may be misleading. Moreover, even the authors state that "the 'killing' of velocity was accomplished with less commotion on the deep side than on the shallow."

A study of Figs. 26 and 27 indicates that the right or far bucket was swept clear, whereas the left or near bucket, namely, that opposite the equivalent of a "stilling pool," was covered by back-roll. This is, to some extent, a measure of the effectiveness of a given arrangement for the prevention of scour.

Inasmuch as the experiments described by the authors apparently did not involve simulation of the stream bed, nor any observation of scour, it is the more desirable and important that the results on the stream bed should be observed at the foot of the actual structures.

RALPH L. PARSHALL,* ASSOC. M. AM. SOC. C. E. (by letter).—The control of scour below dams resulting from the impact of the water passing over the spillway, presents a problem of great importance in the design of such structures, for the reason that the erosion, unless prevented, comprises a potent element of failure.

In April, 1917, the writer designed and built a concrete spillway for a small reservoir near Windsor, Colo. (Fig. 45). This spillway, which is essentially a chute, has a width of 50 ft. at the crest, narrowing to 8 ft. in a distance of 75 ft., with a uniform grade or drop of 8.5 ft. in that distance. The bottom width is increased to 24 ft. in the next 10 ft. of length. The axis of the crest of the spillway forms an angle of 80° with the north side of the channel which is straight, while the south side curves in plan from a width of 50 ft. to 8 ft., as stated. The side slopes are 1 on 1. The depth of this converging section is 2 ft. The side walls at the lower end are 4 ft. high.

A vertical drop of 4 ft. occurs in the grade at the lower end of this chute. Across the channel at the drop is a vertical concrete baffle-wall, 4 ft. high and 8 in. thick, joined to the 1 on 1 side slope of this basin and set 1.5 ft. above the floor line. This vertical wall is supported by three equally spaced buttress walls on the lower face of this transverse baffle-wall; 5 ft. down stream is a transverse parallel wall, 1.5 ft. high, on the floor of the basin. A hole is left at the floor line of this low wall for drainage purposes. Most of these features are shown in Fig. 45.

These transverse walls are for dissipating the energy of the stream by impact. The lower or secondary wall creates a water cushion and chamber for the discharge as it passes over the end of the approach channel.

This spillway was built largely to forestall an emergency caused by a sudden rise of the water surface within the small reservoir, such as might be

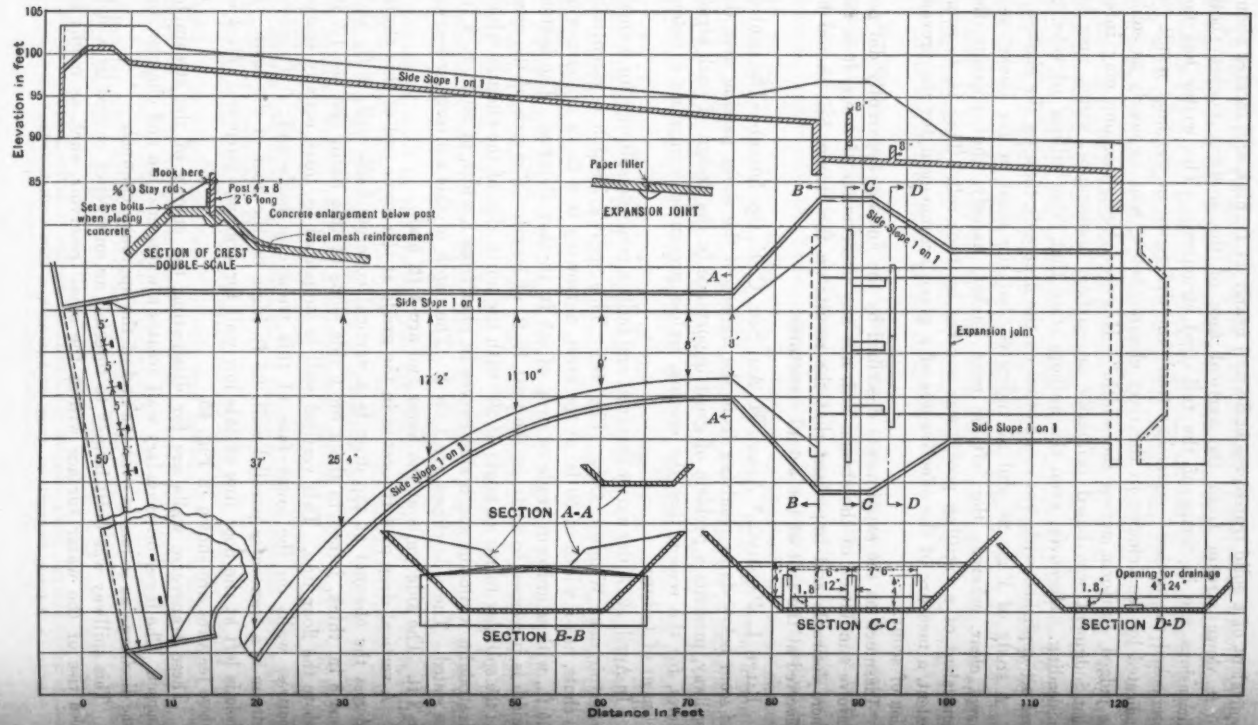

FIG. 45.—PLAN OF CONCRETE SPILLWAY FOR RESERVOIR NEAR WINDSOR, COLO.

Distance in Feet

caused by a freshet in the stream. The writer has never seen this structure in action, but has been informed that for relatively small discharges it appears to function properly.

An interesting example of scour below dams is shown at the Halligan Dam, on the North Fork of Cache la Poudre River, about 35 miles northwest of Fort Collins, Colo.* This structure (Fig. 46) is of reinforced cyclopean concrete. The width of the base is 51 ft.; the extreme height, 94 ft.; and the length, along the top of the dam, 350 ft. The dam, completed in May, 1910, is of the arch type with a constant radius of 324 ft. The foundation is a hard seamy granite mixed with red talc formation. Table 11 shows the flow over the spillway for the period, 1919 to 1926, inclusive.

TABLE 11.—DISCHARGE OVER HALLIGAN SPILLWAY.

Year.	SPILLWAY IN ACTION.		DISCHARGE, IN SECOND-FEET.	
	Period.	Days.	Maximum.	Average.
1919	None	None	0	0
1920	May-June-July	57	850	420
1921	May-June	21	640	240
1922	None	None	0	0
1923	May-June-July	44	2 740	490
1924	May-June	29	710	385
1925	None	None	0	0
1926	April-May-June	40	570	170

These data were taken from a record of reservoir gauges showing the depth of water in tenths of feet above the crest elevation. The discharge was computed by the formula, $Q = C\,L\,H^{\frac{3}{2}}$, in which C is assumed to be 3.5. The length of crest is 110 ft. Since the completion of the dam there has been reported, on more or less reliable information, a depth of 4.7 ft. on the crest of the spillway. For this head the discharge would have been approximately 3 900 sec-ft.

After a period of about 18 years of service, there appears to be no scour below this dam. As indicated, the extent of the discharge over the crest of spillway is dependent on the annual run-off from the water-shed above the reservoir. In some years there has been no flow over the dam, while for others the maximum has been nearly 4 000 sec-ft. These maxima, as shown, occur for very short periods. Fig. 46 shows a discharge of about 700 sec-ft. passing the crest, while Fig. 47 gives a more detailed view below the dam. Both views indicate, when compared with photographs taken at the completion of the dam,* that there has been very little if any increase of scour, because of the nature of the formation.

H. W. DENNIS,† M. AM. SOC. C. E. (by letter).—There is a well-defined growing tendency to take advantage of experiments on models as a guide in the design of major structures, and the authors have indicated such an appli-

† Chf. Civ. Engr., Southern California Edison Co., Los Angeles, Calif.

cation and submitted their results for the benefit of the Engineering Profession. They have called attention to the question as to the quantitative interpretation of the results, although it is clear that qualitatively they are valuable.

The following may be a contribution to the subject from the standpoint of the quantitative interpretation of the hydraulic scouring action to be expected when a large quantity of water is discharged into an uncompacted material. In this case, it was the dump from the Florence Lake Tunnel, constructed by the Southern California Edison Company for conveying water in a comparatively large quantity from the Florence Lake Reservoir to the Huntington Lake Reservoir of that Company.

Although the outlet portal of the tunnel was excavated in earth and required a concrete lining for a distance of about 800 ft., the remainder of the tunnel was excavated in solid granite, and the material was deposited, as was convenient, near the portal of this tunnel. The elevation at the portal is 7 000 ft. above sea level, and Huntington Lake, when full, is at Elevation 6 950. Accordingly, provision was required that the water should be permitted to discharge without undercutting the tunnel portal. With an anticipated maximum discharge from the tunnel of about 2 300 sec-ft., a steel pipe 12 ft. in diameter was inserted in the end of the concrete lining and was constructed on a 7.85% grade for a distance of 258 ft., so as to bring the actual outlet at an elevation of 6 980 ft., where the pipe was supported by a concrete head-wall. The diversion into the tunnel is controlled by gates, and the first operation through this outlet structure afforded opportunity to take measurements of the scour which would be produced by flow up to a maximum available capacity. At the time of the experiment, this was limited to 1 875 sec-ft., due to a reduced elevation of the upper reservoir.

Contour surveys were made before any water was diverted and also after the maximum flow (1 875 sec-ft.) had been allowed to run for several hours, at the end of which time no further apparent scour of the channel was taking place at the outlet structure. The outlet structure, under conditions of minimum and maximum flow, is shown in Figs. 48 and 49, respectively. Fig. 50 shows the plan and profile, including contours so taken.

Fig. 50 shows a large rock located almost exactly on the center line of the pipe and about 55 ft. from the outlet. The presence of this rock was unknown at the time of laying out the work, and, of course, it functioned somewhat as a baffle and assisted in destroying the energy of the discharging water. The natural weir created below this pipe was such that, when no water was discharging, the water stood at Elevation 6 978, whereas, during the operation, the general elevation of the water on this weir was 6 987 ft.

No horizontal or vertical curve occurred in the pipe near the outlet, and accordingly the general slope of the jet corresponded to the condition recited by the authors as obtaining at Pit No. 3 Dam, in that the direction of flow is downward rather than truly horizontal.

The size of the material which remained as a natural lining of the pool at the conclusion of the observation would be roughly classed as "one-man stone".

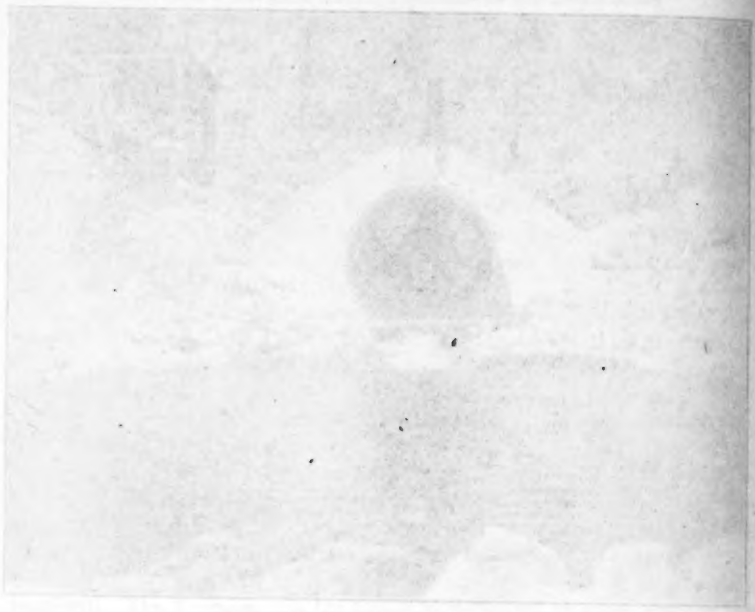

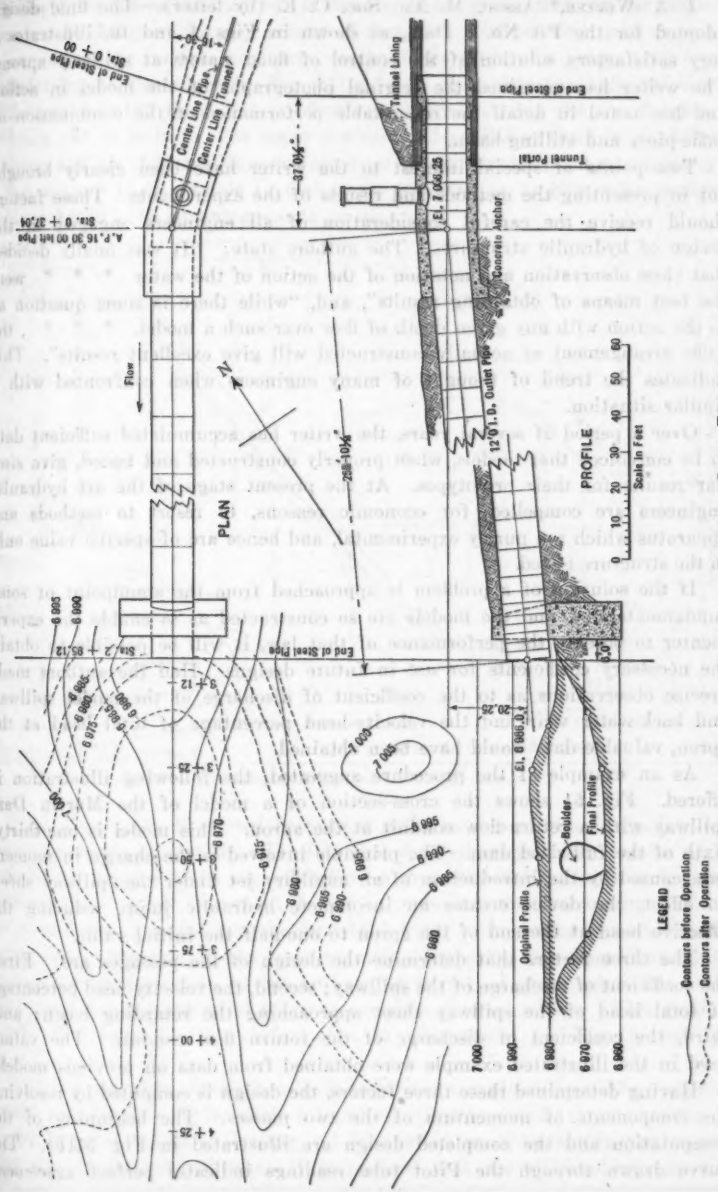

FIG. 50.—PLAN AND PROFILE OF FLORENCE LAKE TUNNEL.

I. A. WINTER,* ASSOC. M. AM. SOC. C. E. (by letter).—The final design adopted for the Pit No. 3 Dam, as shown in Figs. 1 and 10, illustrates a very satisfactory solution of the control of flood waters at spillway aprons. The writer has examined the original photographs of the model in action and has noted in detail the remarkable performance of the combination of baffle-piers and stilling-basin.

Two points of special interest to the writer have been clearly brought out in presenting the methods and results of the experiments. These factors should receive the careful consideration of all engineers engaged in the design of hydraulic structures. The authors state: "It was finally decided that close observation and notation of the action of the water * * * were the best means of obtaining results", and, "while there is some question as to the action with any given depth of flow over such a model, * * * , the baffle arrangement as actually constructed will give excellent results". This indicates the trend of thought of many engineers when confronted with a similar situation.

Over a period of several years, the writer has accumulated sufficient data to be convinced that models, when properly constructed and tested, give similar results for their prototypes. At the present stage of the art hydraulic engineers are compelled, for economic reasons, to resort to methods and apparatus which are purely experimental, and hence are of specific value only to the structure tested.

If the solution of a problem is approached from the standpoint of some fundamental law and the models are so constructed as to enable the experimenter to observe the performance of that law, it will be possible to obtain the necessary coefficients for use in future designs. Had the authors made precise observations as to the coefficient of discharge of the model spillway and back-water weir and the velocity-head percentage of total head at the apron, valuable data would have been obtained.

As an example of the procedure suggested, the following illustration is offered. Fig. 51 shows the cross-section of a model of the Martin Dam spillway with a return-flow conduit at the apron. This model is one-thirty-sixth of the full-sized dam. The principle involved is the change in momentum caused by the introduction of an auxiliary jet under the spillway sheet. In effect, the device creates an incomplete hydraulic jump, reducing the effective head at the end of the apron to one-half the initial value.

The three factors that determine the design of the passages are: First, the coefficient of discharge of the spillway; second, the velocity-head percentage of total head of the spillway sheet approaching the retarding basin; and, third, the coefficient of discharge of the return flow conduit. The values used in the illustrated example were obtained from data on previous models.

Having determined these three factors, the design is computed by resolving the components of momentum of the two masses. The beginning of the computation and the completed design are illustrated in Fig. 51(*b*). The curve drawn through the Pitot tube readings indicates perfect agreement

* Hydr. Engr., Alabama Power Co., Birmingham, Ala.

with the theory as established. It is reasonable to assume that similar structures can be designed for any height of dam, depth of overflow, and change in momentum, up to the maximum depth of the hydraulic jump.

Referring to the curve in Fig. 51(*a*), it is seen that the high velocity at the approach (40 to 55 in.) is effectively reduced during the travel across the basin (55 to 70 in.). The upper surface of the spillway sheet is parabolic in shape and its influence is manifested up stream to the point of tangency of the apron. It is possible to design the basin so as to give a horizontal surface, should it be advantageous to do so.

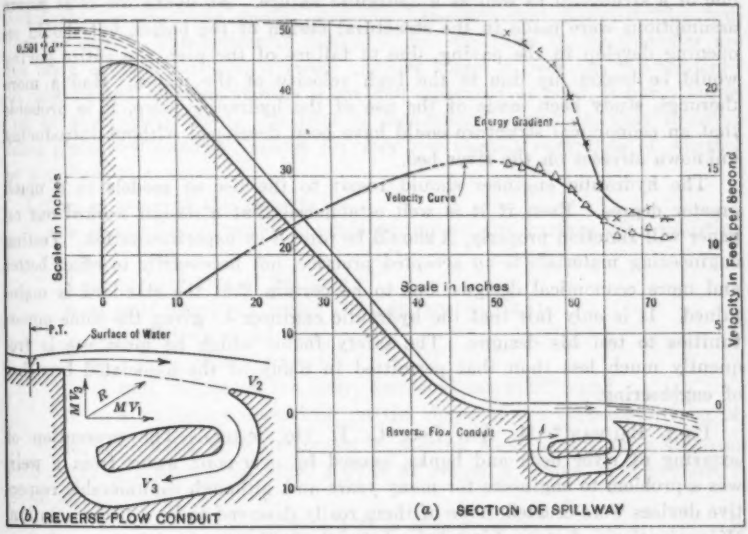

FIG. 51.—MODEL OF MARTIN DAM SPILLWAY.

This illustration is offered because it explains one of the fine points of the design shown in Fig. 51. The fact that the most satisfactory results were obtained by using a 15-ft. step-off indicates that the resulting eddy under the spillway sheet is an important factor in reducing the momentum. Also, the second row of baffles and the final back-water weir creates two additional basins which function in the same manner. Directing the sheet downward, against the baffle-piers is, as the authors point out, of great value, but only when there is sufficient relief below to permit a reversal of flow. This fact is clearly illustrated by the performance in Experiment 11, Fig. 4, and in Table 3.

The use of baffles alone often leads to serious complications. They merely change the direction of the water without effectively reducing the momentum.* If the structure is to be lasting, all dissipation must be within the water. This can be appreciated when it is realized that the stilling-basin at the

* "The Hydraulic Jump as a Means of Dissipating Energy," Technical Rept., Pt. 3, Miami Conservancy Dist.

Pit No. 3 Dam is called upon to dissipate approximately 1 000 000 h.p. If this is not accomplished by the resulting back-water, the hazard to the structure is indeed great.

Concrete is one of the best materials to withstand high velocities at pressures of more than one atmosphere, as long as it is not called upon actually to absorb energy. The writer knows of cases where concrete buckets were used for a similar purpose, with the result that in a very short time the steel reinforcement was exposed.

The question of performance of the design, as shown by the authors, is one of a structural as well as a hydraulic nature. No doubt the most severe assumptions were made in the structural design of the baffles, but should an opening develop in the paving, due to failure of the pier, the entire paving would be broken up due to the high velocity of the water. Had a more thorough study been made of the use of the hydraulic jump, it is probable that an economical structure could have been developed without introducing unknown stresses on the river bed.

The hydraulic engineer should resort to the use of models to a much greater degree. Even if it is well established that a design worked out on paper will function properly, it should be proved by experimentation. Testing engineering materials is an accepted practice, not necessarily to effect better and more economical designs, but to be certain that the standard is maintained. It is only fair that the hydraulic engineer be given the same opportunities to test his designs. The safety factor which he must use is frequently much less than that permitted in many of the associated branches of engineering.

Paul Bauman,* M. Am. Soc. C. E. (by letter).—The prevention of scouring of river beds and banks, caused by over-pour water from a weir, was a problem to engineers for many years and, although innumerable respective devices were created, none of them really deserved to be called a solution. Misconceptions of the subject helped greatly to delay a satisfactory solution, the principal one being the failure to differentiate between the effect of impact of falling water and the effect of a change of the distribution of water-thread velocities as related to their distribution for the normal flow of the river.

Judging from the description of the results of experiments on models of Pit River Diversion Dams Nos. 3 and 4, respectively, it is safe to state that the authors have found a solution, thereby contributing a valuable addition to the knowledge of practical engineers as well as a scientific "nut to be cracked" by those who are interested in the "why" of hydraulic puzzles. Whether or not the arrangement of baffle-piers, as finally chosen by the authors, will prove as successful for an actual flood of 70 000 cu. ft. per sec. as it did for a corresponding discharge over the model dams, is a question which only experience can answer definitely.

The writer, however, believes that, as far as the stilling action is concerned, no appreciable difference between the model and the actual conditions

* Designing Engr., Quinton, Code and Hill, Los Angeles, Calif.

will show unless pulsations should develop due to disturbances in the unprotected river channel below the dam. It must be realized that the natural process of bed-forming in a river is handicapped by any artificial obstruction, such as a weir or a dam, inasmuch as its main factor—the transportation of débris—is more or less interrupted.

Before any hydraulic computation on the weir itself is done, it is, therefore, quite important to study the behavior of the river in its natural bed some distance below. A river flowing on alluvium forms its slope to suit itself. Governing in the formation of the bed is the flow for which the volume of transported débris is a relative maximum. The respective depth is often called the "bed-forming depth" and the respective flow likewise "the bed-forming flow." The hydraulic radius, r, and the slope, s, for this flow are the main characteristics of a river. At low stage, a river has the tendency to raise its bed, whereas at high stage, and especially at flood, it has a lowering or a scouring effect. It must be understood, therefore, that scouring takes place continuously (except for very low stages) regardless of whether or not there is a weir.

Let m = mass of the water;
v = velocity of water threads acting on the surface of a resisting body;
A = surface area of the body;
w = unit weight of water (62.5 lb. per cu. ft.);
μ = coefficient of friction;
V = volume of the water;
γ_0 = unit weight of the body, corrected for uplift; and,
K = a coefficient depending on the shape of the exposed surface, A.

Then, the kinetic force or impact of flowing water acting on a resisting body, such as a particle of sand, a piece of gravel, a pebble, or a boulder, is equal to,

$$F = 1\ P = K\ m\ v \quad \ldots\ldots (1)$$

and, since $m = \dfrac{w\ A\ v}{g}$,

$$P = \frac{K\ w\ A\ v^2}{g} \quad \ldots\ldots (2)$$

and the resistance, R, of the body is equal to,

$$R = \mu\ V\ \gamma_0 \quad \ldots\ldots (3)$$

When $P = R$, motion of the body is impending. Therefore, combining Equations (2) and (3) and solving for v:

$$v = \sqrt{\frac{V\ \gamma_0\ g\ \mu}{K\ A\ w}} \quad \ldots\ldots (4)$$

which is the velocity required to move the body; that is, the water-thread velocity at the bottom of the river. Observations will show, however, that much greater volumes of débris are moved at times than are given by Equation (4). This is due to the fact that, beside the scouring force, P, a force, D, is active as shown in Fig. 52.

Let f = area of cross-section of a water column;

$s = \sin \alpha = \frac{h'}{l}$ = slope of the water surface;

d = depth of the stream; and

μ' = average coefficient of friction.

Then, according to the law of energy,

$$l \times D = w\, d\, f\, h' \quad \ldots\ldots (5)$$

If f is made equal to 1 sq. ft.,

$$D = 62.5\, d\, s \quad \ldots\ldots (6)$$

which is called the dragging force. The resistance, R', of 1 sq. ft. of river bed (see Fig. 53) is,

$$R' = \gamma_0\, t\, \mu' \quad \ldots\ldots (7)$$

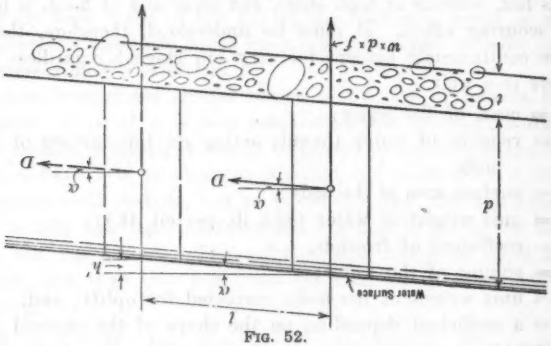

FIG. 52.

and when D is equal to R', Equations (6) and (7) may be combined to determine the depth, t, of the river bed that is in motion, or the limiting size, t of the pebbles or boulders moved. This is equal to,

$$t = \frac{62.5\, d\, s}{\gamma_0 \times \mu'} \quad \ldots\ldots (8)$$

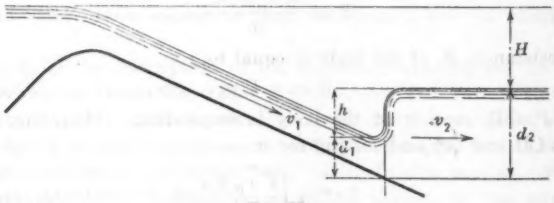

FIG. 53.

As long as t (Fig. 52), therefore, is a little smaller than the smallest diameter of aggregates forming the river bed, no motion will occur. This state of inertia corresponds to a flow during which neither scouring nor settling of débris occurs. It applies particularly to rivers with stony beds, such as the Pit River, because sandy beds are seldom at rest. The abrupt change

in pressure between the water in the upper layers of a sandy river bed and the relatively fast-moving water threads immediately above has a lifting effect on the top particles which, once loosened, are readily carried away. The vertical velocity corresponding to this change in pressure has been observed to be from one-tenth to one-thirtieth of the horizontal velocity.

It is quite important to design the weir with due respect to the natural conditions of the river. The main source of scouring of over-pour water only too often lies in a poor adjustment of the weir to the natural bed of the river and above all of the apron. Weir construction is done as often as possible at low water and the temptation to put the apron on top of the then existing bed with a minimum of excavation is considerable. The bed-forming flow alone sometimes will lower the bed enough to cause the water to jump off the high apron, producing impact and eddies and probably doing more damage than a great flood would with a well-designed apron. The aforementioned handicap to the shifting of débris adds to the seriousness of this occurrence.

If the weir is assumed to be built so as to prevent percolation, it is governed by hydrodynamic, static, and, last but not least, economic features only. As to the first, it must be remembered that all the mathematically derived equations of hydraulics must be supplemented with empirical coefficients in order to make them applicable for practical use. Although these coefficients may often be chosen successfully from those determined for similar conditions elsewhere, the most reliable determination, undoubtedly, will result from experiments on models representing the actual conditions as closely as possible. This has been done by the authors. The greater the velocities involved in the problem, the greater the discrepancy between the strictly theoretical and the actually observed conditions and, therefore, the greater will be the importance of experiments because little is known about the "rushing or shooting" flow; that is, the flow at an average velocity, v, greater than wave velocity, v_w, inasmuch as ordinary hydraulic formulas strictly apply to "quiet" flow; that is, for $v < v_w$ only.

The discharge from a weir usually represents the case where water of higher velocity is absorbed by water of lower velocity. If the change of velocity would occur very suddenly or, in other words, along a cross-sectional plane and the absolute velocity of the tail-water were rather small, a hydraulic jump would occur, mathematically expressed as follows (Fig. 53):

$$v_1 \, d_1 \, b = v_2 \, d_2 \, b \ldots\ldots\ldots\

By algebra,

$$d_2^2 - d_1^2 = (d_2 + d_1)(d_2 - d_1) \quad \ldots\ldots(13)$$

Substituting Equation (13) into Equation (12) and solving for:

$$d_2 = \frac{v_1^2}{4g} \pm \sqrt{\frac{v_1^2}{2g}\left(\frac{v_1^2}{8g} + d_1\right)} \quad \ldots\ldots(14)$$

which is a well-known formula. Note that, since d_2 cannot become negative, the sign before the radical is always plus. If the discharge is altered so as to diminish the height, h, of the jump until it finally becomes zero, then $d_2 = d_1$. Substituting d_1 for d_2 in Equation (14) and solving for v_1:

$$v_1 = \sqrt{g\, d_1} = v_w \quad \ldots\ldots(15)$$

or,

$$d_1 = \frac{v_1^2}{g} = 2\, h_1$$

This means that in order to produce a jump, the velocity head, h_1, must be at least as great as one-half the depth, or the velocity, v_1, must be at least equal to the wave velocity, v_w. Another condition for the elimination of a jump follows from,

$$h = \frac{v_1^2 - v_2^2}{2g} \quad \ldots\ldots(16)$$

in which, h becomes zero for $v_1 = v_2$ or, in other words, no jump occurs if the tail-water velocity is equal to or greater than the velocity of the over-pour water in the plane of contact. Neither the latter condition nor the one for a hydraulic jump, however, is ordinarily present where a flood discharge over a weir in a (natural) river is concerned, but one or more standing waves may form as an "outburst" of kinetic energy accumulated in the falling water, due to a more or less sudden change in slope. While, in principle, the standing wave is nothing but a modified jump, its height is not determinable by means of Equation (14) for weirs with a relatively high drop, H (Fig. 54), and only approximately, for those with a relatively low drop. The reason is that only part of the kinetic energy is transformed into potential energy while the remainder is transformed into thermal energy due to the formation of a superficial eddy. Inasmuch as this energy is non-injurious to either the protected or the unprotected river bed, it is evident that the tendency must be to decrease the undesirable standing wave and to encourage the formation of a large superficial eddy. In principle, this may be accomplished by means of a smooth transition between the down-stream slope of the weir and the apron (Fig. 54) and by the proper width, length, and elevation of the latter or, in other words, by providing a sufficient depth, d_2. The efficiency of this eddy depends on the ratio of $\frac{H}{d_2}$ (Fig. 54), which is best determined on models.

The absorption of kinetic energy takes place to such a degree that the water emerging from beneath the superficial eddy always flows with an average velocity that does not exceed the wave velocity. The volume, in cubic feet,

of a superficial eddy required to perform this transformation of energy has been determined by Professor Theodor Rehbock* as being between,

$$V_E = 3.60\ Q \sqrt{\frac{H}{g}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (17)$$

and,

$$V_E = 7.20\ Q \sqrt{\frac{H}{g}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (18)$$

in which, Q equals discharge, in cubic feet per second, and H equals drop (see Fig. 54).

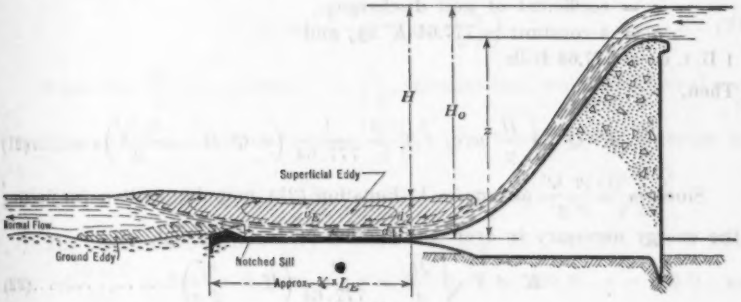

FIG. 54.

The two limits of Equation (17) indicate that an efficiency is involved which, considering the fact that the superficial eddy is transforming energy, is quite plausible.

If K = a constant, corresponding to 3.60 in Equation (17);
Q' = discharge per unit width of channel;
η = efficiency in percentage; and
H_0 and d_2 are as shown in Fig. 54;
Equation (17) may be written,

$$V_E' = \frac{K}{\eta}\ Q' \sqrt{\frac{H_0 - d_2}{g}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (19)$$

The efficiency is then given by:

$$\eta = \frac{K\ Q'}{V_E'} \sqrt{\frac{H_0 - d_2}{g}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (20)$$

It is evident that the efficiency, η, can be determined on models by computing the numerator, assuming that Q' and H_0 are constant and that d_2 is variable, and by measuring the respective cross-sectional area, V_E'. Plotting the resulting values of η as ordinates and the corresponding values of d_2 as abscissas will give points on a curve such that the maximum indicates the desirable depth, d_2, which should be proportionally applied to the weir as closely as conditions permit.

* "Betrachtungen über Abfluss, Stau- und Walzenbildung bei fliessenden Gewässern", Berlin, 1917, Jul. Springer.

Let $K' = \frac{K}{\eta}$, which is constant for a small change of H and v_2;

c_p = specific heat of water;

ΔT = increase of temperature within the superficial eddy;

L_E = effective length of the superficial eddy;

Q'' = discharge per linear foot of weir $= \frac{B}{b} Q'$;

b = length of weir crest;

B = width of apron;

z = height of weir crest above apron;

c = coefficient of weir discharge;

a = a constant $= 777.64\ K'\ 2g$; and

1 B. t. u. = 777.64 ft-lb.

Then,

$$K'\ Q' \sqrt{\frac{H}{g}}\ w\ c_p\ \Delta T = \frac{1}{777.64} \left(w\ Q'\ H - \frac{m\ v_2^2}{2} \right) \ldots\ldots\ldots (21)$$

Since $m = \frac{w\ Q'}{g}$ and $c_p = 1$, Equation (21) may be written (neglecting the energy necessary to overcome friction on the way, L_E),

$$K'\ \Delta T \sqrt{\frac{H}{g}} = \frac{1}{777.64} \left(H - \frac{v_2^2}{2\ g} \right) \ldots\ldots\ldots\ldots (22)$$

and,

$$\frac{777.64\ K'\ 2\ g}{\sqrt{g}}\ \Delta T = 2\ g \sqrt{H} - \frac{v_2^2}{\sqrt{H}} \ldots\ldots\ldots (23)$$

Substituting the value, a:

$$\Delta T = \frac{1}{a} \left(2\ g \sqrt{H} - \frac{v_2^2}{\sqrt{H}} \right) \ldots\ldots\ldots\ldots (24)$$

Considering that $v_2 = \frac{Q'}{d_2}$, and $Q' = \frac{b}{B} Q''$, Equation (21) can be solved into the form:

$$\Delta T = \frac{2\ g}{a} \left(\sqrt{H} - \frac{b^2\ c^2\ (H + d_2 - z)^3}{B^2\ d_2^2\ \sqrt{H}} \right) \ldots\ldots\ldots (25)$$

The total derivation of ΔT by the parameters, H and d_2, is given by:

$$\delta\ (\Delta T) = \frac{\delta\ (\Delta T)}{\delta\ H}\ d\ H + \frac{\delta\ (\Delta T)}{\delta\ d_2}\ d\ (d_2) \ldots\ldots\ldots (26)$$

and the superficial eddy is most effective if ΔT becomes a maximum, which means that $\frac{\delta\ (\Delta T)}{\delta\ H} = 0$ and $\frac{\delta\ (\Delta T)}{\delta\ (d_2)} = 0$, simultaneously, and,

$$\frac{\delta\ (\Delta T)}{\delta\ (H)} = 0 = \frac{1}{\sqrt{H}}$$

$$d_2^2 \sqrt{H}\ B^2\ 3\ c^2\ (H + d_2 - z)^2\ 1\ b^2 - c^2\ (H + d_2 - z)^3\ b^2\ \frac{d_2^2}{\sqrt{H}}\ B^2$$

$$\overline{\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad} \ldots (27)$$

$$d_2^4\ H\ B^4$$

$$0 = d_2^2\, B^2 - b^2\, 3\, c^2\, (H + d_2 - z)^2 + b^2\, c^2\, (H + d_2 - z)^3\, \frac{1}{H} \ldots\ldots (28)$$

$$\frac{\delta\,(\Delta\, T)}{\delta\,(d_2)} = 0$$

$$= - \frac{d_2^2 \sqrt{H}\, B^2\, 3\, c^2 (H + d_2 - z)^2\, 1\, b^2 - c^2 (H + d_2 - z)^3\, b^2\, 2\, d_2 \sqrt{H}\, B^2}{d_2^4\, H\, B^4} \ldots\ldots (29)$$

$$0 = - d_2\, 3\, c^2\, (H + d_2 - z)^2\, b^2 + 2\, c^2\, (H + d_2 - z)^3\, b^2 \ldots\ldots\ldots (30)$$

By adding Equations (28) and (30), substituting $\frac{(Q'')^2}{2\,g}$ for $c^2\,(H + d_2 - z)^3$, and simplifying the equation, the result is:

$$d_2^3 = \frac{(Q'')^2\, b^2}{g\, B^2} \left(1 - \frac{d_2}{2\,H}\right) \ldots\ldots\ldots\ldots\ldots\ldots (31)$$

When $H = \frac{d_2}{2}$, the quantity, $1 - \frac{d_2}{2\,H}$, becomes zero, which indicates at once that it is a limiting condition because $\frac{(Q'')^2\, b^2}{g\, B^2}$ then becomes $+\ \infty$, whereas, for $H = +\ \infty$, the quantity, $1 - \frac{d_2}{2\,H}$, becomes $+\ 1$ and $d_2 = \sqrt[3]{\frac{(Q'')^2\, b^2}{g\, B^2}}$.

The result of Equation (31) is shown in Fig. 55. At Pit No. 3 Dam, $Q'' = \frac{70\,000}{267} = 262$ cu. ft. per sec.; $b = 267$ ft.; $B = 200$ ft., $z = 102$ ft.; and $H_0 = 120$ ft. Therefore, $H = 104.75$ ft. and d_2 (by Equation (31)) $= 15.25$ ft. At Pit No. 4 Dam, $Q'' = \frac{70\,000}{136} = 515$ cu. ft. per sec.; $b = 136$ ft., $B = 160$ ft., $z = 40$ ft. $\pm$; and $H_0 = 67$ ft. $\pm$. Under these conditions, $H = 50.00$ ft. and $d_2 = 17.00$ ft.

As to the actual conditions, it is estimated that for $Q = 70\,000$ cu. ft. per sec., $d_2 = 17.00$ ft., and $H = 103.00$ ft., at Pit No. 3 Dam, and $d_2 = 21.00$ ft., and $H = 46.00$ ft., at Pit No. 4 Dam, which shows enough similarity to the depth, d_2, and the drop, H (as given by Fig. 55), to warrant a very effective superficial eddy. In computing its volume, therefore, it seems permissible to use,

$$V_E = 3.60\ Q \sqrt{\frac{H}{g}}$$

For Pit No. 3 Dam,

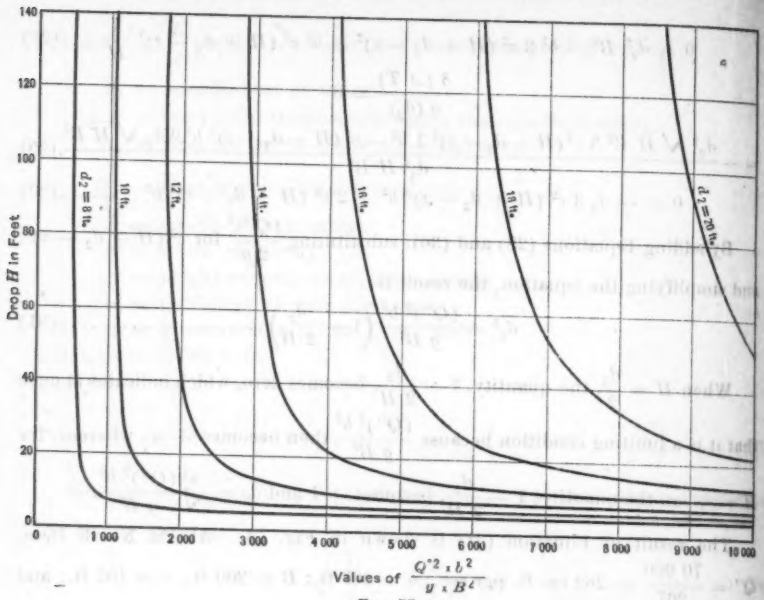
$$V_E = 3.60 \times 70\,000 \sqrt{\frac{103}{32.20}} = 452\,000 \text{ cu. ft.}$$

or a cross-sectional area of,

$$A_E = \frac{452\,000}{200} = 2\,260 \text{ sq. ft.}$$

The mean depth, $d_E = d_2 - d_1$ (Fig. 54). As (Fig. 56) d_1 is, roughly, 4 ft., $d_E = 17 - 4 = 13$ ft., which gives an effective length,

$$L_E = \frac{A_E}{d_E} = \frac{2\,260}{13} = 175 \text{ ft., more or less.}$$



Drop H in Feet
Values of $\frac{Q^2 \times b^2}{g \times B^2}$

7 ft.
8 ft.
9 ft.
10 ft.
12 ft.
14 ft.
$d_1 = 16$ ft.

FIG. 56.

Similarly, for Pit No. 4 Dam,

$$V_E = 3.60 \times 70\,000 \sqrt{\frac{46}{32.20}} = 300\,000 \text{ cu. ft.}$$

$$A_E = \frac{300\,000}{160} = 1\,875 \text{ sq. ft.}$$

$$d_E = d_2 - d_1 = 21 - 8 = 13 \text{ ft.}$$

and,

$$L_E = \frac{1\,875}{13} = 145 \text{ ft., more or less.}$$

From this it is evident that baffle-piers or any other kind of obstructions are superfluous in all cases where the river bed is protected by an apron under the full length of the superficial eddy as far as impact and kinetic energy are concerned. If, in spite of the effect of absorption, dangerous scouring occurs for a considerable distance down the river, it is due to the fact that the highest velocities of the emerging water occur at the bottom because of the absorption of energy from the surface. This is contrary to the normal flow conditions in a river where the velocity immediately above the bottom is a relative minimum. To prevent scouring, due to these high velocities (see Equation (4)), at the bottom, the river bed would have to be protected far beyond the lower end of the superficial eddy which, however, in most cases, would add to the cost in such a way as to make the structure economically impossible.

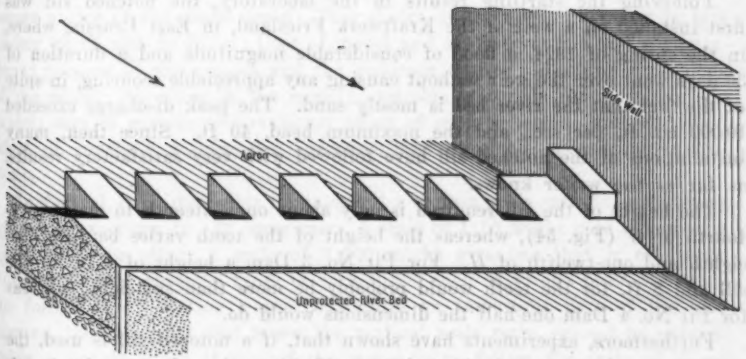

FIG. 57.—NOTCHED SILL.

Guided by these considerations Professor Rehbock has invented a device called "Zahnschwelle",* or "Notched Sill" (Fig. 57), which is placed at the down-stream end of the apron for the sole purpose of establishing the natural flow conditions immediately below. As the average velocity at the down-stream end of the apron is smaller than the wave velocity, the kinetic energy and its action on the notched sill is small as compared with that on the baffle-piers, which are exposed to the most terrific onslaught of falling water,

* U. S. Patent No. 1 561 796.

and, therefore, call for the best reinforced concrete, strengthening of the apron, and, last but not least, sound foundations. It must be realized that at Pit No. 3 Dam, for instance, the better part of about 800 000 kinetic h.p. is "killed" within the zone of the baffle-piers. This undoubtedly calls for adequate structures, especially where concave surfaces are struck, lest the "killing" is done by the "horses" instead of the piers.

It is for these reasons and the fact that the notched sill has successfully stood the actual flood tests that the writer ventures to call it the best solution of the scouring problem, both from a scientific and an economic standpoint.

The principle of its action is that the rushing water sheets immediately above the apron are deflected in an upward direction by the vertical face of the teeth, thereby producing a long and flat ground eddy immediately below the sill which revolves as shown in Fig. 54; that is, its lowest sheets move in an up-stream direction. This movement is counteracted by the lower threads of fan-shaped jets pressed through the gaps between the teeth so as mutually to "destroy" energy without appreciable scouring of the unprotected river bed (deposition has been observed in most cases instead). The upper fan-shaped threads prevent the main stream, deflected upward by the teeth, from dropping down on the bottom which it would otherwise tend to do. Through the concentration of water threads near the surface, the discharge velocities there are increased. This, with the simultaneous decrease of the bottom velocities, leads to the normal distribution of velocities in the discharging stream.

Following the startling results in the laboratory, the notched sill was first installed on a weir of the Kraftwerk Friesland, in East Prussia, where, in the spring of 1924, a flood of considerable magnitude and a duration of 30 days went over the weir without causing any appreciable scouring, in spite of the fact that the river bed is mostly sand. The peak discharge exceeded 10 000 cu. ft. per sec., and the maximum head, 40 ft. Since then, many installations of the notched sill have followed with very satisfactory results, as far as the writer knows.

The height of the sill required is only about one-sixteenth to one-twenty-fourth of H (Fig. 54), whereas the height of the teeth varies between one-eighth and one-twelfth of H. For Pit No. 3 Dam a height of 4 ft. for the sill and 8 ft. for the teeth would probably be more than sufficient; whereas for Pit No. 4 Dam one-half the dimensions would do.

Furthermore, experiments have shown that, if a notched sill is used, the apron may advantageously be only two-thirds to three-fourths the length of the superficial eddy, or, in the present case, say, 120 to 130 ft. long for Pit No. 3 Dam and 100 to 116 ft. long for Pit No. 4 Dam, respectively.

The writer is indebted to the authors for their kind co-operation in furnishing plans necessary for the calculations involved.

MORROUGH P. O'BRIEN,* JUN. AM. SOC. C. E. (by letter).—Although a few model experiments have been made in the United States, the prevailing opinion among American hydraulic engineers seems to have been, at least

* Asst. Prof., Mech. Eng., Univ. of California, Berkeley, Calif.

until very recently, that they are more a matter of academic interest than a basis for actual design. The present series of experiments are encouraging since they indicate that this attitude is changing. A recent German publication, "Die Wasserbaulaboratorien Europas", which describes the European hydraulic laboratories and their methods of study, shows that in those countries where engineering knowledge is most advanced and economic pressure great, model experiments find their widest use as a guide to hydraulic design. In the introduction to this volume, Dr. de Thierry, one of the foremost hydraulic engineers in Germany, makes the statement that, far from being an expensive luxury, laboratories for model studies are an absolute necessity for the economic design of hydraulic structures.

In the use of models for hydraulic studies, there are certain limitations which, if they are not known and properly taken into account, may cause the results to be grossly in error. The principles of dimensional analysis and dynamic similarity, on which the whole theory of models is based, cannot be applied blindly. In deriving these model laws, certain assumptions are made and, consequently, the conditions in the models must be carefully analyzed to see whether these assumptions are approximately realized. From an examination of many model experiments, the writer is of the opinion that a scale effect is to be expected in nearly every type of model, but that, by carefully regulating the conditions in the model, an experienced investigator can keep this scale effect or error within allowable limits.

In making model studies, the first step, and the most important one, is the proper choice of the model scale. This choice is dependent on many factors among which may be listed: Cost of model and of observations and computations; purpose of experiment and the accuracy desired; absolute dimensions of the model; velocities in the model; available materials for surfacing the model; ease of making observations; effect of surface tension and viscosity; effect of constant atmospheric pressure; and available measuring instruments.

In general, it is impossible to state that a certain scale ratio is satisfactory for model experiments. In some cases, a scale of 1:10 might give too small a model while in others a scale of 1:500 might give one that is too large. For experiments on some types of structures, such as bridge piers, in which the formation of surface waves constitutes an important part of the phenomena, the velocities, and hence the vertical scale ratio, cannot be reduced below a certain point if size of the waves is to follow the scale of linear quantities. If there is a possibility of a reduction in pressure at important points in the model, the scale of the model is limited by the fact that the atmospheric pressure is the same for both model and prototype. In river models, where the depths and velocities are likely to be small, the manner of flow may be determined by the viscosity. The scale ratio chosen should be such that the cost of the experiment will not be excessive and that the results will be sufficiently reliable for the purpose at hand. Besides using geometrically similar models, it is possible to reduce the cost by using distorted models, vertical sections, and half-models. The studies of the Berak Power

Plant, in India, were made with a complete model to a scale of 1:96 and with vertical sections through the sector gates, bottom outlets, and spillways to scales of 1:36 and 1:52. The hydraulic and economic requirements are always in opposition and the proper compromise between them can only be made after considerable experience in this kind of work.

The accuracy and reliability of experiments on models depend on the scale ratio and, of course, on the accuracy of observation. Studies at the Hydraulic Research Institute, at Munich, Germany, show a very good agreement, both as to the discharge and the erosion, between a model built to a scale of 1:50 and its prototype, one of the small dams of the Mittlere Isar Project. In these experiments the size of the model was reduced by making it a half-model which was allowable since the structure was symmetrical about the center line of the stream. A few years ago a model of the Harbor of Stockholm, Sweden, constructed to a horizontal scale of 1:300 and a vertical scale of 1:100, was tested at the Technical University of Stockholm, and it was found that the velocities indicated by the model agreed within 10% with those in the harbor. This divergence was decreased when the layer of slightly saline sea water in the harbor was reproduced in the model to the proper scale. While the turbines at Lille Edet were being tested, a rough check was made on the agreement between the actual conditions of flow and those shown by the model, which had been used in the design. It was only possible to examine the principal currents, but these were found to agree exactly.

The great savings in cost of construction that are very often made possible by model experiments are shown very clearly in the publication previously mentioned describing the European laboratories. As an additional instance may be cited the power plant of the Swedish Government at Trollhättan where it was proposed to increase the head on the plant by constructing underground conduits from the tail-race to a point in the river below a controlling section. The proposed plan would have cost about 3 000 000 Swedish crowns. A model experiment was made at the Technical University and it was found that these conduits would not have the desired effect, due to peculiar eddies at the intake. As a result of the model studies it was decided to place much shorter conduits on the opposite bank of the river at a cost of 900 000 crowns. Full-scale experimentation would have wasted several million crowns.

In making experiments on river models, particularly on the dissipation of kinetic energy at the foot of a spillway, it is of the greatest importance to know the water level in the river bed below the dam for different stages of flow. If a controlling section occurs below the apron, it is necessary to increase the roughness of the model locally until the proper flow line is obtained. Otherwise, the depth of flow can usually be controlled by means of an adjustable weir.

J. C. STEVENS,* M. AM. SOC. C. E. (by letter).—In November, 1927, the writer conducted some experiments on a one-twelfth size model of the diversion dam for the Leaburg hydro-electric development. This is the

* Cons. Hydr. Engr. (Stevens & Koon), Portland, Ore.

second of a series of hydro-electric power plants to be constructed on McKenzie River by the City of Eugene, Ore.

The object of the experiments was to ascertain (1) the effect the proposed dam would have on flood heights above it; (2) the type of baffles on the apron most effective in preventing scour; (3) the most satisfactory relation between height of dams and height of gates; and (4) the manner in which the flood-gates should be operated, with the apron and baffles selected to avoid scouring the river bed. This development consists essentially of a diversion dam to raise the river level 20 ft., a canal of 2 200 sec-ft. capacity, 5 miles in length, and a power house where this flow is utilized under 90 ft. of head, thereby creating 20 000 h. p.

The Leaburg Diversion Dam will consist of a low overflow weir with roller type of gates on the crest, 100 ft. long and 12½ ft. high, supported by piers. There are three such gates and, in addition, a 30 by 18-ft. sluice-gate, for auxiliary regulation.

Provision is made for passing 90 000 sec-ft. over the dam with all gates open. The dam must not raise flood water more than 2½ to 3 ft. higher than would occur in the river without it. A field laboratory was constructed to which water could be drawn under control from the Walterville Canal, which supplies City Plant No. 1.

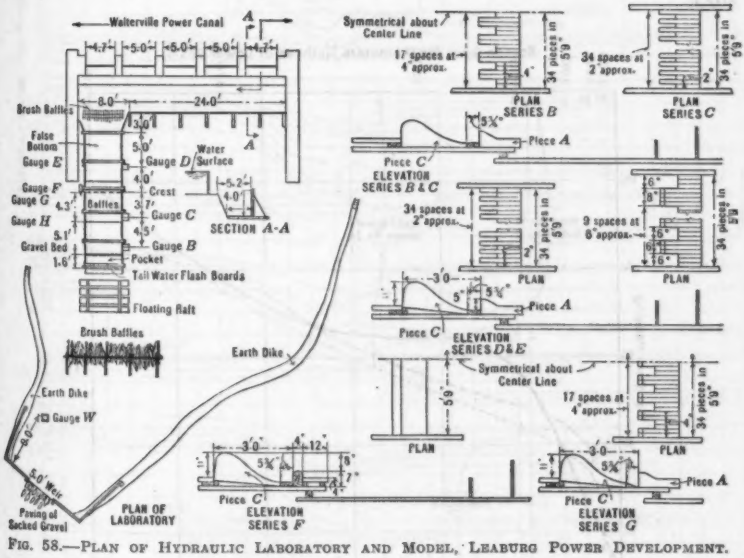

FIG. 58.—PLAN OF HYDRAULIC LABORATORY AND MODEL, LEABURG POWER DEVELOPMENT.

Fig. 58 shows a plan of the laboratory and the dam and baffles used for the six series of experiments made. Fig. 59 shows the setting of the model and baffles in the flume. It was specified that stock for Pieces *A*, *B*, and *C* be cut to the stock sizes shown and then soaked in water completely

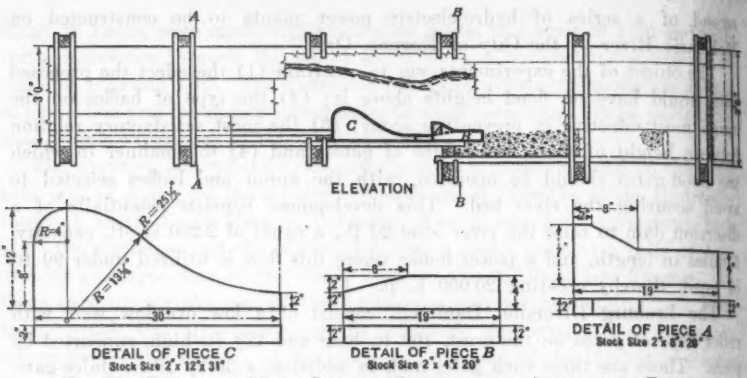

FIG. 59.—DETAILS OF MODEL DAM AND BAFFLES, WITH ASSEMBLY IN FLUME, LEABURG POWER DEVELOPMENT.

submerged for at least ten days prior to milling. After milling, the pieces were submerged in water until used. The object was to secure pieces accurately dimensioned when thoroughly saturated. It was permitted to use No. 1 clear white pine, cedar, or redwood, but all must be of the same stock.

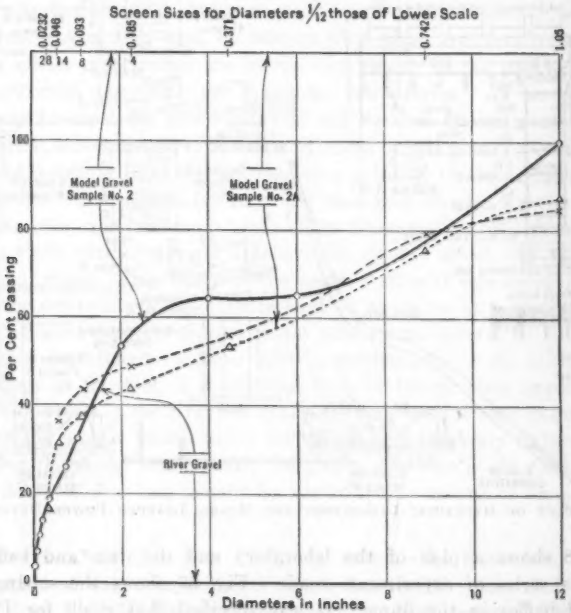

FIG. 60.—GRADING OF RIVER AND MODEL GRAVELS.

Water was drawn from the wasteways of the power canal into a 6 by 4-ft. timber flume. It was quieted above the dam by brush baffles; then it was passed over the model dam and gravel bed, dropped into a small pond, and thence, through another set of brush baffles and over the 5-ft. rectangular measuring weir.

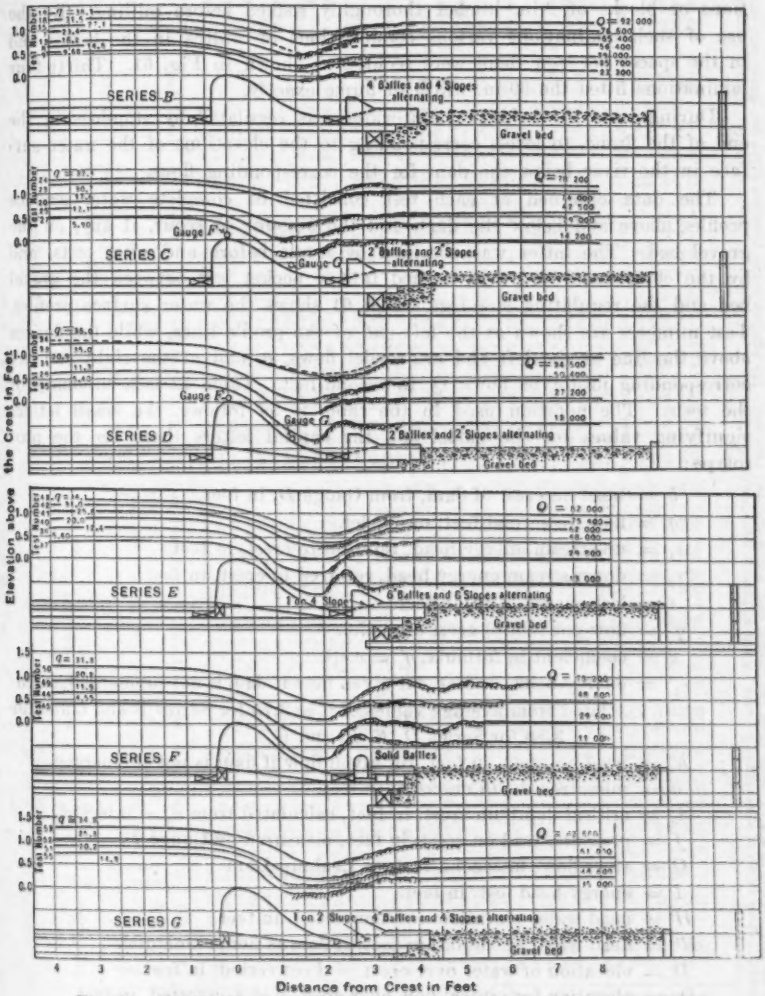

FIG. 61.—EXPERIMENTS ON MODEL DAM, LEABURG POWER DEVELOPMENT.

After passing the aprcn with its baffles, the water flowed over a bed composed of sand and small gravel graded similarly, but sized as nearly as possible to one-twelfth those of the bed of the prototype. How nearly

the prototype gravel bed was imitated in the model is shown in Fig. 60. The river gravel tested was a composite of five 100-lb. samples taken from the river bed at the dam site. The model gravels were made up from screened and recombined river sands and gravels.

As shown on Fig. 59 the model dam and baffles were made up of laminations or blocks of 2-in. lumber thoroughly soaked before milling. By the use of such laminations various combinations of widths in the baffles and in the spaces between them were secured as shown in Fig. 61. Thirty-four laminations fitted the 69-in. width of flume exactly.

During tests the height of tail-water was regulated by stop-logs in the end of the flume, to levels corresponding to the elevations of the water surface in the river below the dam for the corresponding flows.

The data obtained at each test consisted of complete water surface profiles above and below the dam, and the amount of scour, if any, on the gravel bed. The latter was obtained by levels before and after tests, and by the observance of gravel washed into a pocket left between the gravel bed and the regulating stop-logs. Fig. 61 shows the water surface profiles. Test numbers are shown at the left end of the profile lines, while the figures above the line at the left end are model flows, q, and at the right end are corresponding prototype flows, Q, in second-feet. Table 12 is a summary of the tests. The notation used in the table is as follows, the small letters signifying values for the model and the capital letters those for the prototype:

h = head on crest of dam, from Gauge D, in feet.
q = flow, in second-feet, on model.
e_1 = up-stream energy head, referred to crest, in feet.
e_2 = down-stream energy head, referred to crest, in feet.
i = lost energy head, in feet.
q' = flow per foot of crest of model.
c = coefficient in formula, $q' = c\, e_1^{\frac{3}{2}}$.
e_1' = energy head, in feet, for given flow if dam is not submerged, calculated from average values of $c = 3.75$ for Series B and C and for $c = 3.80$ for Series D, E, F, and G.
h' = head on crest, in feet, for given flow if dam is not submerged.
d = measured depth on crest, in feet.
d_c = critical depth on crest, in feet, calculated from $d_c = 0.098\, q^{\frac{2}{3}}$.
f = pressure head on crest, in feet, measured by Gauge F.
Q = river flow, in second-feet, at Leaburg Dam.
I = energy head lost, in feet.
H = head water elevation = h converted, in feet.
H' = head-water elevation, in feet, if dam is not submerged.
D = elevation of water over crest = d converted, in feet.
D_c = elevation for critical flow over crest = d_c converted, in feet.
F = elevation of pressure head on crest = f converted, in feet.

Fig. 62 shows various hydraulic curves pertaining to the experiments, all referred to the prototype.

TABLE 12.—SUMMARY OF EXPERIMENTS ON MODEL OF LEABURG DIVERSION DAM AND CONVERSION TO PROTOTYPE QUANTITIES.

Series and test.	On Model.														On Prototype.									Remarks.

* Tests 15, 16 and 17 show effect of lowering tail-water. While adjusting flash-boards for Test No. 17, tail-water was lowered too far. This obliterated the jump and produced a smooth standing wave with trough over the gravel bed, which scoured the bed. No further scour resulted after tail-water was properly adjusted and jump re-established. † Scour due to double jump.

The various gauges used are shown in Fig. 58, and are described in Table 13. In addition to the gauges in Table 13 a profile board consisting of 2 by 6-in. timber was set on edge lengthwise over the center of the flume.

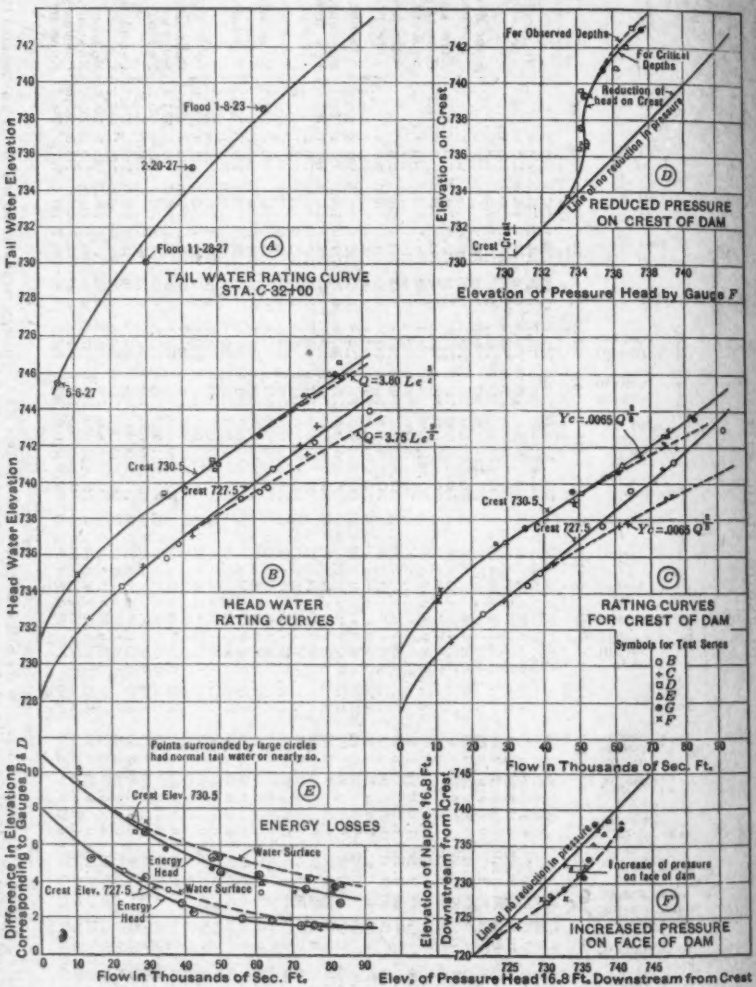

FIG. 62.—HYDRAULIC CURVES, LEABURG DIVERSION.

Distances were marked thereon up stream and down stream from the crest of the dam. Elevations were taken on each foot mark, and the longitudinal profile of the water surface was determined by measuring, with a level rod, the distances to the water surface from the top edge of the profile board.

Of the experiments made, five series were with open baffles; that is, square-faced piers with spaces between them, and one series with a solid baffle or weir the full width of the apron.

An examination of the profiles (Fig. 61) will show that in all cases where the open baffles were used the hydraulic jump occurs well on the apron. For low flows it occurs just over the baffles. As the flow was increased, it tended to move down stream, but remained on the apron.

The solid baffle in Series *F* invariably produced a double jump; the second occurred over the gravel bed, and was attended with more or less scour. The advantage of open baffles in controlling the position of the jump and in preventing scour is apparent, as it permits the use of a much shorter apron.

The arrangement of laminations used to produce various widths of baffles and openings had no effect that could be detected. This is to be expected since the retarding force is practically the same as long as the aggregate width of baffle and opening remains the same. For convenience of construction, baffles 4 ft. in width, with openings of like width between them, were adopted.

The upward slope of the openings between the baffles was 1 on 4 in all except Series *G*, in which a slope of 1 on 2 was used. No difference could be detected; hence, a 1 on 4 slope was adopted for ease of construction.

TABLE 13.—List of Gauges.

Gauge.	Kind.	Location and remarks.
D	Hook	In stilling well, with inlet 4.0 ft. up stream from crest of dam on left side of flume. Used to determine height of head-water.
B	Staff	In stilling well, with inlet 8.2 ft. down stream from crest, on left side of flume. Used to determine height of tail-water.
C	Staff	In stilling well, with inlet 3.7 ft. down stream from crest on left side. Used for tail-water height on apron. Installed after Run No. 17.
E	Staff	Piezometer connection on right side, 4.0 ft. up stream from crest. Used as check on Gauge *D*. Installed after Run No. 24.
F	Staff	Piezometer connection on right side of flume at center line of crest of dam. Used to determine pressure head on crest. Installed after Run No. 24.
G	Staff	Piezometer connection 1.4 ft. down stream on right side of flume and just above face of dam. Used to determine pressures on face of dam. Installed after Run No. 24.
H	Staff	Piezometer connection 4.5 ft. down stream from crest, on right side of flume just over gravel bed. Used to indicate pressures just below apron.
W	Hook	In stilling well in pond, 9 ft. up stream from rectangular weir. Used to determine head on the weir.

Fig. 63 shows a cross-section of the dam and a plan of the baffles as finally adopted for construction. It will be observed from Series *B* and *C* Fig. 61, that submergence of the dam begins with 15 000 sec-ft., but that the effect of submergence is not felt above the dam until a flow of 40 000 sec-ft. is reached. This is shown in Fig. 62 (*B*) for a crest elevation of 727.5.

The fall in the water surface and also the energy head lost as water passes the dam are shown in Fig. 62 (*E*). For the maximum flow of 90 000 sec-ft. the head lost is only 1.5 ft.; for the more frequent flood of 40 000 sec-ft., the drop in water surface is 3.1 ft.; and the energy head lost is 2.6 ft.

Some interesting data were secured on the cavitation effect as water passed the crest of the dam. Gauge *F* was a piezometer gauge in the side of the flume in line with the center line of the crest of the dam as shown in Series *C* and *D*, Fig. 61. It therefore registered the pressure head of the water at this point. The profile readings gave the actual depth at the crest. The difference is the reduced pressure or cavitation effect produced by the change of direction of water as it passed the crest. These data are shown at (*D*) Fig. 61. The difference amounted to 6 ft. for the higher flows.

The increased pressure on the down-stream face of the dam was similarly obtained by the profiles and piezometer, Gauge *G*. This increase in pressure is shown at (*F*) Fig. 62.

During tests with flows corresponding to 40 000 sec-ft., or more, a lead pencil, if placed beneath the nappe on the face of the dam, would play up and down on the face. In some instances its range of travel would be almost over the entire face from near the crest almost to the baffles. There was undoubtedly an oscillation of the vacuum near the crest and the increase of pressure on the face, that accounted for this phenomenon. It could not be due to eddy motion between the baffles and the face, for in that case the pencil would have risen into the nappe. Instead, it remained on the face sliding and rolling along it.

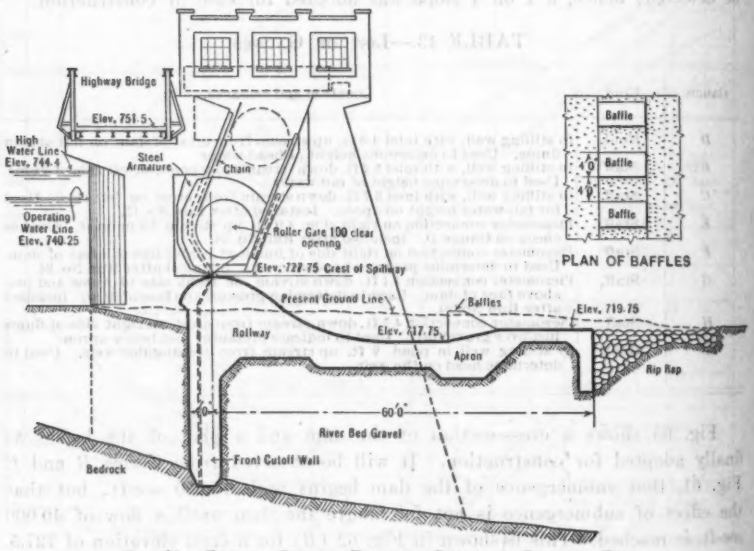

FIG. 63.—TYPICAL SECTION THROUGH SPILLWAY, LEABURG DAM.

During extreme floods the river gravels will be rolled along the bed whether or not there is a dam. If scour can be prevented at the immediate toe of the dam, it is the best that can be hoped. The experiments showed that with either type of baffles used, scour accompanied the formation of a

second wave beyond the apron, and that no scour occurred immediately below the apron. With a large flow and the tail-water held considerably lower than will actually occur, the water passed over the baffles as clear and smooth as if they were not there. A standing wave formed a considerable distance below the apron, that scooped a broad depression in the gravel bed.

In practice, such a condition can only occur if one large gate were wide open during a flood. Considerable experimenting was done with various gate openings and as a result the plan will be adopted of opening the three roller-gates together, to maintain the desired head above the dam during floods. If this plan had not been adopted, it would have been necessary to increase the height of the baffles more nearly in conformity with those used on the Pit River dams.

The writer believes the type of open baffle used on the Leaburg Dam will be more effective in maintaining a hydraulic jump on the apron than the truncated or sharp-nosed deflectors and piers used for the Pit River dams, and that either type is far superior to a solid weir.

I. C. STEELE* AND R. A. MONROE,† MEMBERS, AM. SOC. C. E. (by letter).—Floods of unusual magnitude occurred in Pit River during the latter part of March, 1928, and afforded the opportunity of observing and photographing the action of the baffle-piers at both Pit No. 3 and Pit No. 4 Dams. The maximum flow over Pit No. 3 Dam was approximately 15 000 sec-ft., with a depth of over-pour of 6.3 ft. (Fig. 64). At Pit No. 4 Dam the discharge was approximately 17 000 sec-ft. and the maximum depth of over-pour was 11.5 ft. (Fig. 65). The stilling action of the baffle-piers at both dams was highly satisfactory.

It should be observed (Fig. 66) that at Pit No. 3 Dam the two end splitter-piers are only half-piers and the sloping wing-walls were not provided with baffles. At the left wing-wall the water which was deflected from the end baffle-pier combined with the water passing directly between the half-pier and the wall and intermittently climbed the wall (Fig. 64). This action was expected, but is not considered to be of serious moment because the volume of water which rides the wall is quite small. It may be necessary at some future time to increase the side-wall protection at this particular locality by placing rip-rap on the bank above the existing concrete wing-wall.

At Pit No. 4 Dam it was observed that, for the flows noted, no better results occur on the depressed apron side, which indicates that the deeper stilling-pool is of little consequence. Unfortunately, the baffle-pier on the shallow side next to the right wing-wall was not constructed because of its location under the diversion flume. In addition, the right wing-wall is sloping as contrasted with the vertical side of the heavy division wall at the left side of the depressed apron. As a consequence there is created, along the right wing-wall, wave action which is not noticeable across the remaining width of the apron.

* Chf., Div. of Civ. Eng., Pacific Gas & Elec. Co., San Francisco, Calif.
† Asst. Chf., Div. of Civ. Eng., Pacific Gas & Elec. Co., San Francisco, Calif.

An inspection was made of the baffle-piers and the apron below Pit No. 3 Dam shortly after the flood had subsided to determine what damage had occurred. Fig. 66 indicates the location and extent of certain pitting and erosion which had taken place since the completion of the structure. About midway between each of the splitter-piers small holes from 3 to 12 in. deep had developed apparently by the grinding action of rocks caught and held by the eddy which probably existed at this point. Approximately 75 cu. yd. of rock and débris were left on the apron at the completion of the construction work.

The faces and edges of the concrete piers show no erosion whatever except that two of the corners of the down-stream pier near the left wing-wall were chipped to a depth of 3 or 4 in., presumably by large rocks from slides which developed on the hillside above the wall. Several large rocks which evidently came from this location were found lying on the apron. These slides were due to a saturated condition of the hillside occasioned by heavy rains and, in time, this slope will become stabilized.

The efficiency of the baffle-pier designs in preventing erosion is indicated by the condition of the river bed immediately below the concrete apron. An area of limited extent on the right side has been scoured out approximately 1 ft. in depth. In the center of the channel, rocks and gravel have piled up several feet above the apron level. This material undoubtedly came from the débris which was left on the apron when the dam was constructed and from the slides on the hillside above the wing-wall, as previously noted. The area on the left side of the channel has not been disturbed materially.

The experiments mentioned by Mr. Ewald confirm the results of similar experiments in the Pit model tests. It is believed that baffles of the shapes and in the locations shown in Mr. Ewald's experiments might form an obstruction which would be subject to considerable shock. In the Pit River experiments it was soon observed that the best results were obtained by forcing the water to dissipate its energy within itself, the splitter and baffle-piers being placed rather far apart and acting more as guides to create cross-currents which would be directed largely against each other. Observations, although confined to the surface, indicated that the water throughout its entire depth was under great turmoil, and that the major portion of the kinetic energy was being destroyed by this action. Generally speaking, it is admitted that obstructions to the free and direct flow of the water away from the dam should be avoided, but it is obvious that special conditions encountered at a particular dam site must govern. As previously stated, the foundation and river-bed conditions of both Pit No. 3 and No. 4 Dams were quite unusual.

In the Pit model experiments the control weir mentioned by Mr. Ewald and others was placed at the lower end of the apron and at the point of free fall to the stream bed below. It was thought that this would simulate the natural barrier offered to flood waters by the stream bed below the aprons of the main structures. No such control weirs were actually constructed and, consequently, no secondary drop exists.

Mr. Scheidenhelm correctly states that "the most reliable criterion for comparison of the various means of preventing scour is the action on the

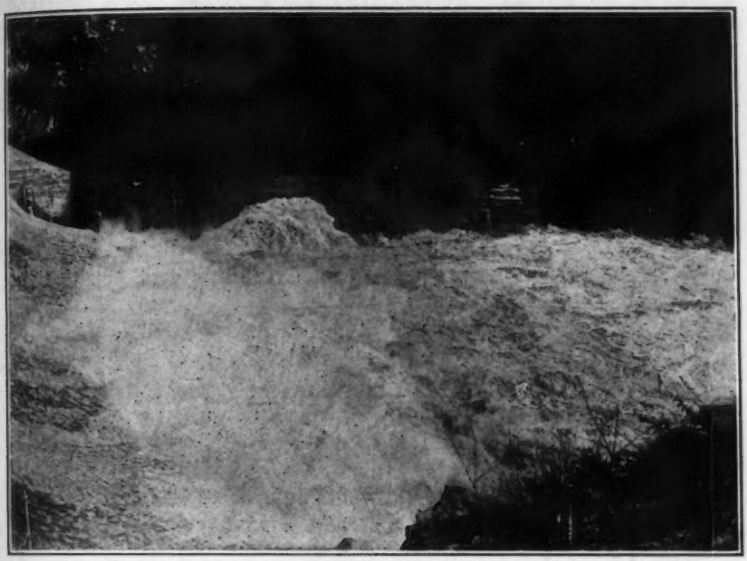

FIG. 64.—BAFFLE-PIERS AND APRON OF PIT RIVER DAM NO. 3, UNDER DISCHARGE OF 12 000 SECOND-FEET.

FIG. 65.—LOOKING DOWN ON BAFFLE-PIERS OF PIT RIVER DAM NO. 4, UNDER DISCHARGE OF 10 000 SECOND-FEET.

stream bed itself", and more conclusive evidence regarding the advantages or disadvantages of this design will be available after several years of actual performance. Results of three years' operations of Pit No. 3 Dam and one year of Pit No. 4 Dam indicate that the structures as designed are functioning in a very satisfactory manner.

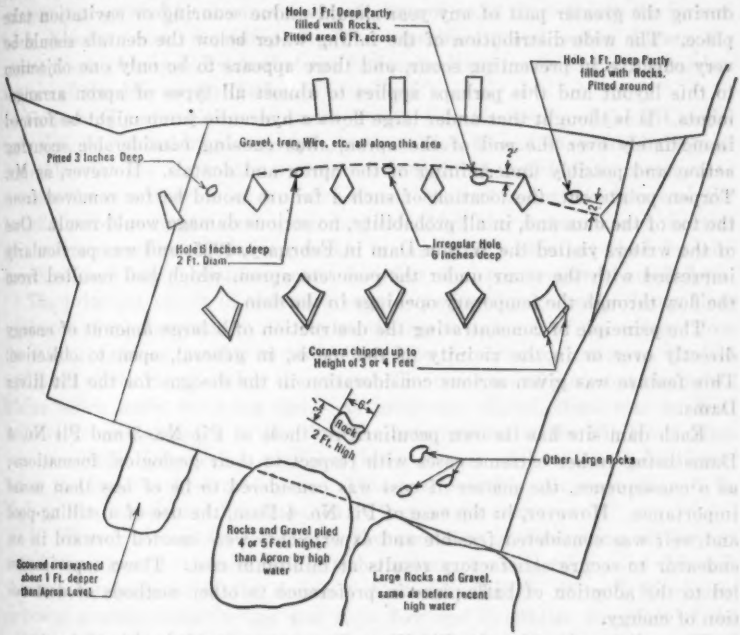

FIG. 66.—CONDITION OF THE APRON OF PIT NO. 3 DAM, MAY, 1928.

It is felt that the appearance of the surface and movement of currents of the water, a study of the action in and about the piers, and, what is perhaps more to the point, the smoothness of the flow immediately down stream, should afford a reliable indication of the effectiveness of the stilling device. A close study of the photographs of both tests and actual floods, such as Figs. 64 and 65, cannot but impress one with the excellent results from the standpoint of destruction of kinetic energy.

The experiments described by Mr. Sherman are very instructive. The principal differences between the design of the baffles of the Gatun Spillway Dam and those of the Pit River Dams, lie in the shapes and positions of the piers and in the bucket of the dam. It is thought that the Pit River design will cause a destruction of a greater percentage of the energy within the water itself. Published data on the Gatun Spillway were studied with a great deal of interest in connection with the preparation of designs for the Pit River Dams.

The data submitted by Mr. Torpen describing the tests for the Bull Run Dam are exceedingly interesting and enlightening and the plan adopted appears to afford a very satisfactory solution of a difficult problem. It would be very instructive to learn of the scouring effect of the fast moving water over the apron, particularly in the vicinity of the lower end of the bucket. No doubt, as in the case of the Pit River Dams, suitable repairs can be made during the greater part of any year should undue scouring or cavitation take place. The wide distribution of the falling water below the dentals should be very effective in preventing scour, and there appears to be only one objection to this layout and this perhaps applies to almost all types of apron arrangements. It is thought that under large flows a hydraulic jump might be formed immediately over the end of the apron, thus causing considerable scouring action and possibly undermining of the apron and dentals. However, as Mr. Torpen points out, the location of such a failure would be far removed from the toe of the dam and, in all probability, no serious damage would result. One of the writers visited the Wilson Dam in February, 1925, and was particularly impressed with the scour under the concrete apron, which had resulted from the flow through the temporary openings in the dam.

The principle of concentrating the destruction of a large amount of energy directly over or in the vicinity of the toe is, in general, open to objection. This feature was given serious consideration in the designs for the Pit River Dams.

Each dam site has its own peculiarities, those at Pit No. 3 and Pit No. 4 Dams being rather extreme cases with respect to their geological formations; as a consequence, the matter of cost was considered to be of less than usual importance. However, in the case of Pit No. 4 Dam, the use of a stilling-pool and weir was considered feasible and experiments were carried forward in an endeavor to secure satisfactory results at minimum cost. These experiments led to the adoption of baffle-piers in preference to other methods of destruction of energy.

The splitter-piers for the Pit River Dams are provided with 12 by 12-in. by ½-in. steel-plate noses, and no concern has been felt regarding the possible danger from floating logs. This might be more of a problem in other sections of the country.

The data submitted by Mr. Parshall relative to the Halligan Dam on the North Fork of the Cache La Poudre River are very interesting and indicate that in some cases the scour on an unprotected foundation below a relatively high dam may be of little consequence. The determining factor is without doubt the hardness or the resistance of the foundation to erosion. This cannot always be discovered by inspection, and, in some instances, over-pour dams founded on apparently hard rock have suffered extensive erosion. This particularly applies in cases where the over-pour is not confined to the center of the dam, but is allowed to spill across the entire crest length, in which case erosion of the canyon walls and the abutments is probable.

The description by Mr. Winter of the Martin Dam Spillway which embodies a return-flow conduit at the apron, is of interest. Doubtless such an installation will reduce the effective head at the end of the apron. The

directing of the water sheet downward at jump-off seems important to prevent the over-pour sheet from hurdling the piers and it is believed that for all flows over the Pit River Dams the water sheet will plunge into the basin waters rather than be deflected and perhaps carried along the surface. It is also necessary that there be sufficient relief below to permit the reversal of the flow mentioned by Mr. Winter. During the model tests the existence of a reverse current was verified by the movement of chips of wood thrown into the stream some distance below the jump-off. The experiments and action during the recent floods clearly indicate that the hydraulic jump more nearly approaches the toe of the dam as the discharge increases.

Undoubtedly a more precise means of recording the results of the Pit model tests than is afforded by photographs, such as Figs. 64 and 65, would have been desirable. At the time, this was not considered of sufficient importance to warrant the construction of a model stream channel below the dam and the installation of accurate measuring devices. Also, the storage above the test dam was too small to make it possible to maintain a constant head for any length of time over the spillway crest for other than comparatively small flows.

The principal object of the tests was to confine the hydraulic jump close to the toe of the dam, and to destroy on the apron as much of the energy from the falling water as possible in order to reduce the scouring action on the bed and banks of the stream below the apron. The two rows of piers tend to create basins which assist in doing this. As previously stated, there was no final back-water weir although at the time the construction of the Pit No. 3 Dam was completed there was a very low natural weir of boulders immediately below the lower end of the apron. This was probably not more than 3 ft. high on the average and has since partly been swept away.

Mr. Winter's remarks relative to the necessity of dissipating all energy within the water if the structure is to be lasting, are well taken, and this was the primary purpose of the design. A study of Figs. 64 and 65 clearly indicates a tremendous boiling and cross flow and illustrates the effect of the water impinging on itself and a comparatively even flow at the lower end of the aprons. All the energy cannot, of course, be so dissipated and some wear or scouring of the concrete is anticipated. In this regard it is interesting to note that during the model tests only two six-penny nails were required to hold the curved baffle-piers in position on the apron. However, in the final plans, the concrete piers and apron were designed and reinforced to withstand the full force of the water sheet across the entire cross-section area of the piers. This did not lead to any unusual or extreme construction. A part of the apron slab was designed to act with the pier to prevent possible over-turning. No fear is felt that the apron will be broken up by the action of the water. Should any of the concrete protective work show signs of dangerous wear, it is accessible for repair during the major part of the year, as the power house takes the entire river flow, except during flood periods in the spring months.

Mr. Bauman has submitted a very interesting mathematical analysis of a subject which is particularly difficult to treat analytically. His basic formulas for determining the length of river bed which should be protected

below a dam are well established and should be of assistance to engineers who in the future may be confronted with problems of this character. In particular, his method will be of value in pointing the way for further research, but in the final analysis it is believed that investigation by means of models and observation of completed structures will be necessary to obtain data which can be relied on with certainty.

Reference to the notched or dental weir method of protecting the down-stream channel from scour has been made by several discussors and there seems no doubt that this device might be used to advantage in many cases.

Mr. Stevens has submitted an enlightening discussion particularly in that he presents data obtained from a number of tests on models using the dental or notched weir to prevent erosion. Apparently, the situation at Leaburg had been carefully analyzed before deciding to use the dental weir to the exclusion of other methods of preventing scour. This series of experiments is especially noteworthy in that data were secured giving the complete profile of the water surface under the various tests. The effect of the scour on the stream bed was also determined. It is to be noted that the solid weir did not give as satisfactory results as the notched type, which fact could be inferred from the Pit River model tests. The data obtained as to the height and location of the dentals to give the best results should be of assistance to future investigators. The observation that a considerable percentage of submergence was necessary before the up-stream water level was affected, was to have been expected from results obtained in other investigations, but might easily be overlooked by an engineer not familiar with this phenomenon.

In conclusion, it might be observed that each discussor presents some particular method of handling the problem of scour below dams, but that none of the discussors apparently has utilized a baffle-pier design similar to the type used below the Pit River Dams. The basic idea of the Society's Special Committee on Irrigation Hydraulics in having this paper published was to bring out additional information regarding other successful methods of preventing scour below dams, and it is felt that in the many discussions offered much valuable data have been accumulated and that a great deal of attention is being given to this problem.

The authors wish to express their appreciation for the many contributions to their paper. Acknowledgments are also due the following engineers who were in immediate charge of the tests: Walter Dreyer, Assistant Engineer in Charge of Design, Grover C. Green, Field Engineer, Clinton de Witt, Assistant Engineer, and Arthur W. Kidder, Assistant Field Engineer, all Associate Members of the Society. The engineering for Pit No. 3 and Pit No. 4 projects was under the direction of A. H. Markwart, M. Am. Soc. C. E., Vice-President in Charge of Engineering, Pacific Gas and Electric Company. John D. Galloway, M. Am. Soc. C. E., was Consulting Engineer on both dams.

Paper No. 1707

METHODS USED IN THE CONSTRUCTION OF TWELVE PRE-CAST CONCRETE SEGMENTS FOR THE ALAMEDA COUNTY, CALIFORNIA, ESTUARY SUBWAY*

By Alvin A. Horwege,† Assoc. M. Am. Soc. C. E.‡

With Discussion by Joseph A. Kitts, Assoc. M. Am. Soc. C. E.

Synopsis

This paper describes in detail the construction of the twelve pre-cast concrete segments of the Estuary Subway between Oakland and Alameda, Calif. It includes a brief statement of the nature of the work and of general conditions, a description of the mixing plant, distributing system, and forms, and the method used in pouring the different sections of a segment.

Purpose of Construction

The site of the Oakland-Alameda Estuary Subway was formerly occupied by the railroad bridge of the Southern Pacific Railroad Company and used as a suburban connection between Oakland and the Alameda Pier, and is within several hundred yards of the highway and street-car bridge connecting Oakland and Alameda.

Because of the heavy increase of the shipping in the Oakland Estuary these bridges had become a serious menace to the traffic in the Upper Estuary and, at the solicitation of the War Department Engineers, Alameda County began an investigation which resulted in the approval of plans and the voting of bonds for the construction of an estuary subway which will eliminate both bridges and give the Upper Estuary Harbor an unobstructed channel for shipping.

‡ Mr. Horwege resigned from the Society on February 9, 1929.

Nature of Work

Early in 1925, the California Bridge and Tunnel Company was awarded a contract to construct the Estuary Subway between Oakland and Alameda, Calif. In general, the work consisted of two open-cut approaches totaling 930 ft.; two portal buildings totaling 136 ft.; a rectangular section on the Oakland side, 342 ft. long; a transition section, 37 ft. long, connecting the rectangular to the circular section; a circular section built in place on the Oakland side, 578 ft. long; and twelve pre-cast concrete tubes, each 203 ft. long, to be built in Hunters Point Dry Dock, floated across the Bay, sunk in place, and joined under water.

General Conditions

Time was an important element in the construction of these tubes. The Bethlehem Shipbuilding Corporation was reluctant to permit the dock to be tied up a reasonable length of time, from the standpoint of economy to the contractors. The rental of the dock was limited to six months, after which a severe penalty was to be added to the contract rental. The result was that the contractors were forced to provide a rather elaborate plant, considering the quantity of concrete to be poured—29 000 cu. yd.—and to use steel forms throughout. To permit rapid erection, three full shifts of men were employed during the construction period.

Delivery of Material

Practically all the material, except the cement, was delivered in barges. (See Fig. 1.) The cement was hauled from the railroad, a distance of 2 miles, in trucks as it was used. At first an attempt was made to store a reserve supply on the job, but because of rehandling, this proved more costly than to haul as it was needed.

The rock and sand were delivered in barges of 400-ton capacity and unloaded with an electric hoist and steel derrick equipped with a 60-ft. boom and a 1-yd. clam-shell bucket. The material was dumped into a receiving hopper at the end of the dock, from which it was conveyed by a system of 24-in. belt conveyors to a storage pile. These piles were confined by wooden retaining walls filled with the material to give them stability. The first conveyor was 94 ft. long, and dumped on the second conveyor, 114 ft. long, at an angle of about 15°; and this, in turn, delivered to a movable distributing conveyor, 40 ft. long, which spread the material in piles, about 75 ft. long, at right angles to the belt conveyor. The sand was segregated from the rock and, of course, could not be conveyed from the barge at the same time as the rock.

Mixing Plant

Adjacent and parallel to the stock piles a ramp, 20 ft. high, was erected, from which a crane, fitted with a clam-shell bucket, fed the hoppers on top of a two-story mixing house. (See Fig. 1.) Two 1-yd. concrete mixers were placed on the ground floor of the mixing house. Batchers for the rock, and inundators for the sand, a separate set for each mixer, were placed on the second floor. The inundators, because of the almost uniform moisture content

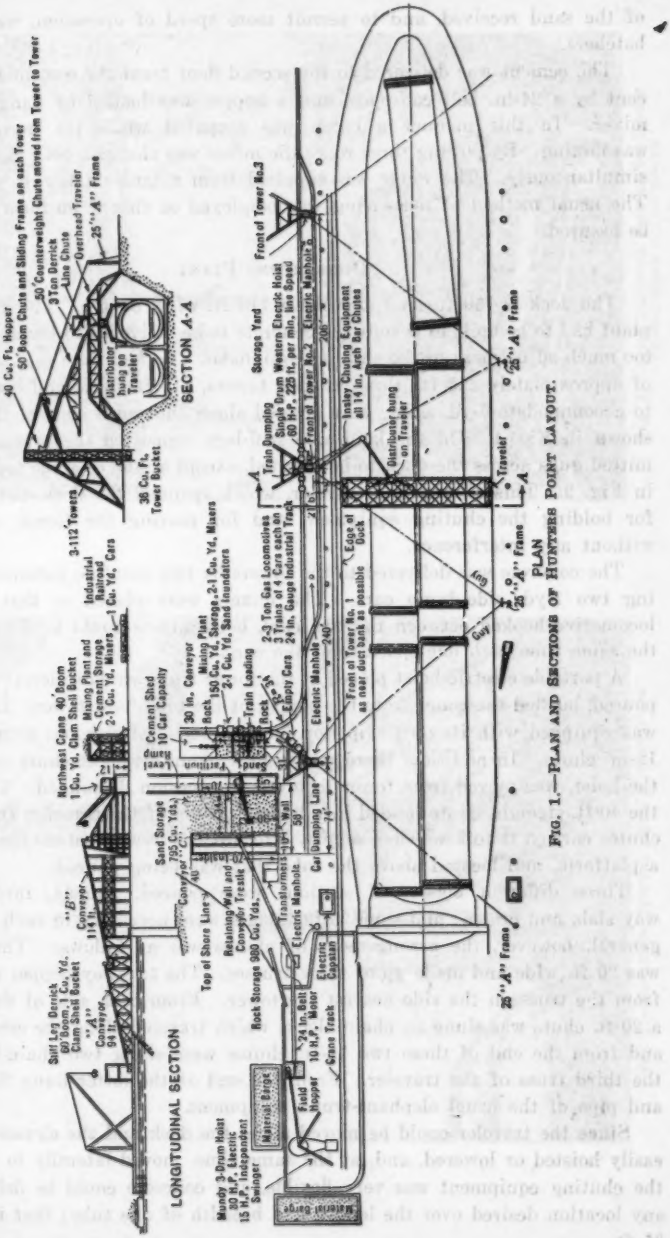

FIG. 1.—PLAN AND SECTIONS OF HUNTERS POINT LAYOUT.

of the sand received, and to permit more speed of operation, were used as batchers.

The cement was delivered to the second floor from the cement house adjacent by a 24-in. belt conveyor, and a hopper was loaded by hand above the mixer. In this manner a batch was prepared while the previous batch was mixing. By pulling three ropes the mixer was charged, both mixers acting simultaneously. The water was supplied from a tank on top of each mixer. The usual method of measuring was employed so that a uniform mix could be assured.

Distributing Plant

The dock is 750 ft. long and about 110 ft. wide, on top. The distributing plant had to be built to permit the concrete to be delivered to the dock without too much adjustment of the chuting equipment. To facilitate this, at intervals of approximately 225 ft., three wooden towers, 112 ft. high, and large enough to accommodate 1-yd. skips, were erected along the south edge of the dock as shown in Fig. 1. On the land side stiff-legs supported the towers and permitted guys across the dock to be omitted, except at the extreme top as shown in Fig. 2. This allowed the traveler, which spanned the dock and was used for holding the chuting equipment and for moving the forms, to operate without any interference.

The concrete was delivered to the towers by two gasoline locomotives hauling two 1-yd. side-dump cars. The mixers were placed so that with the locomotive hooked between the two cars, both mixers could be discharged at the same time with one spotting of the cars.

A portable electric hoist placed at the tower from which concrete was being poured, hoisted the concrete to the hopper at the top of the tower. Each tower was equipped with its own skip, top hopper, and a steel boom with 40 ft. of 12-in. chute. In addition, there was a 40-ft. counterweight chute which, like the hoist, was moved from tower to tower as occasion demanded. The end of the 40-ft. straight chute landed in a hopper on top of the traveler, from which chutes carried it to a wooden hopper, fitted with two-way gates operated from a platform, and located above the tube that was being poured.

Three different classes of sections were poured, namely, invert, roadway slab, and crown; and some adjustments were necessary in each case. In general, however, the arrangement of chutes was as follows: The traveler was 20 ft. wide and made up of three trusses. The two-way hopper was slung from the truss on the side nearest the tower. From each side of the hopper, a 20-ft. chute was slung on chain-blocks which traveled along the center truss, and from the end of these two 15-ft. chutes were slung two chain-blocks on the third truss of the traveler. From the end of the latter hung the hopper and pipe of the usual elephant-trunk equipment.

Since the traveler could be moved along the dock and the chutes could be easily hoisted or lowered, and, at the same time, moved laterally to the dock, the chuting equipment was very flexible, and concrete could be delivered to any location desired over the length and breadth of one tube; that is, 203 by 35 ft.

Concrete

Table 1 gives the various gradings for the Class "A" mix used in the construction of the tubes, proportioned for 1 cu. yd. of concrete in place and certain characteristics based on a series of tests.

TABLE 1.—Concrete Data.

Grading, *n*	0.53	0.54	0.55	0.56	0.57
Fineness modulus of sand	5.87	5.91	5.95	5.99	6.03
Cement, sacks	8	8	8	8	8
Sand, in cubic feet	11.19	11.7	11.4	11.2	11.9
Rock, in cubic feet	21.0	21.4	21.8	22.2	22.6
Ratio of cement to voids	1.28	1.26	1.24	1.21	1.19
Ratio of sand to voids	1.14	1.09	1.05	1.01	0.98
Ratio of mortar to voids	1.96	1.91	1.86	1.81	1.76
Density	0.82	0.825	0.833	0.842	0.85

A shrinkage of 3% in setting was allowed, and the proportions produced not less than 1 cu. yd. of concrete in place.

The grading, *n* (0.55), and the fineness modulus (5.95), were most satisfactory for the conditions and, with a slump of from 6½ to 7½ in., the concrete developed a strength of 3 000 to 3 500 lb. in 28 days.

Forms

On the Hunters Point work the inside crown forms were of steel and the outside crown forms had steel ribs and wooden lagging. Wherever possible, forms were mounted on trucks and ran on tracks from one tube to the next, except where it was necessary to transfer them from one side of the dock to the other, as shown in Fig. 3. For the roadway slab and the crown, the original intention was to pour one-third of a tube at a time and the complete tube in the case of the invert. This, it was found, caused too much delay because of the time necessary for the setting of the concrete, and additional steel forms were constructed where wooden forms could not be used, and wooden forms were built on the job in the other instances.

Preliminary Work

It was possible, with considerable crowding, to lay five tubes in the dock at one time, except for those with horizontal curves, in which instance only four could be laid. When three straight tubes had been completed, they were floated out. The remaining two were only partly finished and were flooded without any damage. This allowed prompt resumption of the work after flotation. The tubes were laid in two rows on each side of the dock, with one tube at the bow end of the dock at an angle to its axis, the others being parallel.

Because of the enormous load on the floor of the dock, 5 000 tons for each tube, the weight was distributed by 12 by 12-in. timbers placed longitudinally on 2-ft. centers, on the floor of the dock and shimmed where a depression did not permit full bearing. Across this layer were placed 12 by 12-in. timbers, 38 ft. long, spaced to conform with the invert forms and, roughly, on about 3½-ft.

centers. These timbers were leveled carefully at a fixed elevation so that calculations for the setting of forms were the same for all tubes. Great care was taken to provide uniform bearing in this case and thus prevent excessive settlement. Fig. 4 shows the subsequent stages of construction work herein described.

Saddles

The center portion of the tube for a width of 10 ft., 1½ in. on each side of the center line, was supported on wooden saddles which remained in place until the tube was floated. The center section was made from 4 by 16-in. timbers, 7 ft. long. Bolted to these at one end and to 6 by 12-in. posts at the other, were secondary saddles made from 4 by 12-in. timbers. They were also supported twice in the middle of the span with 4 by 6-in. posts. All saddles were cut to conform with the outside curvature of the completed tube. The secondary saddles were unbolted just prior to floating the tubes and were pulled from under the tube afterward. This was necessary in order to provide clearance for the end bracket at the end of the tubes. Fig. 5 is a view of a lower cradle and outside form, showing the method of erection.

Outside Invert Forms

On each side of the wooden saddles were placed the outside invert forms. These were steel ribs built as cantilevers and tied together into 19½-ft. sections. There were seven ribs with wooden nailing strips fastened to curved angles at 3 ft. 3-in. centers. Between these were wooden ribs, 2 in. wide, to reduce the span. (See Fig. 5.) Each invert section was separated from the next by 22-in. spacing which permitted them to be swung, in the case of the horizontal curves, without interference.

After these invert forms were set in place with cranes, they were lined and leveled by hard-wood wedges on top of 8 by 12-in. longitudinal timbers and braced with struts to the floor of the dock. The lagging of 2 by 12-in. material was next laid on top of the invert forms and the wooden saddles up to the horizontal diameter. As this lagging served a double purpose, that of the outside forms and the protection for the water-proofing, and remained on the tube, it was not nailed to the form ribs except to draw a warped end down. Outside invert forms were provided for two complete tubes.

End Brackets

At each end of the tube the design specified an end bracket, which consisted of a square block of concrete through which the circular portion of the tube passed, as shown in Fig. 6. These served a double purpose; that is, as bases for landing the tubes in place on concrete blocks, and for joining the tubes. The forms for the end brackets were of steel, except for the wood bottom which remained in place until the tube floated off it. There were four complete forms for the invert; two inside rings; two outside sets of plates up to a little above the horizontal diameter; and one form for the top outside and the end face.

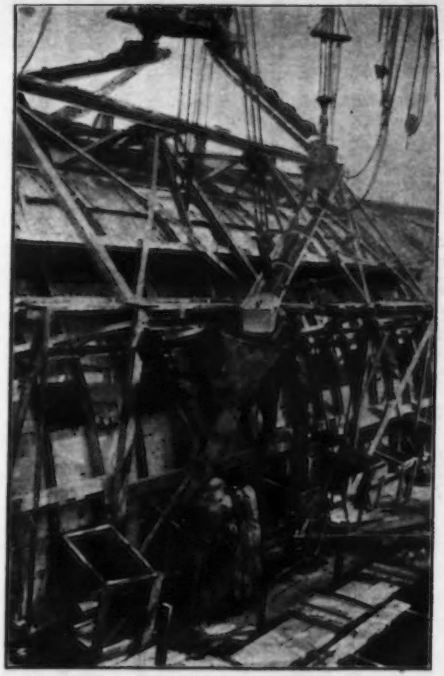

FIG. 7.—POURING CONCRETE IN CROWN SECTION.

Invert Water-Proofing and Steel

After the invert lagging and the end bracket invert forms were placed, the water-proofing for the tube, below the horizontal diameter, was laid on the lagging and ended by metal flashing in the end brackets. The water-proofing consisted of three layers of cotton fabric in hot asphalt. The bottom 20 ft. was next covered with a 1-in. layer of grout to protect the water-proofing from the reinforcing steel that was next placed. The steel was set on 2-in. concrete blocks 2½ in. high. It was found that the weight of the steel forced the blocks through the water-proofing unless it was protected.

Inside Invert Forms

The inside invert forms were made of steel and were hung to the outside forms by means of steel brackets and bolts. The bolts passed through the water-proofing, the holes being later patched. They extended from a point approximately level with the bottom of the roadway slab to a point 8 ft. from the center of the tube. This left an opening 16 ft. wide in the bottom of the tube, which was supposed to be screeded to conform to the inside curvature. Because it was necessary to pour the concrete rather wet so that it would flow properly around the network of steel, it was found that the steel forms had to be supplemented with wooden sections 4 ft. wide to reduce the opening to 8 ft. Both the steel and wooden forms were securely fastened with ⅞-in. bolts to the reinforcing steel and rested on the 2½-in. concrete blocks on top of the steel. Four of the tubes had an 8-in. longitudinal wall under the center of the roadway slab. A projection, 16 in. high, was formed in this opening. Otherwise, the concrete was screeded and finished smooth while being poured. The form sections were 22 ft. long and a sufficient number for one complete tube was provided.

Invert Concrete

The entire invert, which contained about 715 cu. yd., was poured continuously and required about 11 hours to complete. For the first half of the tube, the bottom was filled to the lower part of the form. The chutes were then changed to the outside and the sides filled to the top. At the same time the concrete would run forward and fill the bottom ahead of that previously poured. Sometimes it was found advisable to switch back and fill the bottom for the remainder of the distance, but the bulk of the concrete was poured at the top and allowed to run down along the outside forms. Before the top was set too hard it was worked by hand to conform to the longitudinal joint prescribed by the County Engineer. This included a key to which was fastened either a copper or galvanized water-stop 10 in. wide, one-half of which was in the invert concrete. The forms were stripped as soon as the concrete had set sufficiently and all irregularities were smoothed off and plastered.

Roadway Slab Forms

Within 10 hours after the invert was poured four rails were laid on the concrete on longitudinal stringers properly spaced and braced to take the trucks

of the roadway forms. These forms were then rolled out of the previous tube on to this track and jacked up to grade. The forms consisted of three sections, 21 ft. 8 in. long, mounted on eight trucks and made of steel. Between them were suspended two sections 16½ ft., made of wood, on the job, and sheathed with No. 10 gauge plates. Each section was separated along the center line and, in the case where the center wall was under the road slab, vertical forms with suitable turnbuckles for adjustments were suspended to these forms. In other cases, the opening between them was covered with a No. 10 gauge plate. On the outside edge were hinged wing forms which were swung up against the invert concrete by turnbuckles and then securely held by wooden struts. The wooden forms were held by wooden posts and wedges.

As soon as the forms were set to grade the road-slab steel was placed and side longitudinal forms of wood set in between the steel were built. Screeds, all the interior fixtures, and bulkheads at the end, were placed and the concrete for one-half the tube was poured. This amounted to about 158 cu. yd.

The forms were allowed to stand for 48 hours when they were collapsed and moved either to the other half of the same tube, or to the next tube.

Reinforcing Traveler for Crown Steel

Twenty-four hours after the road slab was poured, two 50-lb. rails were laid on top of longitudinal stringers. The reinforcing traveler was then moved on to the road slab and jacked into place. This traveler consisted of four sections, each 20 ft. long. Three sections were mounted on trucks, and the fourth was suspended by 12 by 12-in. stringers between two of those on the trucks. This arrangement was used only when moving; when spotted, the fourth section was jacked up directly from the road slab. The others had jacks mounted on the trucks. All were provided with turnbuckles for spreading to the proper width, and collapsing after the steel was in place.

Each section was made up of a steel bed-frame, on which were mounted three wooden lateral trusses. Running longitudinally were metal angle-bars at intervals of about 10 ft., which later were supplemented by wooden members between, and all built to conform to the prescribed radius of the reinforcing steel, that is, 16 ft. 2½ in. Each section was separated about 5 or 6 ft. according to the needs and closed with spliced angles. Fig. 4 is a view of the reinforcing steel traveler with crown steel in place.

When the traveler was set to grade and spread to the proper width, the arch or crown reinforcing steel was placed on it. As in the invert, there were two rings of this tied together with longitudinal steel and also to the invert rings which protruded from the invert concrete. The ring steel varied from ¾ in. to 1 in., according to the tube, and was spaced on 12-in. centers. The longitudinal steel was ¾ in. throughout and was spaced on 6-in. centers.

Outside Crown Forms

The original outside crown forms were made up of three sections each 21 ft. long. Each consisted of two pairs of trusses hinged at the top and heavily cross-braced between. To this frame was bolted 3 by 12-in. wooden lagging

When the length was increased to make possible the pouring of one-half the tube instead of one-third, two more 15-ft. sections were built of similar design. Four rows of doors were provided on each side through which the concrete could be poured and a 10-ft. space, where there was no lagging, was left at the top.

The bottom rested on top of the outside invert forms at the horizontal diameter and was bolted securely to it. Just above this point holes were provided to allow a row of 1¼-in. bolts to pass to the inside crown forms. These were spaced about 4-ft. centers and were the only lateral support for these forms. When these forms were set, hook-bolts were passed through holes provided at intervals and hooked to the reinforcing steel and tightened. The reinforcing traveler was then collapsed and moved out to the next set up. Fig. 4 shows a view of an outside crown form in place; also, a section of the outside crown form being lifted and moved with the gantry.

Inside Crown Forms

The inside crown forms were next moved into place under the reinforcing steel which was suspended from the outside crown forms by the hook-bolts. These forms consisted of three sections, 23 ft. long, each mounted on trucks, as shown in Fig. 3. Two sections, 15 ft. long, were built in San Francisco, Calif., when the "pour" was increased, and were suspended between the original sections. The first three sections were provided with jacks for raising and steamboat ratchets for spreading to the proper width. The others had no such mechanism, but when bolted to the first were rigid enough to follow the others. All were hinged at the top.

The general design consisted of a heavy bed-frame mounted on trucks with two heavy pairs of trusses rigidly cross-braced and covered with No. 10 gauge plates. A heavy waler ran longitudinally just above the horizontal diameter to take the 1¼-in. through bolts from the outside crown forms. Near the bottom was a hinged wing form. When moving, this was hooked up and kept there until the form was set at the proper grade, and spread when it was lowered to a sloping wooden filler strip. Struts were then placed from the track stringers to the base of these wing forms and wedged, and the jacks were slacked off. The forms then rested on the sloping filler pieces and became a rigid self-contained unit.

After the 1¼-in. through bolts were set, the interior fixtures placed, and a bulkhead was provided at the center of the tube, the forms were ready for concrete. Horizontal and vertical curves were formed by means of tapered filler pieces between the sections of forms. These were carefully calculated and the forms had to be spotted accurately to make them conform to the required curvature.

End Bracket Form

As soon as possible after the outside crown forms were placed, the back top of the end bracket form was set. For ease in handling, this was divided

into three pieces and the reinforcing steel for the portion was placed against it. The front section was next placed and the form was ready for pouring.

Crown Section

The crown section amounted to about 700 cu. yd., for one-half the length of the tube and was poured in about 12 hours. This was divided into three operations. The first was through the lower row of doors. (See Fig. 7.) The steel was spread to allow the hopper chutes to be inserted into the center of the wall. These hopper chutes had a bend in the spout so as to turn the concrete in a vertical direction and prevent the rock from hitting the steel and separating from the mortar. There were 13 to 14 chutes on each side, placed directly opposite in pairs. Ten men on a side were stationed between the forms to tamp and spread the concrete while it was being poured. When the forms were filled to the row of doors, the hoppers and chutes were raised to the next row, the lower doors were closed, and the process was continued. When the forms were filled to the second row they were closed and the chutes were raised to the top opening and the remainder of the concrete was poured from that point. The top of the end bracket was poured last. Six men with air hammers vibrated the inside crown forms during the pouring.

Forty-eight hours after completing the "pour" the outside crown forms were moved to the next position. The outside invert forms were moved at this time, also. Twenty-four hours later the inside crown forms could be moved.

Water-Proofing and Lagging

As soon as the outside crown forms were moved men with chipping hammers smoothed up the concrete so that the water-proofing would not be injured. Scaffolding was then set up and the upper half of the tube was water-proofed. The lagging, for protection, was then installed and hoop rods every 3 ft. held it in place. Temporary wooden forms were set up against the lagging below the horizontal diameter to hold that lagging against the concrete after the invert forms were removed and before the hoop rods could be placed all around the tube. As soon as the rods were tightened these wooden forms were removed.

Concrete Bulkheads

Bulkheads were built to close the ends of the tubes for purposes of flotation and submersion. Below the roadway slab a heavily reinforced concrete bulkhead was built. Wooden forms were used in this work.

Wood and Steel Bulkheads

Above the roadway slab the construction was varied to suit the pressure. Under high heads 24-in. steel I-beams were set vertically at 1-ft. centers, against a shoulder provided in the end bracket. They were covered with 6 by 8-in. timbers, laid flat, and then sheathed with 1 by 6-in. tongue-and-groove stock. The whole was water-proofed, the edges being run into a keyway pro-

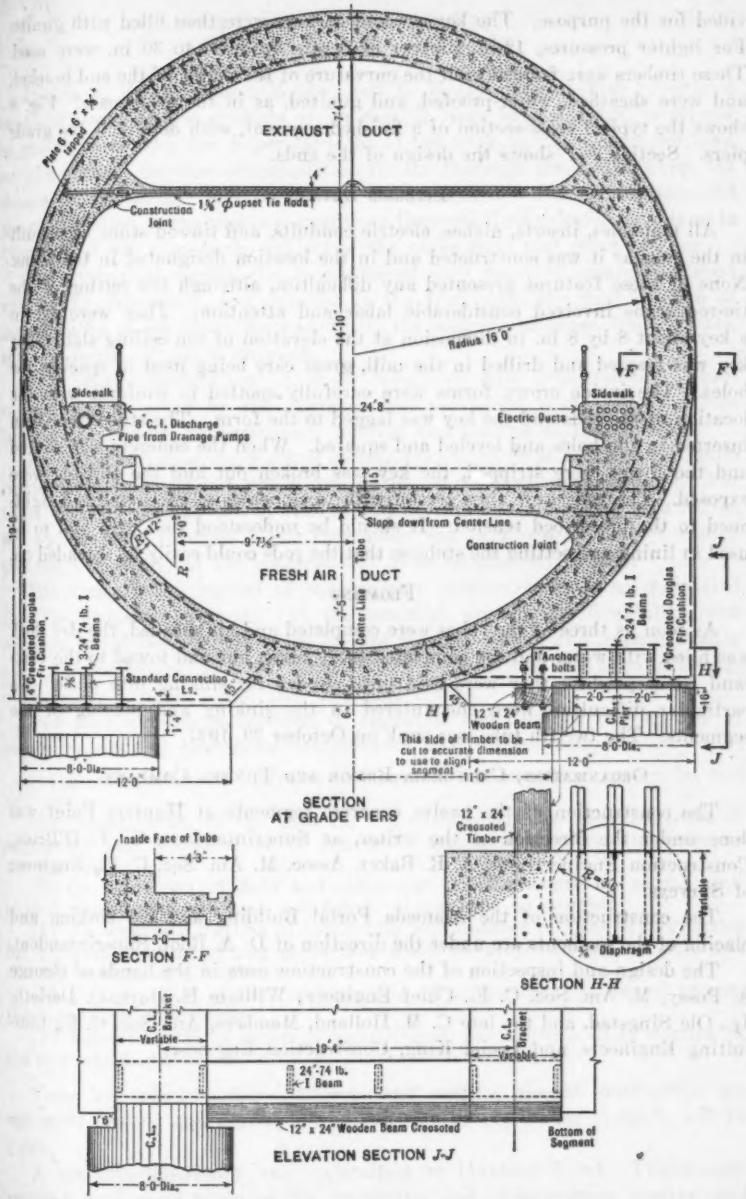

FIG. 8.—TYPICAL SECTIONS OF PRE-CAST SEGMENTS.

vided for the purpose. The keyway and corners were then filled with gunite. For lighter pressures, 12-in. timbers of depths from 20 to 30 in. were used. These timbers were framed to fit the curvature of the inside of the end bracket, and were sheathed, water-proofed, and gunited, as in the other case. Fig. 8 shows the typical cross-section of a finished segment, with details at the grade piers. Section *F-F* shows the design of the ends.

Interior Detail

All manholes, inserts, niches, electric conduits, and tie-rod stubs were built in the tube as it was constructed and in the location designated in the plans. None of these features presented any difficulties, although the setting of the tie-rod stubs involved considerable labor and attention. They were set in a key about 8 by 8 in. in dimension at the elevation of the ceiling slab. The key was framed and drilled in the mill, great care being used in spacing the holes. The inside crown forms were carefully spotted to conform with the location of the rods and the key was lagged to the form. The stubs were then inserted in the holes and leveled and squared. When the concrete was poured and the forms were stripped, the key was broken out and the threads were exposed. The rods were then set up with turnbuckles at each end and tightened to the prescribed tension. It should be understood that care had to be used in lining and setting the stubs so that the rods could easily be threaded on.

Floating

As soon as three of the tubes were completed and bulkheaded, the dry dock was filled with water and the completed tubes taken out and towed to the Oakland Estuary where they were held until needed for sinking into place. No particular difficulties were encountered in the sinking and placing of the segments. The twelfth tube was sunk on October 29, 1927.

Organization, California Bridge and Tunnel Company

The construction of the twelve concrete segments at Hunters Point was done under the direction of the writer, as Superintendent, G. T. O'Brien, Construction Engineer, and A. R. Baker, Assoc. M. Am. Soc. C. E., Engineer of Surveys.

The construction of the Alameda Portal Building and the sinking and placing of the segments are under the direction of D. A. Root, Superintendent.

The design and inspection of the construction were in the hands of George A. Posey, M. Am. Soc. C. E., Chief Engineer; William H. Burr, C. Derleth, Jr., Ole Singstad, and the late C. M. Holland, Members, Am. Soc. C. E., Consulting Engineers, and Locial King, Construction Engineer.

DISCUSSION

JOSEPH A. KITTS,* ASSOC. M. AM. SOC. C. E. (by letter).—This paper is a valuable record of the methods of pre-casting large tube sections, as viewed by the engineer who was Superintendent of the work for the Contractor, and he (the author) deserves commendation for the thorough manner in which the details of equipment and operations are presented. The writer observed the construction of the twelve segments as Concrete Technologist for Alameda County and will discuss the subject of the paper from that point of view.

The cylindrical-shaped, closely reinforced shell required concrete of good workability, flowability, and cohesion in the fresh mix; the final location of the structure in sea water demanded that the concrete be dense, impermeable, and, of course, of ample strength.

With due consideration of these conditions and requirements, ample cement was specified by the engineer and provisions were made for controlling the testing, proportioning, mixing, and placing of the concrete.

For Class "A" concrete, 2 bbl. of cement per cu. yd. in place and a minimum compressive strength of 2 500 lb. per sq. in., at 28 days, were required. For Class "B" concrete, 1½ bbl. of cement and a compressive strength of 2 000 lb. per sq. in. were required. The contractor was held responsible for results and the workability of the concrete had to be satisfactory to him.

The aims in the control of the concrete production were, to maintain: (*a*) The required strength; (*b*) the essential workability, flowability, and cohesion in the fresh mix; (*c*) the highest possible density and impermeability under the conditions; and, (*d*) a uniform concrete with a minimum of honeycomb seams between pours, and shrinkage cracks.

New developments in methods of aggregate and concrete testing, and of proportioning, and production control were used. These comprise:

(1) A comprehensive physico-mathematics of concrete materials and mixtures.
(2) Co-ordination of the tests for the various physical characteristics of aggregates, and co-ordination of aggregate, aggregate mixture, and concrete mixture tests.
(3) Co-ordination of field and laboratory measurements by actual, dry-rodded, loose-measured, and inundated volume, and by weight.
(4) An algebraic method of combining any number of sizes of aggregates for uniform grading of any coarseness modulus, proportioning by size, and absolute volume of particles.
(5) Co-ordination of the fundamentals of the various theories of proportioning concrete mixtures.
(6) Establishment of constant technological control as a daily routine of the concrete manufacture.

These are comprehensive subjects and only a general outline of the aggregate testing and aggregate and concrete proportioning methods will be given.

A concrete laboratory was maintained at Hunters Point. Preliminary research tests were made of the aggregates and of aggregate, mortar, and

* Cons. Concrete Technologist (Kitts & Tuthill), San Francisco, Calif.

concrete mixtures, varying the grading, fineness modulus, and consistency for two cement contents (1.5 and 2.0 bbl.) to determine the strength, density, water-cement ratio, weight, cement-space ratio, filler-voids relations, etc. One man-hour of laboratory control was maintained for 10 cu. yd. of concrete. Routine tests of aggregates as received, were made to determine specific gravity, density, fineness modulus, grading, moisture content, bulking, absorption, and content of silt, organic matter, and inferior particles. Calculation and re-adjustment of proportions of aggregates and water were made as required by the natural variation in the grading, density, moisture, absorption, and bulking of the individual aggregates as received. A laboratory duplication was made of each change of proportions to check the physical characteristics expected for that grading, cement, and water content. Routine slump, wash, and compression tests were made for each pour.

Aggregate Test Methods.—The new features of the procedure of testing aggregates are the "weight-volumetric" method of measurement, the regular use of a full container, and the co-ordination of measurements. The procedure is as follows:

(*a*) Weigh the water, filling container.
(*b*) Weigh the loose, moist aggregate, filling container.
(*c*) Dry the aggregate and weigh it.
(*d*) Make a standard sieve analysis.
(*e*) Make a standard silt test.
(*f*) Make a standard test for organic matter.
(*g*) Weigh the dry-rodded aggregate, filling container.
(*h*) Weigh the dry-rodded aggregate, inundated.
(*i*) Allow this to stand 3 hours, then drain, blot, and weigh it.

Having determined these values by measurement, the following may be computed:

(*j*) The apparent density of the dry-rodded aggregate $= \frac{(a) - (h) + (g)}{(a)}$.

(*k*) Apparent specific gravity of the aggregate particles $= \frac{(g)}{(j) \times (a)}$.

(*l*) Apparent density of loose, moist aggregate $= \frac{(c) \times (j)}{(g)}$.

(*m*) Weight of moisture to weight of dry aggregate $= \frac{(b) - (c)}{(c)}$.

(*n*) Bulking of dry-rodded volume by moisture and loose measurement $= \frac{(g)}{(c)}$.

(*o*) Volume of moisture to dry-rodded volume $= \frac{(g) \times [(b) - (c)]}{(c) \times (a)}$.

(*p*) Weight of dry-rodded aggregate per cubic foot $= 62.4 \times (k) \times (j)$.

(*q*) Weight of water absorbed to weight of dry aggregate used $= \frac{(i) - (g)}{(g)}$.

(*s*) Volume of water absorbed by apparent volume of aggregate $= \frac{(k) \times [(i) - (g)]}{(g)}$.

(*t*) Relation of proportion of moisture by volume of dry-rodded aggregate to proportion by weight in the corresponding loose, moist aggregate $= \frac{(o)}{(m)} = \frac{(a)}{(g)}$.

Measurement (*a*) provides a check for the standard container and also makes it possible to use a bucket or other suitable vessel of unknown volume in case of need.

TABLE 2.—TYPICAL CHARACTERISTICS OF SAND AND ROCK.

Factors.	Sand.	Rock.
Apparent density (dry-rodded)	0.663	0.576
Apparent specific gravity	2.654	2.695
Moisture content (by absolute volume)*	0.136	0.014
Absorption (by absolute volume)	0.04	0.025
Bulking of dry-rodded volume	1.245	1.069
Fineness modulus	3.136	7.31
Discolored rock (by absolute volume)	.....	0.094
Inferior rock (by absolute volume)	.....	0.014

* "Absolute volume," as used herein, denotes "apparent volume," as generally termed by concrete physicists. It is the volume within the surfaces of the particles in the cases of aggregates and cement, and the volume at normal temperature in the case of water.

Results of Aggregate Tests.—A fine and coarse sand were tested before each delivery, by assistants stationed at the point of origin, and pre-mixed by the dealer in proportions determined by the assistants. Two sizes of rock were pre-mixed in the same manner. The materials varied somewhat in physical character with each delivery. Typical physical characteristics of the sand and rock, as received at Hunters Point, are as given in Table 2.

Typical gradings of the aggregates, as received, are as shown in Table 3.

TABLE 3.—TYPICAL CONCRETE AGGREGATE.

Sieve No.	Percentage Retained.	
	Sand.	Rock.
100	97.9	100.0
48	82.6	99.9
28	54.7	99.8
14	43.2	99.6
8	29.2	99.5
4	6.0	97.6
⅜-in.	0.0	86.0
¾-in.	....	47.6
1½-in.	....	0.0
Fineness modulus	3.14	7.30

New Method of Grading Aggregates.—An algebraic method of grading three or more sizes of aggregates for practical uniformity of any fineness modulus, as used on this work, should be of considerable interest to those familiar with the graphical method of determining proportions for uniform grading as developed by the late William Barnard Fuller, M. Am. Soc. C. E.*

* "The Laws of Proportioning Concrete," *Transactions*, Am. Soc. C. E., Vol. LIX (December, 1907), p. 67.

The new method combines the fineness modulus principle with the grading equation, $r = 1 - \left(\frac{d}{D}\right)^n$, in which, r is the proportion (by absolute volume) retained by a given screen opening of d in., D is the maximum size of aggregate, and n is an exponent. A grading of any desired fineness modulus is possible by controlling the value of n. The practical values of n vary from 0.45 to 0.60, increasing with the cement content and fineness modulus. When n is 0.5, the curve is a parabola corresponding to Fuller's theoretical grading. From this curve, he deducted a weight of sand equal to the weight of cement used, thus increasing the fineness modulus with the cement content, but losing a measure of uniformity.

The writer's method is to select the maximum desirable fineness modulus consistent with character of aggregate, cement content, and workability, and then find the corresponding value of n.

The desirable fineness modulus for Class "A" concrete was found in the preliminary tests to be 6.00. The grading equation for fineness modulus = 5.99 and $D = 1\frac{1}{2}$ in., is,

$$r = 1 - \left(\frac{d}{1.5}\right)^{0.56}$$

and the grading is as listed in Table 4.

TABLE 4.—MATERIAL GRADED FOR CLASS "A" CONCRETE.

Sieve No.	Square opening, inches in diameter.	Proportions Retained by Absolute Volume.	
		Mixed aggregate, r.	Sand, $\frac{(r - r')}{(1 - r')}$.
100	0.0059	0.9550	0.8556
50	0.0117	0.9340	0.7882
30	0.0234	0.9032	0.6998
16	0.0469	0.8564	0.5892
8	0.0937	0.7884	0.3209
(4)	0.187	0.6884*	0.0000
$\frac{3}{8}$-in.	0.375	0.5399	.....
$\frac{3}{4}$-in.	0.75	0.3217	.....
$1\frac{1}{2}$-in.	1.5	0.0000	.....
Fineness modulus.....	.....	5.99	3.19

* The value of r' is 0.6884 and is the proportion of coarse aggregate.

The fineness modulus of the coarse aggregate is determined by proportion to be,

$$\frac{5.99 - 3.19\,(1 - r')}{r'} = 7.25$$

The fine and the coarse aggregates were accordingly pre-mixed for the ideal fineness moduli of 3.19 and 7.25, respectively, the dealer accomplishing this generally with satisfactory accuracy.

New Basis of Concrete Proportioning.—An (a) absolute volume of mixed aggregate composed of a uniform grading of particles (by diameters and

absolute volumes as in Table 4), with (b) an absolute volume of cement to a unit volume of concrete and (c) an absolute volume of mixing water to a unit volume of cement, was used as an exact basis of mixture. For example, a typical basis of mixture for Class "A" concrete (assuming 1 cu. yd. of concrete) is as follows:

Absolute volume of cement.....$2 \times 4 \times 0.485 = 3.88$ cu. ft.
Mixing water .....$2 \times 4 \times 0.80 = 6.40$ " "
Absolute volume of aggregate $\left(\text{graded to } r = 1 - \left(\frac{d}{1.5}\right)^{0.56}\right)$

$$\frac{27}{0.97} - 3.88 \text{ (cement)} - 6.40 \text{ (water)} = 17.56 \text{ " "}$$

(The determined yield of concrete in place is 0.97 of the sum of the absolute volumes of aggregate, cement, and water).

With aggregates as given in Tables 2 and 3, the absolute volumes of fine and coarse aggregates are determined from the fineness moduli and the total volume of aggregates as follows:

$$17.56 \times \left(\frac{7.3 - 5.99}{7.3 - 3.14}\right) = 5.53 \text{ cu. ft. of sand}$$

and,

$$17.56 - 5.53 = 12.03 \text{ cu. ft. of rock}$$

The mixing water, correcting for moisture content and absorption of the individual aggregates, is:

$$6.40 - 5.53\ (0.136 - 0.04) - 12.03\ (0.014 - 0.025) = 6.00 \text{ cu. ft.}$$

The proportions, measuring aggregates by loose-moist volume, are:

	Loose volume.
Cement	2 bbl.
Added water.....	6.00 cu. ft.
Sand, $\left(\frac{5.53}{0.663}\right) \times 1.245 =$	10.4 " "
Rock, $\left(\frac{12.03}{0.576}\right) \times 1.069 =$	22.3 " "

It should be kept in mind that these calculated proportions are correct only as long as the characteristics of the aggregates remain as given and that about 1 man-hour of laboratory control for every 10 cu. yd. is necessary to keep up with the natural variation of the aggregates.

The characteristics of the usual Class "A" and Class "B" mixes are given in Table 5.

TABLE 5.—CHARACTERISTICS OF CLASS "A" AND CLASS "B" MIXTURES.

Factors.	Class "A".	Class "B".
Fineness modulus	5.9 to 6.1	5.8 to 6.0
Grading, n	0.54 to 0.58	0.52 to 0.56
Barrels of cement per cubic yard	2.00	1.50
Water-cement ratio	0.80 to 0.84	0.90 to 0.94
True mix, cement to dry-rodded aggregate	1 : 3.07	1 : 4.32
Density	0.83 to 0.87	0.82 to 0.86

The usual proportions for 1 cu. yd. were:

	Class "A".	Class "B".
Cement, in sacks	8	6
Sand, loose moist, in cubic feet	11.4	21.8
Rock, loose moist, in cubic feet	21.8	23.1

Compression Tests.—A sample of four to six compression specimens was taken of each pour. Where six specimens were taken, two were turned over to the contractor for independent testing. The specimens were tested at 2, 3, 7, and 28 days and some at other ages.

In view of the erratic nature of compression tests and the law of probability and error in measurement, the probable strength of the samples was determined by taking the average of the following three determinations:

(1) The 28-day strength as measured;

(2) The 28-day strength indicated by the 7-day strength in accordance with the U. S. Bureau of Standards formula, $S_{28} = S_7 + x\sqrt{S_7}$ (x having been determined as 27.7); and,

(3) The 28-day strength as indicated by any two strengths at ages greater or less than 28 days, as determined by the semi-log age rate formula,

$$S = k\ (\log a) + c$$

in which, S is strength at any age, a, in days, and k and c are constants for the particular sample.

Analyses of fifty samples of Class "A" and twenty-three samples of Class "B" concrete show the results given in Table 6.

TABLE 6.—Compressive Strength at 28 Days, in Pounds per Square Inch.

	Class "A", in pounds per square inch.	Class "B", in pounds per square inch.
Minimum	2 965	1 980
Average	3 715	2 725
Maximum	4 415	3 390
90%	3 240 to 4 415	2 240 to 3 390
75%	3 445 " "	2 460 " "
50%	3 775 " "	2 670 " "
25%	3 965 " "	2 950 " "
10%	4 200 " "	3 120 " "

Assuming that the lower 10% of samples is due wholly to the usual adverse errors of compressive tests, the minimum indicated strengths at any age, in any part of the concrete, based on the highest of the lower 10%, are expressed by the following equations:

Class "A",

$$S = 2\,074\ \log\ a + 248$$

Class "B",

$$S = 1\,794\ \log\ a - 356$$

This indicates that the probable minimum strength of the concrete in any part of the shell, at the age of 100 days, is about 4 400 lb. per sq. in. and that in the roadway slab, about 3 200 lb. per sq. in.

Paper No. 1708

THE VIRGINIAN RAILWAY ELECTRIFICATION*

By George Gibbs,† M. Am. Soc. C. E.

With Discussion by Messrs. W. B. Potter, Marcel Japiot, L. K. Sillcox, I. Öfverholm, Ralph Budd, Guido Semenza, F. H. Shepard, E. R. Hill, Norman Litchfield, Sidney Withington, George J. Ray, John P. Hogan, R. D. N. Simham, and George Gibbs.

Synopsis

The paper aims to present the broad engineering features of an important electric traction installation for long-distance freight service of the heaviest character, in a manner which will make clear to railway engineers generally its essentials in design, construction, and operation. In so doing an attempt has been made to avoid undue length or complication in describing details which are of interest to electrical engineers only.

The physical character and equipment of the Virginian Railway on its heavy grade division, the character and amount of business, and the difficulties experienced in caring for its rapid growth under steam conditions, are first described. The paper then proceeds to outline the methods followed in determining quantities and types of apparatus required to handle the given traffic electrically. A general description of the main elements of an electric traction system is given, and the characteristics of the particular system determined upon as most suitable for the given conditions are then briefly described under the usual sub-divisions of the power supply, the high-tension transmission line, the distribution devices along the railway, and the locomotives.

In this treatment stress is laid on some of the special problems solved, such as the adaptation of the combustion features of the power plant to handle successfully the very large momentary fluctuations in power demand required

* Presented at the meeting of February 1, 1928.

† Cons. Engr.; Chf. Engr., Elec. Traction, L. I. R. R.; Cons. Engr., P. R. R., New York, N. Y.

to start the heavy trains on a grade. Also, the inductive effects set up in paralleling electric circuits normally and during short-circuits are explained, as well as the corrective means adopted. The problems involved in the design of a suitable continuous-contact wire system over the tracks are described fully, and the requirements for a successful catenary system and its supports are illustrated, as matters which are vital to a successful traction system and which present features affecting the work of railway engineers generally.

A short description is given of the inspection and repair facilities provided for the locomotives. Also, the special features necessary for the Company's telephone and telegraph lines along the tracks are noted.

The paper closes with a short description of the manner of conducting the designing of the system throughout, the special methods followed in its construction, and a résumé of operating experience.

Introduction

Within the western slopes of the Appalachians in West Virginia is located a series of bituminous coal deposits of great extent, notably the "Pocahontas", the "New River", and the "Kanawha" fields. Because of the favorable mining conditions, and especially because of the high calorific value and free-burning qualities of the coals from these fields, they are in increasing demand for steaming purposes. They are made available in the markets, both East and West, by three railway systems, the Chesapeake and Ohio, the Norfolk and Western, and The Virginian. Conditions surrounding transportation to the Atlantic seaboard only are, however, dealt with in this paper. These three railways have their tide-water termini at ports around Hampton Roads, Virginia, to which, in 1926, they transported more than 27 000 000 gross tons of coal for vessel loading. Of this amount, 45% was "export" coal, that is, destined to points outside the United States, and the remainder was for domestic consumption. Of the eastbound coal, more than 75% was classed as "low volatile".

The Alleghany Mountains present a complicated topography, characterized by a series of lateral spurs having steep contours and enclosing narrow valleys. Under these conditions favorable railway location is difficult and long adverse grades eastbound are necessary, with many viaducts and tunnels and a large amount of curvature. Furthermore, it is extremely expensive to provide additional running tracks; and to secure room for passing sidings is always a problem and, in places, impossible. Unfortunately, also, these difficult conditions obtain in a section where cars must be distributed to and gathered from mine sidings and spurs.

To compete effectively with Pennsylvania mines, which are at least 100 miles nearer the seaboard and, perhaps, several hundred miles nearer the great coal-consuming centers, these more distant West Virginian coal fields must enjoy relatively low mining cost and be served by very efficiently operated railways to secure minimum transportation costs. One important factor contributing to cheap transportation is the maintenance of an intensive service with trains of the maximum permissible weight moved at a speed which is as high as safety permits. Thus, by quick transference of lading from the cars

to vessels at tide-water, the completion of a prompt "shuttle service" between mines and terminal becomes possible. This character of "turn-around" obviously greatly reduces the equipment required to perform a given service and thus contributes in an important way to the possibility of profit from the low freight rate prevailing in this highly competitive commodity.

Electric Traction on the Norfolk and Western Railway

There is an especially close similarity between the Norfolk and Western and the Virginian Railways, as to grades and alignment, in the coal fields and as far east as Roanoke, Va. (Fig. 1). Each has a "gathering section" west of the mountains and must haul eastbound tonnage over heavy grades to the summit before favorable line conditions are reached. In fact, the two roads lie closely parallel for almost the entire distance from the coal fields to tide-water. The experience of the Norfolk and Western Railway Company, which had built up a large eastbound coal business before the Virginian Railway was constructed, may be briefly referred to therefore as indicating modern methods in the development of economical mass transportation of low-grade freight, especially as bearing upon the advantages of electrification to this end.

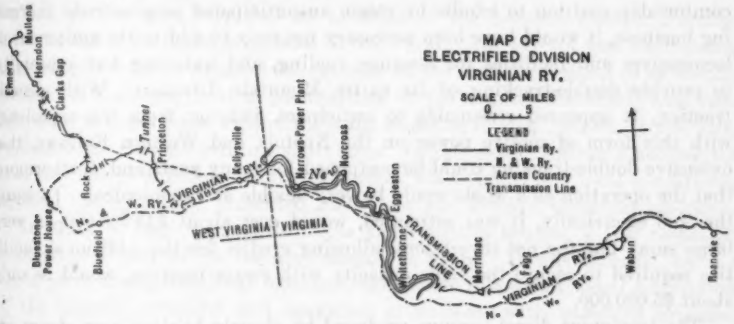

Fig. 1.

The Norfolk and Western Railway Company had used powerful Mallet compound steam locomotives to haul very heavy trains on the mountain grades. The service speed was low, and three locomotives were required per train. In the coal-"gathering" section, comprised within about 30 miles of road immediately west of the mountain summit, the line was double-tracked (except in the single-track ¾-mile Elkhorn Tunnel). With these facilities, however, it was found that service had about reached its maximum possible capacity and economical development. Additional main tracks could only be provided at prohibitive cost through the narrow valleys, where the road was encumbered with mine sidings and coal tipples, and the number of steam locomotives required on this short section was so great as to be a positive hindrance to prompt movements. For example, to handle the coal tonnage of 1914, twenty-four Mallet locomotives were required in as many miles of line, and a round trip—say, 50 miles per day—was about the best average performance which could be secured from each.

The electrification of this "gathering" section of the railway was adopted after an extended investigation as the best solution of operating difficulties and limitations present and future. The installation was completed and put into operation in May, 1915. The new traction method at once effected a reduction in the number of locomotives in service to about one-third that required by steam traction; it doubled, and at times trebled, the daily mileage per locomotive by increasing train speed and by eliminating delays inherent with steam locomotives. Thus, congestion was completely eliminated. During the World War business increased suddenly and very greatly, but notwithstanding this, traffic was handled electrically without difficulty and undue congestion, a feat which the operating officials believe would have been impossible with steam traction.

The Virginian Railway Problem

The Virginian Railway Company had to face similar problems; business had grown constantly until it reached a volume approximating that of its rival, which had more ample track facilities. A comprehensive plan for betterment, therefore, became imperative. In order to place itself in a comfortable position to handle by steam an anticipated progressively increasing business, it would have been necessary not only to add to its equipment of locomotives and facilities for housing, coaling, and watering, but, especially, to provide double-tracking of its entire Mountain Division. With electric traction, it appeared reasonable to anticipate, judging from the experience with this form of motive power on the Norfolk and Western Railway, that extensive double-tracking could be postponed for many years and, furthermore, that the operation as a whole would be very flexible and economical. To equip the line electrically, it was estimated, would cost about $15 000 000—a very large sum—but the net investment, allowing credits for the additional facilities required to secure the same capacity with steam traction, would be only about $5 000 000.

The important direct savings produced by electric haulage over steam are in fuel, time of train crews, and the better utilization of car equipment due to increased speeds, hauling capacity, and reduction in delays. Where, therefore, as in this case, the excess capital fixed charges are not too great, it is reasonable to expect that the improved form of motive power will be directly profitable from the savings and indirectly advisable by reason of its superior flexibility and reliability. After 1½ years of experience with electric haulage on this road, it is gratifying to be able to state that the expectations of the Company have been more than realized in all respects. The direct savings produced have more than met the charges on the net excess investment and the improved operating results have been marked.

Description of the Property.—The Virginian Railway extends from Deepwater, W. Va., at the head of navigation on the Kanawha River, to Sewalls Point, on Hampton Roads, Va., a distance of 443 miles. It was constructed in 1905-07, with a view to obtaining the shortest route and the best possible grades and alignment from the coal fields to tide-water. At present (1928), the average length of haul from mines to tide-water is 405 miles. The road traverses

the Pocahontas, Winding Gulf, and New River Districts of the semi-bituminous (low volatile, or "smokeless") fields and taps a portion of the Kanawha (high volatile) District. It is now serving a total of 110 mines, having a combined potential annual capacity of at least 18 000 000 tons and an estimated recoverable reserve in excess of 1 000 000 000 tons. An additional area having a potential capacity far greater than this figure is tributary to the road.

The Company has two large, modern coal piers at Sewalls Point, designed for the loading of any type of vessel, and each of the two will accommodate four large, or six small, vessels at one time. Each pier is equipped with car-dumpers which can unload a total of 210 cars, or 12 600 tons of coal, per hour.

The railway is single track, except in the 22-mile section on the west slope of the mountains and the 10-mile section west of and approaching the Tide-water Terminal. The aim to provide a coal-carrying railway with grades generally favorable to loaded traffic has been attained, except over the two main mountain ridges intersected within a distance of 134 miles between Elmore, W. Va., and Roanoke (Fig. 1), where topographical conditions necessitate several long heavy grades, producing in effect a "bottle-neck" in the hauling capacity of the entire system.

This section now furnishes an example of the heaviest electric traction development to be found anywhere in the world. The project was undertaken primarily, in order to equalize the capacity of the road throughout so as best to conform to the topographical peculiarities of the country traversed; but, furthermore, to avoid large expenditures for steam equipment, which, it was felt, would become obsolete within a short time. In this paper is given a necessarily brief account of this important installation which under the local conditions, physical and operating, presented many new and difficult technical problems.

In order to keep the length of the paper within bounds, a full technical description of any of its features cannot be given. It was thought, on the whole, more useful to railway men and engineers to furnish a general description of the physical property and operating conditions, with sufficient explanation of the reasons, either operating or technical, for the adoption of the plans and methods followed, as a guide in determining the advisability of heavy electric traction for similar situations elsewhere.

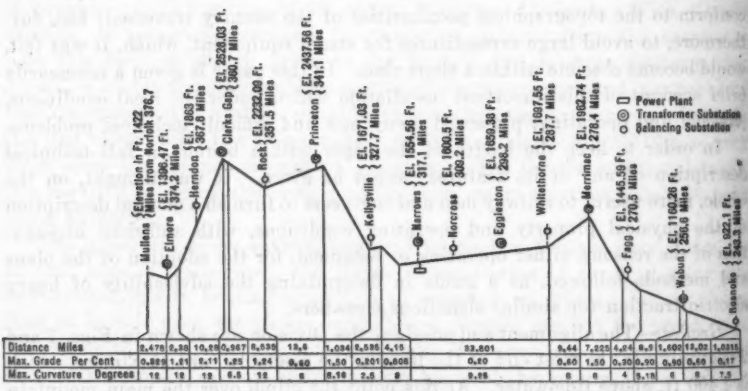
Grades.—The alignment and profile of the Division are shown in Figs. 1 and 2 beginning at the west end of the line, in the assembly yard at Elmore, which is 1 400 ft. above tide-water. At this point the climb over the main mountain ridge starts and continues for 12½ miles on an average 2% compensated grade to an elevation of 2 528 ft. at Clarks Gap, W. Va.; thence over 22 miles of undulating and 0.6% maximum grade to Princeton, W. Va. Near this point the descent occurs and continues for 10.3 miles down a 1.5% grade to Kellysville, W. Va. Thence the line continues over a broken down grade for 6 miles into the valley of the New River, which is followed up stream for 34 miles over a 0.2% adverse grade to Whitethorne, Va. Here, the climb over the Alleghany Ridge begins. This requires about 10 miles of 0.6% grade; it was made a pusher section during steam operation. The mountain summit is reached at Merrimac, Va., from which point the road descends sharply for 7 miles on a

1.5% grade. The remaining distance, 27 miles, to Roanoke is over light grades favorable to loaded movements.

Curvature.—Throughout the entire 134 miles there is a large amount of curvature, varying from 12° maximum and quite generally as sharp as 8°, with the worst curves on the heaviest grades; the mountain section west of Princeton has 60% of its length on such curves. It is evident from Figs. 1 and 2 that both grades and curvature have an important bearing on operating speeds and train loading, and it will be interesting, therefore, to outline the maximum possible service under steam operation.

Steam Haulage Methods

At Elmore, the main assembling point for eastbound tonnage, a train was made up of 5 600 tons trailing weight, summer loading. This was hauled over the heavy grade to Clarks Gap by a road engine of the Mallet type and two Mallet pushers. At that point the pushers were cut off and returned light to Elmore Yard, the train continuing to Princeton with the road engine only. At Princeton, the train was filled to 8 500 tons, summer loading, or 6 000 tons, in winter, for the run to Roanoke. The power for this latter movement was one road engine of the U. S. Mallet type, with a helper engine to assist starting out of Princeton Yard and a helper on the 10-mile grade from Whitethorne to Merrimac.



Distance Miles	2.478	0.38	10.22	0.967	8.530	13.6	1.084	2.535	4.15	53.601			9.44	7.225	4.04	0.5	1.600	13.01	1.0115
Max. Grade Per Cent	0.329	1.21	0.11	1.25	1.24	0.60	1.50	0.201	0.008	0.60			0.60	1.50	0.30	0.90	0.90	0.56	0.17
Max. Curvature Degrees	10	12	12	8.5	12	8	8.16	2.5	8	9.25			8	8	4	3.15	6	8	7.5

Fig. 2.—Track Profile of Electrified Division, Virginian Railway.

The average inclusive speed from Elmore to Princeton, with two stops for water, was about 7 miles per hour. Under best conditions 3½ hours were required for this 36-mile movement. This time, however, was generally exceeded and was often as much as 7 hours, due to bad weather or to poor steaming of the locomotives. The time required for the movement from Princeton to Roanoke was normally from 11 to 12 hours at an inclusive speed of about 8 miles per hour; over-time was frequently required, however. On this part of the run stops were made at four stations for water, at one of which re-coaling and inspection took place.

Westbound the service was wholly an empty-car movement. The trains averaged 2 700 tons and were hauled over the Division by one road engine, without using a pusher on the Merrimac and Kellysville hills. The running time for this light service varied from 12 to 20 hours, depending on the weather, the condition of power, and the congestion on the road.

To conduct this tonnage service the Company used two classes of Mallet steam locomotives, one known as the "U.S." for road haulage over the Division, and another and heavier one known as the "A.E." type, for pushers on the grades. The general characteristics of these locomotives are given in Table 1.

TABLE 1.—Characteristics of Mallet Steam Locomotives Used on the Virginian Railway.

Type.	Wheel arrangement.	Weight of locomotive, in tons.	Weight on drivers, in tons.	Weight of tender, in tons.	Total weight in working order, in tons.	Rated tractive effort, in pounds.
U. S.	2- 8- 8-2	265.5	239	104.5	370	101 300
A. E.	2-10-10-2	343	308.5	107.1	450	147 200

The coal cars used are both hopper and gondola. Of these, 7 100 are of 52 to 55 tons capacity, 500 are of 70 tons, and 2 029 of 110 tons capacity. Overloads of 10% are allowed.

The standard ratings for the trains varied in practice considerably, and were subject to a reduction of 10 to 20% in winter weather and to special reductions at other times, depending on the condition of the steam power, which cannot always be maintained 100% efficient. Furthermore, successful hauling of these extremely heavy trains over a line which is undulating in character, assumes good condition of car draft-rigging and air-brakes, and very careful handling both in starting and stopping. As would naturally be expected, these conditions are not always present and "break-in-twos" were not infrequent.

Due to all the variables mentioned and inherent in steam service, congestion and delays were frequent, especially in bad weather and at times of heavy business, hence provisions for additional facilities became imperative. It was considered that electric traction offered the best and most progressive means of securing these facilities.

Determination of Electric Traction Requirements

Knowing the physical character of the railway, the primary considerations are the power demand at the train and from the system as a whole. These are determined by the weights, speeds, and number of trains in motion at one time.

Train Weight.—Allusion has been made to the very heavy trains operated by steam locomotives, in fact, train weights had been increased nearly to the limit of the allowable stresses at the car couplings in a service conducted over broken grades. At the start of electric operation, therefore, it was believed

best not to attempt a material increase in the standard weight of trains over the low-grade part of the Division, but rather to secure other possible improvements in the operation, especially to shorten the running time, to eliminate pushers east of Clarks Gap, and to handle reliably a fixed train maximum, substantially regardless of weather conditions. In effecting these operating improvements, the type of locomotive and the charactertistics of the electric system throughout should be made flexible enough to permit the running of heavier trains if conditions should so demand in the future.

The train make-up fixed upon as most suitable, all things considered, was 6 000 tons trailing weight up the hill from the assembly yard at Elmore, handled with a head engine and a pusher, this train to be filled out to 9 000 tons at Clarks Gap and handled by a head engine only for the entire 116-mile run to Roanoke. In this way the pusher formerly required on the Alleghany hill from Whitethorne to Merrimac with steam service was eliminated. This train weight and motive-power assignment effects a practical balance between locomotive adhesive requirements on the grades and the electric motor capacity needed for the long sustained runs, and does not increase car draft-rigging stresses beyond those which have been demonstrated as allowable under the physical conditions obtaining on this railway.

Speeds.—It has been stated that it was especially desired to shorten as much as possible the running time between Elmore and Roanoke, which by steam locomotives required frequently as many as 20 hours. Experience on the Norfolk and Western Railway demonstrated that it was undesirable to permit fluctuating speeds which in places might become excessive; in fact, that two standard speeds, reliably maintained, best suited a difficult track profile and alignment. On that road a speed of 14 miles per hour on the heavy grades, where complicated by excessive curvature, and 28 miles per hour on the low grade and light curvature portions of the line have proved to be suitable. In the light of this experience, and because the physical conditions on the two railways are practically the same, these standard speeds were adopted in the electrification of the Virginian Railway.

It should be noted, as will be made clear in describing the design of the locomotives, that the running speeds just mentioned are fixed. They depend only on the motor combinations and do not vary with the grades or loads. Fig. 3 shows the speed assignments adopted for an eastbound run over the Division with a loaded train. It will be seen that about 47% of the distance is covered at a speed of 28 miles per hour and the remainder, which comprises the pusher and the regenerating grades, is run at the relatively low speed of 14 miles per hour.

This set-up results in a running time of 7¾ hours over the 131 miles between Elmore and Roanoke; in practice, however, this may be extended to from 9 to 11 hours, depending on the time taken for filling out the train at Clarks Gap, and for inspection at Whitethorne, which latter is the only other regular stopping place on the Division. It was predicted that under favorable conditions, if not in general practice, it would be possible for an electric locomotive to make a round trip over the Division (262 miles) in 24 hours. This, in fact,

was done frequently during the winter of 1926, and the average mileage per day secured per locomotive in service, in November of that year, was 180. This may be rightly regarded as a fine performance, when it is considered that approximately one-half the number of locomotives are used in pusher and short-run hill services.

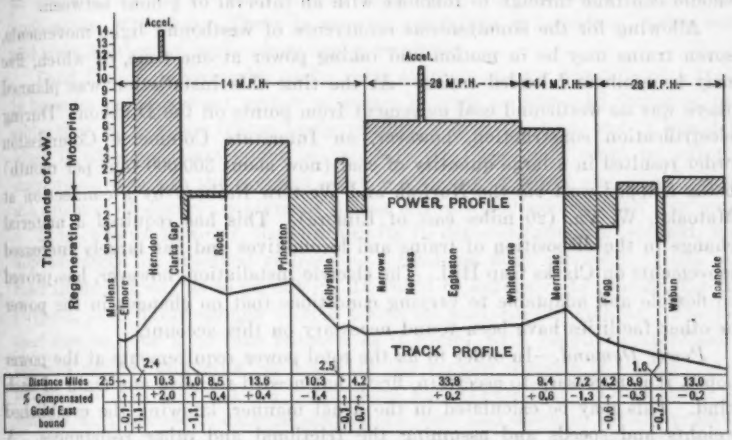


FIG. 3.—ROANOKE-MULLENS ELECTRIFICATION, VIRGINIAN RAILWAY COMPANY. POWER DATA, EASTBOUND.

Yearly Tonnage.—The railway handled 8 306 000 net tons of coal eastbound in 1925, which was an increase of 10% over that handled in 1924. In 1926 traffic took a sudden jump, due, perhaps, to unusual conditions (such as, coal mining strikes in England), and 11 500 000 tons were moved. Assuming, however, a regular and normal yearly increase in business, it was felt that the initial electric equipment should be capable of handling comfortably a total of 12 500 000 tons eastbound per year, and that the plant should be susceptible of ready enlargement to take care of a progressively increasing traffic. The ratio of average to maximum day movement is about 60 per cent. Therefore, the eastbound tonnage on a maximum day becomes 57 000, or a gross of about 80 000 tons of cars and lading. In addition, manifest and local trains and the returning light trains must be moved. A summation of all this tonnage means a total of 110 000 to be moved on a maximum day. In fact, this quantity was actually handled on certain days during 1926.

Number of Trains.—In order to meet the yearly and daily traffic demands outlined, it was estimated that for a heavy day movement fourteen 6 000-ton trains must be hauled up the heavy grade from Elmore in 24 hours. At Clarks Gap these would be combined into nine 9 000-ton trains to be hauled through to Roanoke. In addition, provision must be made for one local freight per day in each direction and a certain amount of switching duty. The empty cars are returned in nine trains of 3 000 tons each, thus balancing car and

locomotive movements eastbound and westbound. Obviously, these trains cannot be spaced evenly over the line as traffic and operating necessities require that a certain amount of "bunching" be allowed. Provision was made, therefore, to permit that two tonnage trains should operate simultaneously on the Clarks Gap Hill, spaced ½ hour apart; also, that two 9 000-ton trains should continue through to Roanoke with an interval of ¾ hour between.

Allowing for the simultaneous occurrence of westbound light movements, seven trains may be in motion and taking power at one time, of which, five may be eastbound loaded trains. At the time this installation was planned there was no westbound coal movement from points on the Division. During electrification construction, however, an Interstate Commerce Commission order resulted in a large quantity of coal (now about 300 000 tons per month) being shipped west *via* the Norfolk and Western Railway by a connection at Matoaka, W. Va. (20 miles east of Elmore). This has required a material change in the disposition of trains and locomotives and has largely increased movements on Clarks Gap Hill. The electric installation, however, has proved so flexible and adaptable to varying conditions that no changes in the power or other facilities have been found necessary on this account.

Power Demand.—In order to fix the total power requirements at the power house, it is necessary to ascertain, first, that needed to move one train of each kind. This may be calculated in the usual manner, knowing the established weights and speeds and assuming the frictional and other resistances. A curve may then be plotted for the train over the entire Division. This curve is applied to the desired train sheet to determine the total power requirements on the assumptions made as to the number and kinds of trains in motion and their spacing. Fig. 3 has been plotted to show graphically an eastbound movement of a loaded train over the line, together with the energy inputs at all points, including arbitrary starts interpolated at critical points to indicate any extraordinary energy requirements. It will be noted that a 6 000-ton train (7 285 tons weight with the two locomotives) on Clarks Gap Hill requires about 14 000 kw. at the train when starting, and the continuous input while running up this 2% grade is about 11 700 kw. The long run up the New River Valley of a 9 000-ton train (9 640 tons with one locomotive) requires about 11 000 kw. during the start and the accelerating period, and 6 500 kw. while running at 28 miles per hour.

At two places substantial amounts of power are regenerated over a considerable time interval, namely, when descending the Kellysville and Merrimac grades, where energy is returned to the contact wire at the rate of about 5 000 kw., the train being held back in this way without the use of brakes and without an appreciable change in speed. The power regenerated during the entire eastbound run is approximately 7 800 kw-hr., which is about 20% of the total energy consumed to propel a loaded train over the Division. A westbound run with an empty train does not regenerate a large amount of power, but the total eastbound and westbound movements, it has been found in actual operation, supply by regeneration more than 8% of the total energy required to operate the road.

It has been found that generally all power regenerated is usefully employed to assist other trains which happen to be in motion, but any surplus current returned is automatically absorbed in special water rheostats at the power plant. Regeneration, furthermore, is very useful in holding smoothly and safely long trains on heavy down grades, and is of material assistance in avoiding "break-in-twos" arising from defective condition or improper application of brakes. There is also an advantage in avoiding undue wear and over-heating of brake shoes and car wheels.

Load Factor.—Obviously, under these extreme energy demands of a train, it becomes an important matter to secure as high a daily load factor as possible, that is, to space trains fairly uniformly over the line, and it would be ideal if seasonal peaks could be avoided. If these ends could be effected, they would result in the greatest possible economy of power and would reduce the amount of electric equipment of the entire installation to the minimum.

It is obvious, however, that uniformity in demand cannot be secured, even approxmately, in practical railroading. Business does not come to the railroad in such a way as to permit it. It would be expensive to provide, for this purpose, yards large enough to hold trains for uniform dispatching. The best that can be done is to take business as it comes, with judgment exercised to prevent undue "bunching" of trains in the various sections of the line to an extent that will overload the power plant and sub-stations. Train sheets for normal and, therefore, extreme conditions were laid down to satisfy practical operation as indicated by experience, always having due regard to the factors producing reasonable plant cost and economy of operation.

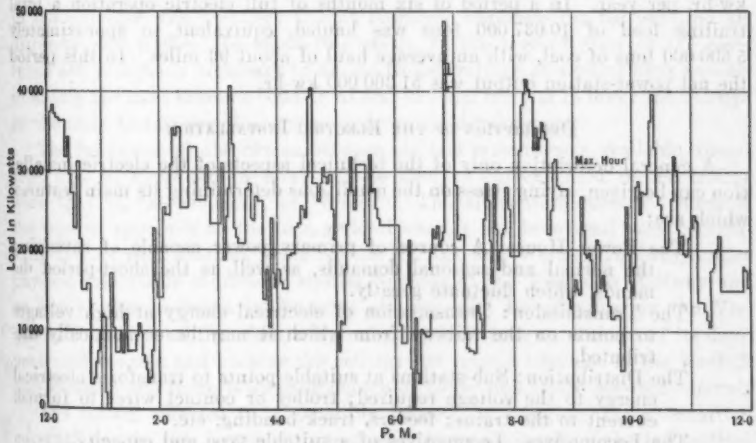

FIG. 4.—TYPICAL HEAVY DAY LOAD, IN KILOWATTS, AT POWER HOUSE.

Daily Load Curve.—A 12-hour curve of loads at the power house, developed from the factors mentioned, for a congested day is given in Fig. 4. It indicates very heavy fluctuations in demand, not only over the hour, but during short intervals. Thus, the maximum 5-min. peaks are of the order of 40 000

to 45 000 kw. and the hourly peaks are about 31 000 kw. Furthermore, the entire load drops at times almost to zero. Under the full electrical operation the peak loads have been substantially as calculated, showing generally a 50% daily load factor, referred to the maximum hour, and at times the load factor has been as high as 65 per cent. As traffic becomes heavier, due to the operation of more trains, the daily average load factor will become greater, but it is estimated that the peak loads will not materially increase.

The loads thus developed at the power house for a normal and for a maximum congested day are shown more clearly in Table 2.

TABLE 2.

Loads.	Normal day, in kilowatts.	Maximum congested day, in kilowatts.
Average load for 24 hours	14 500	20 500
2-hour peak	22 300	29 200
1-hour peak	31 300	31 500
5-min. peak	38 000	43 500

The average daily kilowatt-hour station output was estimated to be about 310 000; the actual output, when handling the volume of business estimated, has averaged 325 000 kw-hr. The yearly station output, of course, depends on the actual tonnage moved. Based on handling a total net coal tonnage of 12 500 000, it was anticipated that the station output would be about 112 000 000 kw-hr. per year. In a period of six months of full electric operation a total trailing load of 10 037 000 tons was hauled, equivalent to approximately 5 500 000 tons of coal, with an average haul of about 96 miles. In this period the net power-station output was 51 300 000 kw-hr.

Description of the Electric Installation

A general description only of the technical aspects of the electric installation can be given, laying stress on the conditions determining its main features, which are:

The Power House: A source of primary power capable of satisfying the normal and seasonal demands, as well as the short-period demands, which fluctuate greatly.

The Transmission: Transmission of electrical energy at high voltages to points on the railway from which it may be economically distributed.

The Distribution: Sub-stations at suitable points to transform electrical energy to the voltage required; trolley or contact wires to furnish current to the trains; feeders, track bonding, etc.

The Locomotives: Locomotives of a suitable type and capacity.

All these features must be designed so as to conduct service successfully irrespective of weather or other variable conditions and in a manner consistent with low installation, operation, and maintenance costs. Furthermore, the system must be such that additions can be readily made to it as traffic grows, and that improvements in apparatus, due to advancement in the

art, may be incorporated without radical and expensive changes in the installation as a whole.

Practical railway operation requires that there shall always be enough equipment provided and power available to permit both normal and congested movements, regardless of the peak loads produced at any point, that is, that traffic movement shall not be subordinated to equipment limitations. Therefore, in determining the quantities of apparatus, this general principle was followed.

The successful development of heavy electric traction for railways is due primarily to advances in the art, which permitted great amounts of power to be transmitted over long distances. As electrical energy is the product of pressure and volume of current, it follows that the higher the pressure the smaller the current required to transmit a given amount of energy, hence the use of very high voltages for power distribution. In early electric traction installations, the distances involved were comparatively short; therefore, moderately high transmission voltages were sufficient for economical results. The distribution voltage in the feeder and contact systems could also be low without unduly increasing the cost of the conductors.

As the distance to be covered increased, transmission voltages were raised for economic reasons, but a more important and difficult problem had to be solved in devising a suitable current-collecting system for the trains. The steel rail formerly used as a contact member necessarily was replaced by an over-head contact wire in which high voltages could be used. Furthermore, new types of motors were developed to utilize high voltages. Logically, the ultimate aim is to find a general system that will permit unrestricted voltages in the collector wire (trolley) to suit economic requirements for any and all distances and traffic. To effect this result, in the present state of the electrical art, it appears necessary to fix the trolley voltage at a point high enough to satisfy the most extreme conditions and in some manner to lower the voltage on the train to suit practical motor and control development.

The fundamental distinction between electric systems now available, therefore, may be expressed in terms of the kind of current used in the trolley wire, that is, "alternating", or "direct". The alternating-current system is the nearest approach so far to a general one; it has been used very successfully for the past fourteen years on the Norfolk and Western Railway, under physical and traffic conditions similar to those of the Virginian Railway and on many other railways in America and abroad. Its adoption on the Virginian Railway was, therefore, a logical procedure, both on account of its demonstrated success, and because the railway lies closely adjacent to the Norfolk and Western and there is an interchange of power and traffic between the two.

The system referred to is generally termed the "single-phase alternating-current", but in this instance three-phase motors are used on the locomotives to obtain certain advantages of this type for the specified haulage conditions, as will be explained later. Single-phase alternating-current, or even direct-current, motors, however, can be used on the locomotives without changes in other parts of the traction system, should it be desired to do so in the future in order to meet changed business conditions.

The main elements and special features of the Virginian electrification will be described, beginning with the source of the power.

The Power Plant

Source of Power.—It is sometimes assumed that an important consideration in determining upon a railway electrification is that advantage can be taken of cheap hydro-electric power. Unfortunately, in the Eastern United States, available water powers are few, and such as exist are not generally near the consumer, and are often not dependable in capacity, so they must be assisted by some form of fuel-burning power plant. Where, therefore, as in the case of the Virginian Railway, high-grade coal is close at hand, a steam plant is suitable and economical, all things considered. It is a reliable means of supply at all times and can be placed so as to meet the needs of the Railway Company.

As an alternative to the construction of a railway power plant for the traction supply, examination was made of the possibility of purchasing power from an existing commercial plant. If power could be secured in this way at a cost not materially in excess of the generating cost of the Company's own plant plus fixed charges, interest, depreciation, and taxes, it would be advantageous, of course, to purchase power and thus save an investment of $4 000 000 in a new plant.

Four different possibilities were examined, but only one commercial power company was prepared to submit a definite proposition and this was so disappointing as to cost, other terms, and conditions, that it was impossible to give it further consideration. As a matter of fact, the load conditions already outlined are so exceptional that it is doubtful whether any existing local company engaged in supplying electric energy to the general public could afford to take on a load of this character, except by devoting special generators and transmission circuits to the railway supply, and thus being under a special handicap in large fixed charges.

Doubtless, there is a field for commercial power companies, especially large networks, in the supply of power for heavy railway traction, but the terms and conditions must meet the ordinary and extraordinary loads of the railway and in order to compete such companies must be satisfied with a low margin of profit, as low power cost is depended upon to furnish the largest direct return on the investment in a railway electrification.

Plant Location.—It will be noted from Fig. 1 that the railway is located in the valley of the New River along which it follows for many miles. This stream varies greatly in volume of flow, but contains at all times an ample supply of water for boiler-feed and condensing purposes. The U. S. Government records for the past 40 years show a water-stage variation of 30 ft. in this river, with maximum floods in 1870 and 1916.

A careful survey was made to determine a suitable power-house site, in view of these high and low-water conditions, at a place where the construction would not restrict the flood prism. Furthermore, it was important to select a site near an established town where employees could be housed. All

conditions were best met at the Town of Narrows, Va., 74 miles west of Roanoke. There, the river valley broadens, and a bend occurs, forming a wide and level plot alongside of which the railway runs at a suitable elevation for connections and sidings to deliver coal and materials to the plant.

General Character.—The plant was designed to insure continuity of service under widely fluctuating loads. Good operating economy was aimed at, but refinements were not included to the extent of unduly complicating apparatus and increasing maintenance difficulties. This seemed to be a conservative procedure, as the cost of fuel is low compared with that found at commercial plants more remote from the coal fields, and as the plant is situated at a considerable distance from skilled labor markets.

There was one consideration which gave the designers concern, namely, the unprecedently great spread between maximum and minimum short-period demands on the steam-generating features of the plant. At certain times, the load at the power house drops off practically to zero (see Fig. 4). At others, there may be only one train on the line taking power and, at still others, there may be four trains, or more. As the instantaneous increments of load may be of the order of 14 000 kw., it is obvious that unusually severe requirements are imposed on the boilers in the production of steam in suitable volume at substantially constant pressure. This same problem had been faced to a lesser degree in the power plant of the Norfolk and Western Railway where the undesirable limitations of the ordinary form of boiler-stoking had been demonstrated.

Therefore, the much more severe load conditions on the Virginian plant appeared to make a change in firing practice desirable and, perhaps, essential. Liquid or gaseous fuel would be ideal, but powdered coal fuel, which has the burning quality of a gas, appeared to offer the most practical solution of the difficulties. The success of powdered fuel had been demonstrated in a number of plants under a variety of conditions elsewhere, thus its use here appeared not wholly experimental. Incidentally, it promised the highest obtainable fuel economy, but its ease of regulation was the main factor determining its use for the Virginian installation.

It is gratifying to be able to state that in the practical operation of this plant for more than 1½ years, the wisdom of using powdered coal has been demonstrated as producing entirely manageable boiler firing under the normal and extreme conditions imposed. The station coal rate has averaged less than ¾ lb. per kw-hr. of net output, or about 14½% efficiency, which, considering the character of the load, is a satisfactory showing. The installed capacity of the power plant was set at 48 000 kw., 1-hour rating, divided into four generating units and five boilers, designed to provide a spare for each.

Building and Foundations.—The local rock is limestone of variable quality, so bedded as to be subject to erosion by underground waters. As the concentrated column loadings were necessarily heavy, special care was taken to explore the site thoroughly by borings to determine sub-surface conditions. Considerable variation in the quality of the rock was found and, unfortunately, the disintegrated portions occurred at certain heavily loaded points.

No cavities were found below sub-grade, but it was thought advisable to establish the low unit pressure of 3 tons per sq. ft. for the heavily loaded stack footings.

In order to establish a reasonable height for the main floor of the building to permit of ready access to the plant, and at the same time to provide economical conditions in the supply of condensing water, the elevation of the basement floor was fixed 30 ft. below high-water mark. This necessitated very substantial walls and floors under the turbine room to withstand the hydrostatic head during flood stages. As the displacement at the basement produced an uplift under these conditions in excess of the total weight of the construction above, it was necessary to insure against any possible movement at such times. This was done by providing a reinforced basement floor slab having concrete ribs between the piers of the turbine foundations, and by anchoring these piers with rods, 1½ in. in diameter, grouted into the rock. Of these anchors, 134 were used. To insure further against any uplift movement, vents were provided in the concrete slab to relieve any pressure which might build up a hydrostatic head.

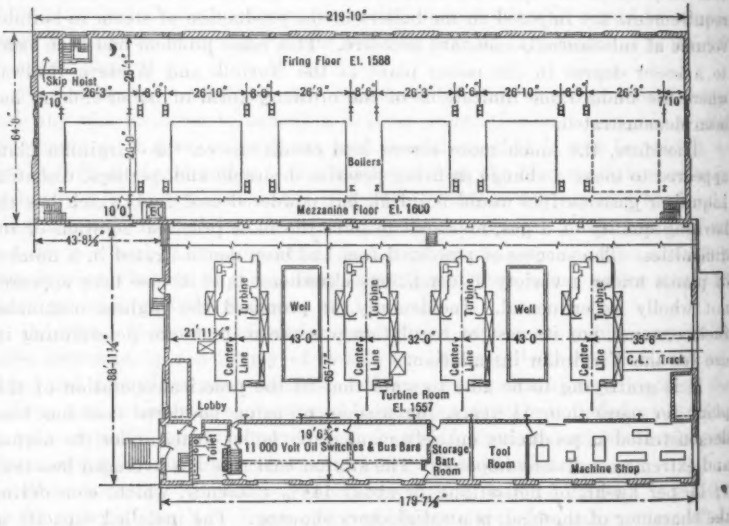

FIG. 5.—FLOOR PLAN, TURBINE ROOM AND FIRING FLOOR, NARROWS POWER PLANT, VIRGINIAN RAILWAY.

The general character and arrangement of the building is shown in the plan and cross-section, Figs. 5 and 6, and in the photograph, Fig. 8. The dimensions and other data of general interest are given in Table 3. The building walls are of brick and are self-supporting; the basement walls are of reinforced concrete. Interior steel framework carries the floors, crane, stacks, and the boiler-room apparatus.

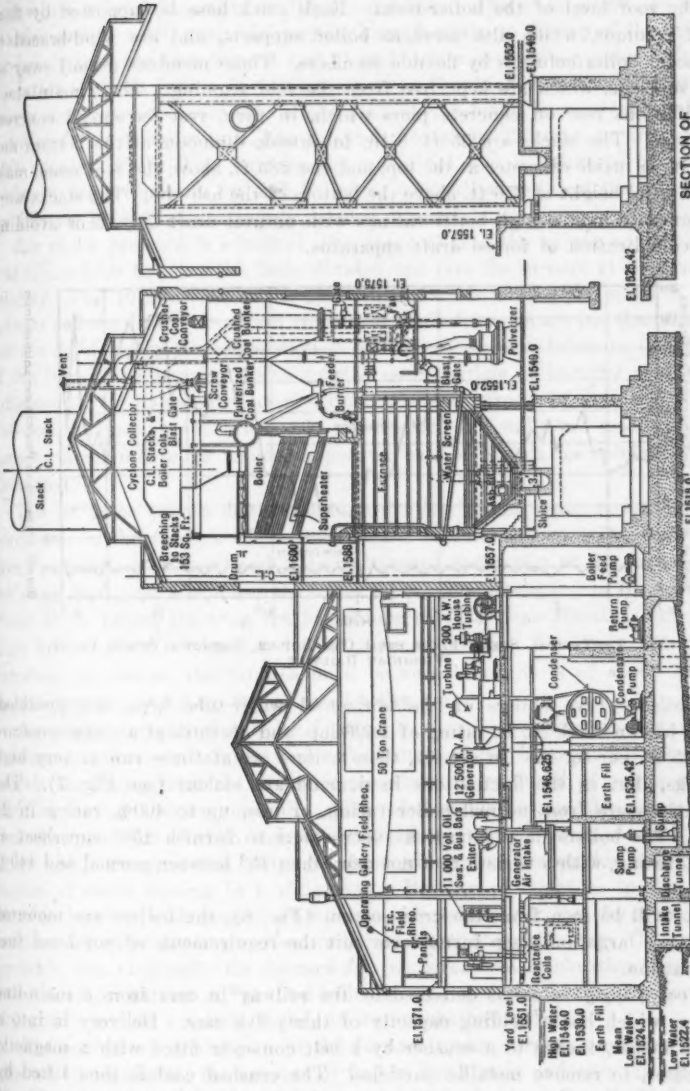

FIG. 6.—PLAN AND CROSS-SECTIONS, NARROWS POWER PLANT, VIRGINIAN RAILWAY.

Stacks.—The two stacks (Fig. 8) are very high, and are constructed of reinforced concrete, supported on, and directly bonded into, concrete mats at the roof level of the boiler-room. Each stack base is supported by four steel columns, which also serve as boiler supports, and are wind-braced to adjacent boiler columns by flexible members. These members permit sway in the supports, which are kept free from the roof framing. These main stack foundations rest on concrete piers which, in turn, rest on spread concrete footings. The stacks are 25 ft. 8 in. in outside diameter at the bottom and 16½ ft. in inside diameter at the top, and rise 285 ft. above the roof mats, making a total height of 376 ft. above the bottom of the ash-pits. The stacks were designed to handle high boiler ratings with natural draft only, thus avoiding the complication of forced draft apparatus.

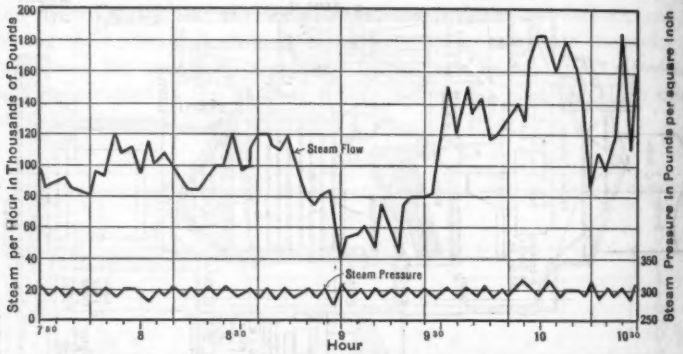

FIG. 7.—TYPICAL STEAM FLOW FROM ONE BOILER, NARROWS POWER PLANT, VIRGINIAN RAILWAY.

Boilers.—Five boilers of the horizontal water-tube type, are provided. Each has an A. S. M. E. rating of 1 520 h.p. and operates at a steam pressure of 325 lb. per sq. in. In service, these boilers are at times run at very high ratings, that is, the fluctuations in demand are violent (see Fig. 7). The variations are from normal boiler rating, or less, up to 400% rating in 2½ min. The boilers have interdeck superheaters to furnish 150° superheat at 160% rating, with a variation of not more than 15° between normal and 440% rating.

As will be seen from the cross-section (Fig. 6), the boilers are mounted over very large and deep furnaces to suit the requirements of powdered fuel combustion.

Coal Supply.—Coal is delivered by the railway in cars from a main-line siding, which has a holding capacity of thirty-five cars. Delivery is into a track hopper, thence to a crusher by a belt conveyor fitted with a magnetic separator, to remove metallic particles. The crushed coal is then lifted by a skip-hoist into bins in the boiler-house, having a total storage capacity of 900 tons. There is also a yard storage space for 2 000 tons, to and from which coal is readily piled and reclaimed by mechanical means.

Pulverized Fuel.—The equipment used to provide powdered fuel takes the crushed coal from bunkers in the power-house building by gravity through spouts into pulverizing mills on the ground floor. The mills grind the coal to a size passing a 150 mesh; delivery is through a pipe to the top of the building by air pressure (see Figs. 6 and 9) and into a cyclone separator. From the latter it drops into a horizontal conveyor in which a screw operates to deliver the pulverized coal into bunkers above the firing floor. One bunker, provided for each boiler unit, has a capacity of about 130 tons, or about one day's supply. From these bunkers the pulverized coal is delivered by screw feeders to ten jet burners for each boiler, so mounted as to inject the fuel into the furnace in divided and nearly vertical streams.

Air under pressure is admitted with the coal into the burner nozzles and acts as a vehicle to carry the finely divided fuel into the furnace at the proper velocity. Fig. 10 is a view of the mechanism for controlling the speed of the burners and the draft. A certain amount of air is drawn in around the nozzles, but the main supply for combustion is introduced through inlets in the walls of the furnace so arranged as to furnish each particle of burning coal with sufficient air for its complete combustion. For the purpose of avoiding excessive temperatures in the brickwork, the furnace side-walls are made hollow, forming a space through which the greater part of the air for combustion is circulated.

The jet flame travels downward toward a horizontal water screen in the lower zone of the furnace where its injection velocity is lost. The flameway then doubles back on itself and is drawn upward at the rear of the furnace by the stack draft over and across the boiler tubes. The jets travel in the furnace about 50 ft. before reaching the boiler-tube surface, thus allowing sufficient time for complete combustion in the furnace proper. To secure this long flameway, of course, the furnace must be very large; it is of about 14 000 cu. ft. contents, or 9.2 cu. ft. per rated boiler h.p.

A certain amount of tubular heating surface is provided in the water screens near the rear wall and across the bottom of the furnace; this serves to protect the lining from the excessive temperatures produced at points where the fuel jet impinges on the walls. The tubes at the bottom also act to prevent the formation of slag, and cause the ash to take the form of small particles which are projected into a pit, from which they are carried away by a stream of water flowing in a sluice-way. Because of doubt as to the most suitable location and amount of furnace side tubing for this form of combustion, a limited heating surface only was supplied in this way. It appears probable that eventually the furnace for powdered coal combustion may contain the major portion of the total boiler-heating surface; that is, this form of firing may lead to a radical change in water-tube boiler design.

The control of combustion in the furnace under varying requirements is effected by regulating the amount of fuel to the burner and also the air supply. Furthermore, individual burners can be "cut in or out" as desired. The combustion is controlled partly automatically and partly by hand. Each boiler is equipped with a control box which contains a system of gearing and

switches to vary the speed of the fuel feed and the movement of the dampers to admit air to the furnace. This apparatus (Fig. 10) is, in turn, controlled from a master switch on the central panel board on which are mounted temperature, pressure, and draft gauges.

The variation of steam pressure in the boiler header actuates a master switch, which regulates movements in the individual control boxes at the boilers. Push-button switches are also provided on the panel to permit of "cutting in and out" individual jets and the adjustment of air and fuel by hand, as required. Thus, the amount of fuel in the furnace at any time can be made to follow closely the plant load conditions and, therefore, the variation in steam pressure can be more uniformly maintained than is possible where there is a large amount of partly consumed solid fuel in the furnace.

As illustrating what has been accomplished in actual practice with this form of firing, Fig. 7 gives a record of the steam-flow meter chart on one of the boilers. The upper line shows that steam requirements varied from about normal to 400% of rating. The lower line gives the record of pressure in the saturated steam header, which fluctuates about 25 lb. under extreme conditions. This is a very satisfactory showing. In practice, it is seldom that the boiler safety valves open on account of excessive rise in pressure.

Steam Turbines.—Four turbo-generators are provided. These have cast steel bed-plates mounted on box girders filled with concrete and supported on concrete piers, thoroughly cross-braced. This heavy monolithic structure is designed to eliminate vibration. Each turbine is furnished with its own condenser (mounted underneath), of the "surface" type, having 20 000 sq. ft. of tube cooling surface. The water supply, amounting to about 20 000 gal. per min. for each condenser, is obtained through an intake tunnel at the upstream side of the power house and discharged through an outflow tunnel down stream.

Each turbine is direct-connected to a generator. This machine is wound for 3-phase 25-cycle current at 11 000 volts. It has a continuous capacity of 10 000 kw. at 80% power factor, single-phase rating. Its single-phase rating for 1 hour is 12 500 kw. A view of the turbine room is shown, Fig. 11.

Transformers.—From the generators the current passes through disconnecting switches to the step-up transformers, which are single-phase and raise the potential to 88 000 volts. Thence, it passes through oil-circuit breakers to the high-tension transmission lines, which deliver current to the sub-stations along the railroad. The step-up transformers, lightning protection, and other sub-station apparatus are placed outside the power-plant building (Fig. 8). The transformers are four in number and are oil-immersed and water-cooled. Each is rated at 10 000 kv-a. continuously, or 15 000 kv-a. for 1 hour, and 20 000 kv-a. for 5 min. following a continuous full-load run. The system power factor is about 85 per cent.

Regenerating Rheostats.—As has been mentioned, on heavy down grades at several places along the railway, a descending train automatically returns electrical energy to the distribution system. Should there be other trains in motion elsewhere and drawing current, the energy thus returned assists in

TABLE 3.—Narrows Power Plant. General Data.

(Installed generating capacity (continuous rating), 40 000 kw.; output per year to move 12 500 000 tons of coal, 120 000 000 kw-hr.)

Building dimensions	Boiler room	217 ft. long, 62 ft. wide.
	Turbine room	176 ft. long, 65 ft. wide.
Areas	Boiler room	13 500 sq. ft.
	Square foot per boiler horse power	1.48 sq. ft.
	Square foot per kilowatt generators installed	0.34 sq. ft.
	Turbine room	11 500 sq. ft.
	Square foot per kilowatt generators installed	0.29 sq. ft.
Elevations above sea level	Basement floor	1 525.0 ft.
	Extreme high water	1 549.0 ft.
Stacks	Height above ash-pits	376 ft.
	Height above concrete mat at roof	285 ft.
	Top inside diameter	16 ft.
Fuel used (coal)	Quality	West Virginia low volatile, 13 500 B. t. u.
	Average daily consumption	250 tons (run of mine).
	Capable of handling machinery	85 tons per hour.
	Outside storage on track	30 cars (3 000 tons).
	Outside storage yard	2 000 tons.
	Inside storage, crushed	900 tons.
	Inside storage, pulverized	650 tons.
Boilers	Number installed	Five; space for one additional.
	Rating, each	1 520 b. h. p., A. S. M. E.
	Heating surface, each	15 210 sq. ft.
	Furnace dimensions	26 ft. 10 in. long, 16 ft. 3 in. wide, and 24 ft. 6 in. high.
	Superheater surface, each boiler	1 770 sq. ft.
	Pulverized fuel burners, per boiler	10
Turbines	Number installed	Four; space for one additional.
	Type	Parallel flow, impulse reaction.
	Speed	1 500 rev. per min.
	Operation	275 lb. steam pressure, 150° superheat, vacuum, 29 in.
	Maximum economy	12.48 lb. of steam per kw-hr.
Generators	Continuous rating, each	10 000-kw., 25-cycle, 3-phase, 11 000-volt.
	Exciters, direct-connected	125-kw., 250-volt, direct-current.
Condensers	Number installed	Four.
	Type	Surface; two-pass.
	Tube surface, each	20 000 sq. ft.
	Condensation water required, each	20 000 gal. per min.
Circulating pumps	Number installed	Four.
	Type	Centrifugal, with direct-connected variable speed, alternating-current motors.
	Capacity, each	20 000 gal. per min.
Condensate pumps	Number installed	Four.
	Type	Centrifugal, with direct-connected alternating-current motor.
	Capacity, each	300 000 lb. per hour, against 135-ft. head.
Boiler feed pumps	Number installed	Three.
	Type	6 in., four-stage, steam, turbine-driven.
	Capacity	650 gal. per min.
Feed-water heaters (open)	Number installed	Two.
	Type	Metering.
	Capacity, each	300 000 lb. per hour.
Feed-water heaters (bleeder)	Number installed	Four.
	Type	Closed.
	Capacity, each	200 000 lb. per hour.
House service water supply	Filters	Three, vertical pressure type.
	Capacity of each filter	350 gal. per min.
	Filter wash tank	One.
	Capacity of tank	7 500 gal.
Auxiliary power turbo-generator	Turbine	One unit, operating 6 000 rev. per min.
	Generator, gear-connected	300-kw., 440-volt, 3-phase, 750 rev. per min.
	Exciter, direct-connected to generator	100 kw., 250-volt, 750 rev. per min., direct-current.

TABLE 3.—(*Continued.*)

Air compressor, vacuum cleaner system	Installed capacity	One, 150 cu. ft., motor-driven, 100-lb. pressure.
	Type	One, vacuum producer, inlets on several boiler-room floors.
Crane	Installed capacity	50 tons with 10-ton auxiliary hoist.
	Type	One electric traveling, in turbine room.

propelling them. Should there, however, be current returned in excess of the amount required by other trains, this excess must be absorbed in some manner to prevent overspeeding the generators at the power house. For this purpose, water rheostats are provided. These are single-pole electrodes placed in the water at the mouth of the discharge tunnel. They cut in automatically and quietly absorb the surplus energy. It is found in practice that these rheostats seldom come into action, because over a long railway line generally a train is in motion to make use of all regenerated energy.

As the foregoing description of the power plant is very brief, additional statistical information is appended in Table 3.

High-Tension Transmission

From the step-up transformers at the power house a main transmission line distributes current to the sub-stations along the railway. Such transmission circuits are generally carried either on the poles or bridges supporting the catenary wire system, or a separate pole line may be located on the right of way. The Virginian Railway is a single-track line, except for 22 miles at the west end. The right of way is narrow, with a great amount of curvature, and is complicated with many tunnels and high viaducts. Moreover, future track changes are probable.

It was decided, therefore, to carry the transmission across country on a separate right of way, planned so as to intersect the railway only at the sub-stations, which are spaced about 20 miles apart. By reason of the rather circuitous alignment of the railway through the mountain passes, it was found possible in this way to secure a direct line transmission 34 miles shorter than the route along the railway right of way. At the westerly end, on the 22-mile double-track section, however, the transmission is carried on the catenary poles. At Matoaka, Va., a tie transmission line 9 miles long was run across country to connect with the Norfolk and Western Railway electric system at Bluestone, Va., thus tying together the power systems of the two companies for use in emergencies, or for the interchange of power.

Towers.—The line traverses a very broken country with many ridges and deep valleys which are heavily wooded. Economy of construction, therefore, required long wire spans. These are, normally, 900 ft. long, but a number are of considerably greater length, the longest being 2 440 ft. Locations for the towers were selected, where possible, upon local ridge crests, thus allowing the desired wire sag with a moderate tower height without encroaching on safe clearances at mid-span.

Square towers of the lattice type were used. These towers are of galvanized steel, and the framing and panel lengths are made suitable for economical transportation and setting up. They were designed to resist the unbalanced stresses caused by two broken wires and the tensions were limited by allowing the wires to slip in the supporting clamps. To the stresses produced under these assumptions was added that caused by a wind pressure of 8 lb. per sq. ft. acting on the projected area of ice-covered conductors plus 12 lb. per sq. ft. on 1½ times the projected area of one tower face. Ice loading of ½ in. radially was assumed as occurring simultaneously with maximum loading and wind pressures. Fig. 12 shows the design of the 88 000-volt suspension towers.

The tower footings consist of stubs and grillages embedded in the ground to provide adequate resistance against uplift, and designed for a low unit value for bearing resistance against settlement, with due allowances for secondary strains, which might develop due to deflections in newly tamped earth back-fill.

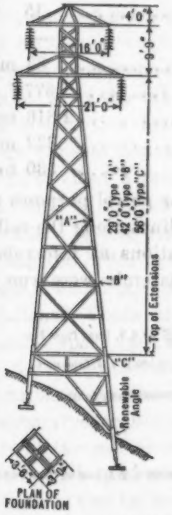

FIG. 12.—PLAN OF 88 000-VOLT SUSPENSION TOWER.

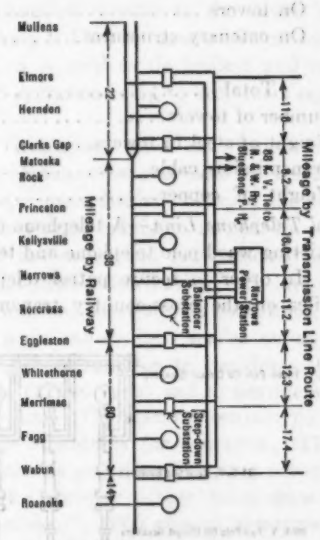

FIG. 13.—DIAGRAM OF POWER DISTRIBUTION SYSTEM.

Circuits.—The towers carry two single-phase 88 000-volt circuits, with the wires, arranged vertically, two on each side. The conductors are of hard-drawn stranded copper, having the following equivalent section:

For the 41 miles of transmission east of Narrows Power-House .....3/0 copper
For the 16 miles westward to Princeton...250 000 cir. mils.
For the 26.5 miles from Princeton to Elmore.....4/0 copper

On the upper cross-arms, the wires are spaced 16 ft. apart horizontally and, to prevent the possibility of the lower wires whipping and striking the upper

ones, those on the lower cross-arm are normally spaced 21 ft. apart horizontally. This separation is particularly necessary at the summits of the mountains where during the winter there is danger of "frozen fog", which is a crystalline mass, often of large diameter and of about the consistency of snow, forming on the conductors. The part of this mass struck by sunlight melts quickly and falls off, whereas the part in the shade remains, thus producing an unbalanced load and causing the cable to whip upward. This would require great vertical separation in order to avoid short circuits if the two cables on one side of the tower were in the same vertical plane.

The conductors are suspended from a string of seven porcelain disk insulators, with clamps so designed that slippage will occur at about 1 000-lb. pull in case of a broken conductor. Anchor towers are provided at crossings over railroads and also where necessary to take dead-end stresses. Miscellaneous data for the transmission line are as follows:

Total length:	
On towers	68 miles
On catenary structures	15 "
Total	83 miles
Number of towers	377
Weight of steel in towers	1 816 tons
Transmission cable	332 miles
Weight of copper	530 tons

Patrol Telephone Line.—A telephone circuit for patrol purposes was added to the existing wood-pole telephone and telegraph lines along the railway right of way. In order to secure patrol telephone stations at intervals of about three miles on the cross-country transmission, laterals were run from the railway.

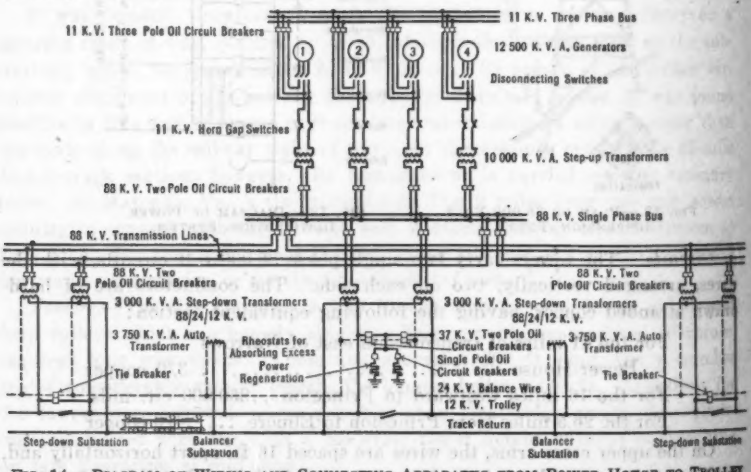

FIG. 14.—DIAGRAM OF WIRING AND CONNECTING APPARATUS FROM POWER HOUSE TO TROLLEY WIRE AND RETURN, VIRGINIAN RAILWAY ELECTRIFICATION.

Distribution

The distributing wiring and apparatus comprehends the various features of the traction system, beginning at the points where the transmission is tapped into the sub-stations. It includes the switching facilities, the transformers, the catenary-supported contact, the balancing wires over the tracks, and also the track-bonding and return conductors.

The general scheme of distribution is shown in Fig. 13 giving the relative location of the power plant and the transformer sub-stations, which are of two classes, "main step-down" and intermediate auto-transformer (or balancer) stations. Fig. 14 shows diagrammatically the complete electrical connections from the power plant to the train.

Attention is especially called to the simplicity of the switching arrangement. At the power house the step-up transformers are semi-permanently connected to the generators and all switching is done at 88 000 volts. At the sub-stations the transformers are connected directly to the trolley and balancing wire, and the principal switching is likewise done at 88 000 volts. One 11 000-volt breaker in each sub-station is used to tie trolleys and balancing wires together in emergencies, normal operation being to keep them separate in each direction from the sub-station.

In this distribution system the "balancing" wire and "balancing transformers" are unusual features. The arrangement was used for the first time on this work to effect a maximum separation distance between the step-down sub-stations and, at the same time, to reduce induction in near-by communication circuits. It was regarded as the safest and most efficient means of accomplishing the latter purpose in an installation having very large concentrated power demand normally and unusual short-circuit conditions.

Sub-Stations.—There are seven main sub-stations spaced on an average about 20 miles apart (see Fig. 13). These function to step-down the 88-kv. current to the trolley working voltage (11 000 volts) and to provide switching and sectionalizing for the catenary lines. The stations contain no rotating or other apparatus requiring regular attendants for operation. The transformers are of the self-cooled type and the switches, lightning arresters, etc., are of types, which need no housing for protection from the weather. Therefore, the stations can be made "out-of-door". The general arrangement may be seen in the view, Fig. 15. All these sub-stations are situated near a telegraph office or signal tower, where an employee is on regular duty and can be called on in emergency to open or close the oil-circuit breakers, under telephone instruction of the Power Director. Statistics regarding these main transformer sub-stations, also the balancing transformer sub-stations, are given in Table 4.

The seven balancing transformer stations are located approximately midway between the main sub-stations, and contain auto-transformers, non-automatic disconnect switches, and lightning arresters only. They have no connection with the 88-kv. transmission, in fact, they cannot be considered sub-stations in the ordinary sense of the word.

TABLE 4.—Data Relative to Transformer Sub-Stations.

	Distance from West End of Division.		
	Miles.	Number of transformers.	Total transformer capacity, in kilovolt-amperes.
Main Transformer Sub-Stations:

Roanoke, Va.	133.0	2	7 500

An important departure from usual practice is in the type of transformer used. It is equipped with a third coil on the low-tension side. This coil furnishes current of double the trolley voltage to a "balancing" wire, which is carried on the catenary poles, and connects all main sub-stations and also the auto-transformers located at seven places along the line, midway between the main and at the easterly end of the contact line. While, in one sense, these auto-transformers are auxiliary sub-stations, their function is, in fact, quite different, as will appear subsequently. Their general arrangement and appearance is shown in Fig. 16.

Balancing System.—The essential elements of this novel form of distribution are shown in Figs. 13 and 14. They are: The three-coil transformers in the main sub-stations; the auto-transformer sub-stations; and the connecting "balancing" wire.

The three-coil step-down transformer has one of its secondary windings connected between the trolley wire and the track, and furnishes the propulsion current at 12 000 volts (11 000 volts, nominal); the other secondary is connected between the balance wire and the track and carries balancing current at 24 000 volts. The contact wire, the track, and the balancing wire thus form a three-wire system having a connecting feeder of double the trolley voltage. The reasons for the higher feeder voltage are: First, higher auxiliary transmission voltage of about 36 000, resulting in economy of copper and permitting greater through feed between sub-stations; second, the contemplated ultimate use of 24 000 volts at the trolley so that the feeder voltage, which is of opposite polarity, will counterbalance the static effect; and, third, the better balancing of track currents to points of load, thereby reducing the inductive effect on adjacent communication circuits.

Inductive Effects.—The conditions producing induction in paralleling circuits must be referred to at some length in order to make the functions of the corrective devices clear. Energy is transferred through space from one

FIG. 15.—TYPICAL MAIN TRANSFORMER SUB-STATION.

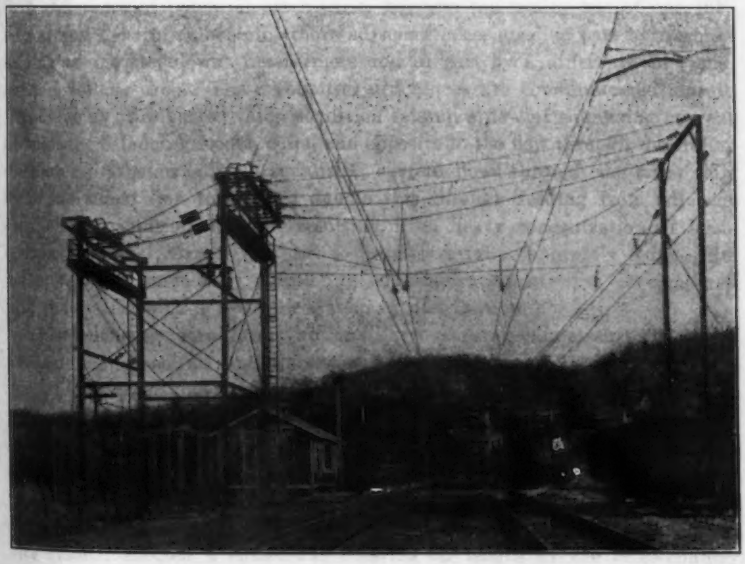

FIG. 16.—TYPICAL BALANCING TRANSFORMER SUB-STATION.

alternating-current circuit to another, due to changes in voltage or amperage of currents in either circuit, and is called "induction". The magnitude of this effect depends on a number of factors and conditions and is common to all forms of power transmission and distribution in varying degree. It is especially great under the condition of derangement of the power lines which causes grounds or short circuits. The extension of the application of powerful electric currents in transportation and for the manifold every-day uses of the public must continue, as must also the use of feeble currents in "communication" systems. Neither should be allowed to exclude the essentials for the successful application of the other, which means that correctives against interference may have to be applied in both systems to insure satisfactory operation.

Various methods, or a combination of methods, may be utilized to reduce or mitigate troubles from induction in communication circuits. Of course, the most effective way is to secure considerable separation between the feeble current line and a paralleling power line. Where a sufficient separation cannot be obtained, a practical method for reducing induction from traction currents is by some form of three-wire traction distribution, of which the latest development for heavy railway work is the balancing wire system mentioned. In stating this, of course, it is understood that the communication line must be the highest modern standard and, in addition, that special devices may be required in it to obtain the fullest immunity, even when all practical correctives have been applied to the power line.

A difference of potential often exists between the trolley bus of one sub-station and the trolley buses of those adjacent, occasioned in part by unequal loading of the step-down transformers and in part by a difference in transmission voltage drop. These potential differences are communicated also to the balancing wire buses, which condition sets up a flow of equalizing current through the balancing feeder, equal and opposite to the flow through the trolley conductor. Substantially no equalizing current flows through the track rails from one sub-station to another due to this through feeding from adjacent ones. This condition, whether resulting from heavy concentration of loads or from abnormal current flow due to insulation failures, greatly reduces the inductive effect on closely paralleling communication circuits as compared with that usual with a two-wire system of distribution.

This balancing wire forms an auxiliary transmission circuit to utilize the installed capacities at adjacent sub-stations more fully than otherwise would be possible; and it effects, also, an improvement in voltage regulation. At the far end of the railway electrification it permitted the installation of an auto-transformer without the necessity of extending the high-tension transmission eleven miles to that point. The somewhat devious route of the railroad, occasioned by the topography of the country, and the wide spacing (20 miles) between main sub-stations, secured by the adoption of this balancing wire system, effected a considerable saving in length of the cross-country transmission by means of long direct-line runs. This would not have been possible with the ordinary and close sub-station spacing; it would have been

necessary to run the line nearly parallel with and close to the railway so as to tie in at the more frequent points.

Sectionalization.—Novel methods were adopted in the circuit switching for this installation. In the event of a short circuit in a trolley section supplied by two sub-stations, the breaker supplying the heavier current caused by the "short" usually opens first, leaving a stub-end short-circuit flow of current from the adjacent sub-station until the current is ruptured at that point. In the meantime severe induction would occur in a two-wire distribution system. In a balancing wire system, however, by using automatic circuit breakers only on the high-tension side of the transformers, the opening of one high-tension breaker and the bus tie breaker leaves both secondary coils of the step-down transformer still connected across the trolley and the balancing wire, which now acts as an auto-transformer, so that stub-end induction effects are avoided at all times.

High-tension breakers, actuated by directional relays, connected in both trolley and feeder conductors on either side of the tie breakers, are so arranged that only the breaker directly feeding the "short" will open, leaving the adjacent section still energized. The bus tie breakers open automatically in case of short circuit. They are also arranged to re-close automatically on the re-energizing of the line from either end, thus establishing through feed to the load from both directions.

The Catenary

The term, "catenary", refers to the form of vertical curve which the messenger cable takes when subjected to a uniform loading between supports; but in connection with an electric traction system the word is generally used to designate broadly the contact devices and supports for such systems over the railway tracks. The contact system is, perhaps, the most vitally important part of a traction installation. It is the means of getting current to the train at any place and under any conditions. As it must be adapted to widely varying physical conditions, and must function properly under all, much ingenuity has been exercised by designers in the development of an effective, durable, and sightly structure and one which can be applied at a reasonable first cost.

The Virginian installation illustrates what has been accomplished in these respects by years of experience with such work. The supporting structures are poles or columns, in single piece; brackets or cross-wires supporting the catenary wire proper; and back-guying to provide anchorage against cross-stresses. The use of high voltage in the trolley wire makes it possible to keep down the dead weight of the system by reducing the size and number of conductors to be supported. In the design of this wire, two elements are of first importance, namely, the contact wire must have sufficient current-carrying capacity to supply all demands and it must provide a sparkless collection of current. To accomplish the latter, the contact wire must be maintained in a fairly level position over the track and be supported so that it has a substantially uniform "contact quality" or "softness". Practical experience in the

design of such a system is of special value in successfully dealing with this difficult problem of sparkless current collection.

The sparking tendency at a contact may be minimized by reducing the amount (amperes) of current collected. While opinions differ as to the maximum quantity collectable, there can be no doubt that the smaller the current the better will be the collection without excessive pantograph pressure on the wire. Logically, therefore, for all reasons, the trolley current voltage should be made as high as practicable. Consequently, the efforts of designers of modern electric traction installations have been directed toward raising the trolley voltage to the highest possible value.

Amount of Current to Be Collected.—The Virginian Railway locomotives consist of three cabs, each of which is equipped with a pantograph having its sliding surface in the form of two parallel thin metal shoes. Each shoe is intended to collect its proportionate share of current. In service the locomotive is run with two pantographs in operation which results in four sliding contacts functioning on the trolley wire. The voltage in the wire is normally 11 000 and the current required at this voltage, to accelerate a train, is from 1 000 to 1 200 amperes per locomotive, or about 300 amperes per contact. During normal running about 150 amperes per contact are collected.

Experience on other railways indicates that 300 amperes can be collected from a single trolley wire with a comfortable margin for the variables occasioned by the usual grade of maintenance of a complicated wire system of the kind. However, in the case of the Virginian Railway, to provide for the possibility that in the future it may become desirable to raise the trolley voltage, the transformers and switches in the sub-stations and on the locomotives have been so constructed that the working voltage may be made 22 000 by simple and inexpensive changes in connections.

Size of Wires.—The contact and supporting wires, over the heavy demand portions of the railway, were designed to carry 1 500 amperes for 10 min. on a hot day without suffering a loss of tension through over-heating sufficiently to result in a badly sagging line. On the light grade portions, the system was designed to carry 850 amperes for 10 min., under similar conditions. The distribution of this carrying capacity is as follows:

The trolley wire is a 3/0 grooved wire of copper tin bronze, drawn to a tensile strength of 60 000 lb. per sq. in. and characterized by its resistance to wear, toughness, and ability to withstand high tensions continuously without permanent stretch. Its conductivity is 65% of that of copper. Above, and parallel to, the trolley wire is an auxiliary messenger of hard drawn copper. This wire acts as an electrical feeder in addition to assisting to secure a soft contact line; finally, the main messenger (catenary cable) has considerable electrical conducting capacity. This messenger is a composite cable, having a stranded core of special composition bronze wires of 125 000 lb. per sq. in. tensile strength and surrounded by a covering of hard-drawn copper wires. No special feeder cables were required in addition to the essential wires of the catenary construction described. In a sense, however, the "balancing" wire is a feeder, but it was used for another main purpose, as has been mentioned.

Suspension Method.—The single trolley, or contact, wire is carried from an auxiliary wire by clips; this latter wire is, in turn, suspended from the main messenger by wire hangers, clipped to the auxiliary. The messenger cable is hung through a string of insulators of the suspension type to a bracket carried from a side pole, in single-track construction (Fig. 17), or from a cross-catenary wire carried by two poles, one on either side of the tracks, in cases of multiple tracks (Fig. 18). This, in general, is normal tangent construction. Special methods of suspension, however, are required to insure a "soft" contact line on curves and through overhead wire switches and section breaks.

Materials.—Reference has already been made to the non-ferrous composition of the wires. In addition, all trolley hangers and clips are of bronze. This non-ferrous wire system produces greater variations in tension, due to temperature changes, than a steel messenger cable, and, consequently, a greater variation in the height of the trolley wire. The tension of the latter, however, was made sufficiently high so that in summer it will not become flabby and thus produce an undesirable variation in contact conditions; and, on the other hand, so that tensions shall be within the elastic limit of the materials in extremely cold weather. No mechanical tensioning devices are used or required under any condition, as in a properly designed system the temperature stresses are relieved by the elasticity of the wires, by the means of carrying them, and by the elasticity of the supporting poles and cross-wires. The frequent occurrence of curves, also, materially assists in distributing stresses.

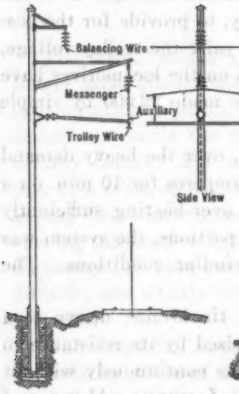

FIG. 17.—TYPICAL TANGENT BRACKET.

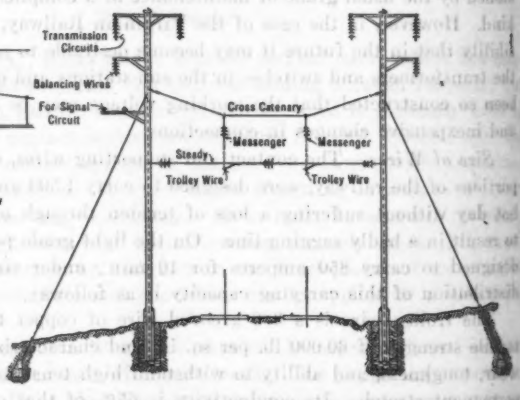

FIG. 18.—TYPICAL TANGENT CROSS-CATENARY BRIDGE.

As it is strung the trolley wire is given a tension of 3 000 lb. at a temperature of 60° Fahr. This tension is expected to increase to approximately 4 800 lb. at a temperature of 20° below zero. The messenger is given a sag of 5½ ft. in a 300-ft. span at a temperature of 60° Fahr.

Curves and Special Work.—Two methods of hanging the trolley wire from the messenger are in general use in America for curved tracks. One is the "chord" construction, in which, by a series of pull-offs, the trolley and messenger are kept approximately over the center of the track in a series of

chords. This form of construction is somewhat unsightly, as the catenary bridges or pull-off poles must be placed comparatively close together to avoid too great a departure of the wires from the track curve. Chord construction was used only in the yards on the Virginian Railway.

The other method—the one used on the main line—is the "curved catenary" construction, in which the trolley wire follows the center line of the track fairly closely around the curve. This is accomplished by the use of inclined hangers, the messenger being offset the proper amount at its supports, as predetermined by calculation. This form permits the supporting structures to be spaced farther apart than in case of chord construction, and the wire system presents a very neat appearance. Where the track curves are very sharp, "pull-offs" for the trolley wire are used in addition, to permit greater spacing of the supporting structure and to limit the incline of the hangers to an angle which will not cause interference with the pantograph on the locomotive.

The sloping hanger construction produces flexibility by allowing the wires to swing around the messenger cable as a center, and tends to eliminate "hard spots". A "hard spot" may be caused either by the increased inertia of a heavy fitting, inserted locally, or by a cusp or kink in the wire; also, by the application to the contact wire of a force (push or pull) in a vertical direction. Any of these conditions has the effect of interrupting the wave produced by an advancing pantograph, which thus may be made to rebound from the wire. This, of course, results in sparking and burning. In the design of the hardware, or fittings, it is the aim to reduce the concentrated weights as much as possible, also to avoid rigidly braced points, vertical cusps, or sudden changes of direction of the wire, and struts that directly push or bear down on the wire.

Section Breaks.—In order to divide the trolley properly into convenient electrical sections insulated one from the other, to prevent faults from being communicated to the whole system, and to isolate sections when making repairs, some form of separation must be used between adjacent sections, which will permit the sparkless passage of the locomotive pantograph across the break. Wooden sticks have frequently been used for this purpose but they are not entirely satisfactory as insulators, are mechanically uncertain, and are so heavy as to cause "hard spots" in the trolley wire, which tend to cause arcs as the pantograph passes.

To avoid the use of wood and to secure a soft line, "air-gap" section breaks are employed. In these, the two sections of trolley wire are lapped past each other, separated horizontally about 12 in. At the point of transfer the wires gradually rise above the level of the contact line and their tension is finally carried back through porcelain strain insulators at a higher level into the trolley of the next electrical section. The lapped trolleys are suspended from the same messenger by hangers and are kept separated horizontally by bronze deflector rods.

Insulators.—The trolley insulators are of the suspension type and are used in strings of three. They are porcelain disks, 10 in. in diameter, cemented into malleable iron housings. Each unit has a rating of 16 000 volts and the three

together will withstand a dry flash-over test of 190 000 volts. In certain tunnels, on account of limited clearance, it was impossible to use the suspension insulators. Therefore, two-piece insulators of the rigid type, two in series, were utilized. Great care was exercised in the design of the tunnel insulation, because of the importance of insuring reliability in the presence of moisture, smoke, and gases, and because of the difficulty of making renewals under traffic.

Supporting Structures.—In general, the side supports, or poles, for the catenary are spaced from 300 to 320 ft. apart on tangents. On curves, the spans must be shorter, for reasons already given. On very sharp curves, special pull-off poles (see Fig. 19) are used in addition to the supporting poles.

For single-track, and for a portion of the two-track, line, the supporting structure is a single pole carrying a bracket (Fig. 17); the major portion of the installation is of this type. For multiple tracks a one-piece pole, on either side of the track and back-guyed, is used (Fig. 18). In this latter construction no rigid cross-member is required. Both tapered tubular poles or H-columns of a uniform section are suitable as vertical supporting members, but in the case of the Virginian Railway the H-column type was employed because of economy, because it is easily climbed by the use of "climbing skates" and because wire attachments are readily made. The cross-member, which carries the main catenary system, is a wire strand, a form of construction the engineers have developed and used with success on other railway electrifications. The distinctive features of the catenary system described, are the production of a relatively cheap and elastic construction which is as light as is consistent with durability and safety. Incidentally, the design offers the least interference to vision along the tracks from the locomotive. Fig. 20 shows cross-catenary construction on yard tracks.

Poles or columns having continuous surfaces are to be preferred over latticed structure supports, not only from the standpoint of first cost, but also because they present vertical surfaces quickly drained and automatically cleaned by rain, whereas lattice-bar columns tend to collect dirt and moisture, which lead to corrosion. Repainting is also a relatively simple and cheap performance.

Foundations.—Heretofore, it has been common practice to set poles on concrete foundations poured in forms in place. In this installation a novel type of setting was devised which greatly reduced the cost of the foundations and did not require the distribution of concreting materials along the tracks, with the attendant added cost and considerable interference to traffic during construction. It was aimed to approximate the simplicity and cheapness of a wooden telegraph-pole setting. In carrying this out the columns were first served with a reinforced concrete casing on their lower ends. This was done in a yard at Roanoke some weeks in advance of distributing the columns to their sites. The design of this reinforcing and protecting casing is shown in Fig. 21.

The foundation proper was made by digging holes of comparatively small diameter in the desired locations along the track; broken stone was then placed

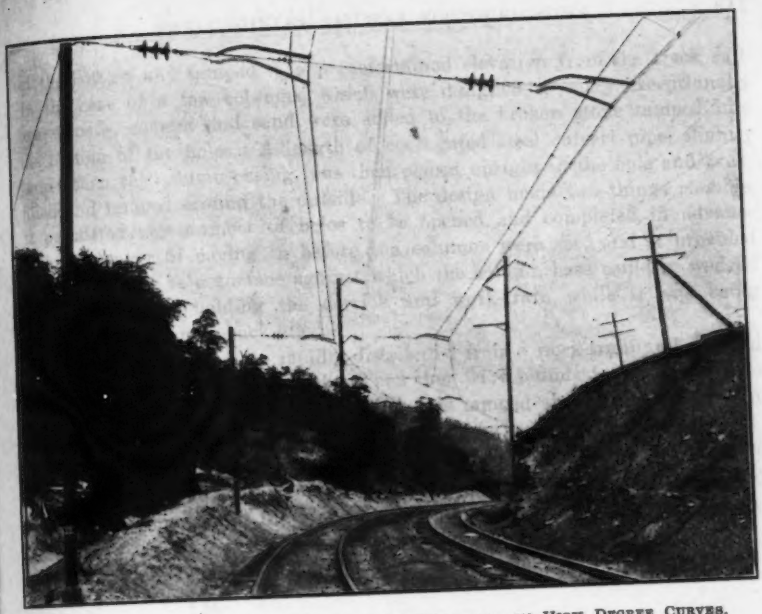

FIG. 19.—TYPICAL TWO-TRACK CATENARY CONSTRUCTION ON HIGH DEGREE CURVES.

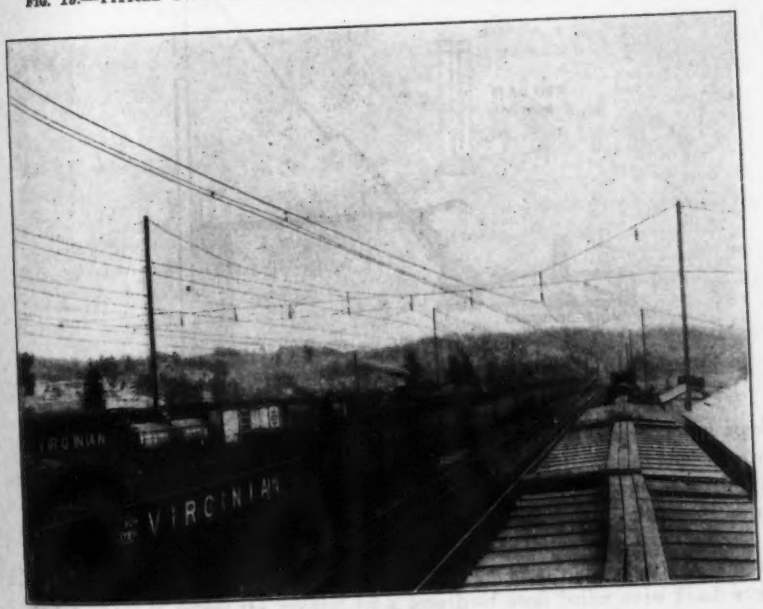

FIG. 20.—CROSS-CATENARY CONSTRUCTION ON YARD TRACKS.

at the bottom and tamped to a predetermined elevation from the track rail. In the case of a few columns, which were designed to carry exceptionally heavy loads, cement and sand were added to the broken stone tamped into the bottom of the holes. A length of corrugated steel culvert pipe, slightly larger than the column casing, was then placed upright in the hole and back-filled and tamped around the outside. The design made two things possible. It permitted any number of holes to be opened and completed in advance without danger of caving in before the columns were set; and it provided the culvert pipe as a surface against which the column base could be wedged and left, without holding the derrick and work-train while it was being plumbed and the hole back-filled.

The cased columns were rapidly distributed from a work-train and dropped in place in the holes by a derrick. Then they were plumbed and the culverts filled with earth and broken stone, which was tamped around the casings. A surprisingly strong bond was thereby obtained between the base and the culvert pipe, as was demonstrated when there was occasion to pull up and re-locate several columns. In such cases, it was found that the column, casing, fill, and culvert pipe came out of the ground as a unit when pulled up by the derrick.

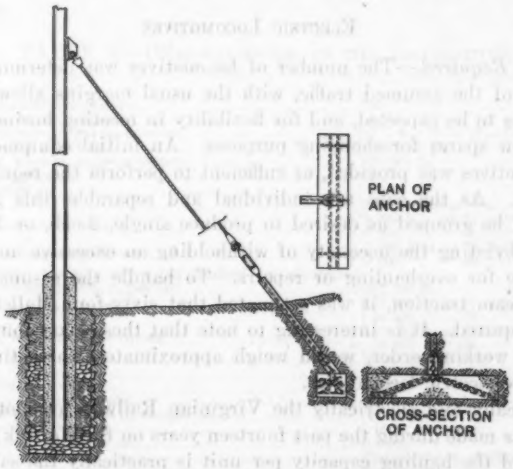

FIG. 21.—GUY AND ANCHOR FOR CATENARY SUPPORTS.

Guys.—The columns are guyed with extra high strength galvanized steel strand attached to anchors set in the ground (see Fig. 21). These anchors are pre-cast rectangular blocks of concrete, 6½ ft. long by 18 in. wide by 14 to 17 in. deep, and weigh from 1 720 to 2 100 lb. each. They are reinforced with longitudinal rods, 1 in. square, and cross-rods, ½ in. square.

The guy strand is connected to the anchor by a steel rod stub which is protected where it enters the ground by a length of steel boiler tube filled with grout. The guy is attached to the anchor by a swivel connection and to the

strand by a turnbuckle. The stresses on these guys and anchors are considerable, amounting at times to 35 000 lb., but experience covering several years (in three other installations) has shown that the construction is an entirely dependable form of pole bracing, where space permits of its use, and that it constitutes a valuable means of lightening and cheapening catenary construction. On tangents, the bracket posts are used without guys; on curves, they are back-guyed.

Track Return.—The means of returning the current from the locomotive to the sub-stations is through the bonded track rails. The running tracks are equipped with both 130 and 100-lb. rails and with lighter rails in sidings and yard tracks. All main running track rails are connected with two bonds per joint. Passing sidings have one bond only per joint; yard tracks are single-bonded, in one rail only. The bonds are No. 1/0 copper with expanded pin terminals, installed under the joint plates. Cross-bonds, each consisting of one No. 4/0 copper wire, are inserted at ½-mile intervals.

At the main sub-stations and balancer transformer sub-stations the track rails are connected to the buses by weather-proof insulated copper cables laid underground in trunking.

Electric Locomotives

Number Required.—The number of locomotives was determined from the train sheet of the assumed traffic, with the usual margins allowed to permit of the delays to be expected, and for flexibility in meeting business variables; also, to allow spares for shopping purposes. An initial equipment of twelve 3-cab locomotives was provided, as sufficient to perform the required schedule comfortably. As the cabs are individual and separable, this gave 36 cabs which could be grouped as desired to produce single, 2-cab, or 3-cab locomotives, and obviating the necessity of withholding an excessive number of cabs from service for overhauling or repairs. To handle the assumed volume of traffic by steam traction, it was estimated that sixty-four Mallet locomotives would be required. It is interesting to note that these sixty-four steam locomotives, in working order, would weigh approximately three times as much as the twelve electric locomotives.

Mechanically and electrically the Virginian Railway locomotive embodies developments made during the past fourteen years on the Norfolk and Western Railway, and the hauling capacity per unit is practically the same as in the case of the latest electric locomotive adopted by the neighboring road. The 3-cab locomotive of the Virginian Railway represents the greatest concentration of tractive effort in one singly controlled machine found in any present-day practice, steam or electric. To secure this, advantage has been taken of the fact that an unlimited number of driving axles can be electrically actuated by control from one point, in the manner familiar in multiple-unit electric passenger-train operation. Great capacity is thus readily secured by semi-permanently connecting together separate frame units, each with its own assemblage of wheels and driving mechanism designed for proper tracking characteristics.

Starting Conditions.—In fixing on a type of locomotive, the difficulty of starting very long and heavy trains on mountain grades must be taken into account. A successful start can be made only in a very gradual manner, by a series of impulses taking up the car-coupling slack in the train progressively, moving very slowly, a few cars at one time, until all are in motion. Otherwise, train "break-in-twos" will result.

Furthermore, on the heavy grades a pusher engine is often required at the rear of the train, and it must come into action at the right time and must take up its share of the load. To insure this coincident action with a train nearly a mile long is often difficult, as whistle signals may not carry to the rear, especially in crooked and narrow wooded valleys. It is interesting to note that on the westerly portion of the Virginian Railway for twenty miles on the heavy grade, there is only one point at which the rear end of the train can be seen from its head. It is, therefore, at times necessary to slack back to give a "bump" signal to the pusher, and often a considerable time interval may elapse in obtaining concerted action between the two locomotives, during which period the one at the rear may be exerting effort against a motionless train. Under these conditions the motors are subjected to high-current inputs and may be damaged unless they are of a type which will meet this severe requirement.

TABLE 5.—Characteristics of the Locomotives.

Number of three-unit locomotives	12
Number of cabs, or units each	3
Classification as to wheel arrangement	(2—8—2) + (2—8—2) + (2—8—2)
Total weight, approximately	1 285 000 lb.
Total weight on drivers, approximately	937 000 lb.
Number of driving axles	12
Number of motors	6
Type	3-phase induction
Total capacity, at 1-hour rating	6 000 h.p. at 14 miles per hour 6 990 " " 28 " " "
Total capacity, continuous rating	5 000 h.p. at 14 miles per hour 6 000 " " 28 " " "
Maximum starting tractive effort (as limited by electrical capacity equivalent to 30% adhesion)	277 500 lb.
Tractive effort, at 1-hour rating	162 000 lb. at 14 miles per hour 94 500 " 28 " " "
Tractive effort, at continuous rating	135 000 lb. at 14 miles per hour 78 800 " " 28 " " "
Maximum safe speed	38 miles per hour
Gear ratio	21 : 100
Diameter of driving wheels	62 in.
" " pony-truck wheels	33 in.
Length over-all (pulling faces of couplers)	152 ft. 3 in.
Rigid wheel-base (each unit)	16 ft. 6 in.
Voltage of trolley current	11 000
Kind of current	Single-phase, alternating
Transformer	Oil-cooled
Phase converter	Synchronous
Air-brake compressor capacity (each unit)	150 cu. ft. per min.

Type.—Fig. 22 shows the wheel and general arrangement of apparatus of one of the units making up a complete three-unit locomotive, and Fig. 23 shows the manner of grouping units in a semi-permanently connected whole. Fig. 24 is a view of one of these electric locomotives in service. The important statistics of the locomotive are given in Table 5.

Tractive Effort.—The tractive effort of this locomotive is probably as high as desirable, in view of keeping within safe car draft-gear stresses. If, how-

ever, it should be demonstrated in the future that longer and heavier trains can be handled reliably, the tractive effort of the locomotive may be readily increased one-third by adding one more unit. Provisions for this contingency have been made not only in the locomotive, but in the power system throughout.

Drive.—The running gear of each cab comprises four driving and two truck axles (Fig. 23). The drive is through side rods from the jack-shafts, each of which is connected to two pairs of wheels by main and side rods. These two driving couples are not interconnected because it was regarded better practice to avoid excessive rigidity of the system. The rod motion is a purely rotary one and, therefore, can be perfectly balanced by counterweights, thus eliminating the effect of dynamic augment at the track, such as necessarily results from the unbalanced reciprocating parts of the steam locomotive. The jack-shaft gears have spring-cushioned rims, one gear being mounted on each end of the jack-shaft.

The use of a rod drive is advantageous, in allowing maximum length of motor armatures, and hence maximum capacity, also in giving a simple form of connection between parts of the mechanism having relative vertical play, due to the wheel equalization and the springs. Furthermore, coupling of the axles by side rods insures maximum total adhesion for the locomotive as it avoids diminution of tractive effort which occurs with separately geared axles, due to inequality of weight distribution and to weight transfer at low-track rail joints, etc.

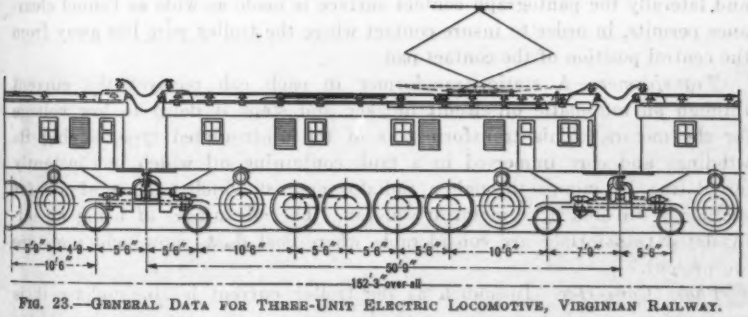

FIG. 23.—GENERAL DATA FOR THREE-UNIT ELECTRIC LOCOMOTIVE, VIRGINIAN RAILWAY.

Motors.—Each locomotive unit has two motors (Fig. 22), one set near each end of its frame and geared to a jack-shaft mounted directly beneath. The motors are 3-phase, having non-variable speed characteristics, that is, they operate at certain set speeds, irrespective of the loading and determined by the combination of motor-pole connections set up. Two standard running speeds were adopted, namely, 14 and 28 miles per hour. The former is used on the heavy grades; the latter on the level and light grades.

It has been found on the Norfolk and Western Railway, in similar service, that these speeds admirably suit the haulage of heavy "drag" freight trains, insuring the maintenance of schedule without excessive speeds over any part of the run. In certain kinds of railway service one inflexible speed

characteristic is objectionable, but in "drag" service where every train is of maximum weight it is advantageous, as the maintenance of absolutely uniform speed, regardless of change of grade, tends to prevent "break-in-twos" due to acceleration and retardation locally within the train itself.

Furthermore, the proper running speed should be accurately gauged and maintained over a road with the grades and curvature found on the Virginian Railway (Fig. 25). When regenerating down grade, the speeds obtainable are about 15 and 30 miles per hour. The change from motoring to regenerating, or *vice versa,* is automatic as the grade changes, without the master controller being thrown to the "off" position. The only action required of the engineman to accomplish the change is a movement of the transformer balancing switch lever.

The three-phase motor is especially well adapted to the difficult train-starting conditions, referred to previously. It is simple and robust in the construction of its revolving element and has no commutator; it is also of large output capacity for a given weight and dimensions.

Current is furnished from the contact wire to the locomotive and controlled through the main electric apparatus. The arrangement and relation of these various parts are shown in Figs. 22, 23, and 24.

Pantograph.—This is a lazy-tong contact device set on the roof of the locomotive cab. It collects current at 11 000 volts from the trolley wire. The mechanism has latitude of motion vertically for the variable wire heights, and laterally the pantograph contact surface is made as wide as tunnel clearance permits, in order to insure contact where the trolley wire lies away from the central position of the contact pan.

Transformer.—A static transformer in each cab receives the current through an automatic oil-circuit breaker and steps it down to low voltage for the motors. This transformer is of the oil-insulated type, having its windings and core immersed in a tank containing oil which is constantly circulating by pumps through a radiator against which a blast of air for cooling is directed by a motor-driven fan. The advantages of using an oil-insulated transformer are considerable where coal dust, snow, and moisture are present.

Phase Converter.—Inasmuch as the trolley current is single-phase it is necessary to provide apparatus on the locomotive to convert it to three-phase for use in the induction motors, hence the term, "split-phase", is sometimes used to describe this type of locomotive. This conversion is effected by means of a rotary "phase-converter", which consists of a synchronous motor with a two-phase wound stator and a wound rotor. One motor stator phase is fed from the transformer and proportional voltage is generated in the other of a phase displaced approximately 90° electrically from the first. One terminal of the generated phase is connected to the mid-point of the transformer secondary, resulting in a "Scott" connection to give three-phase power. The power factor of this three-phase circuit is high (about 95%) by reason of the synchronous type converter used. In an emergency the converter may be operated as a straight induction type.

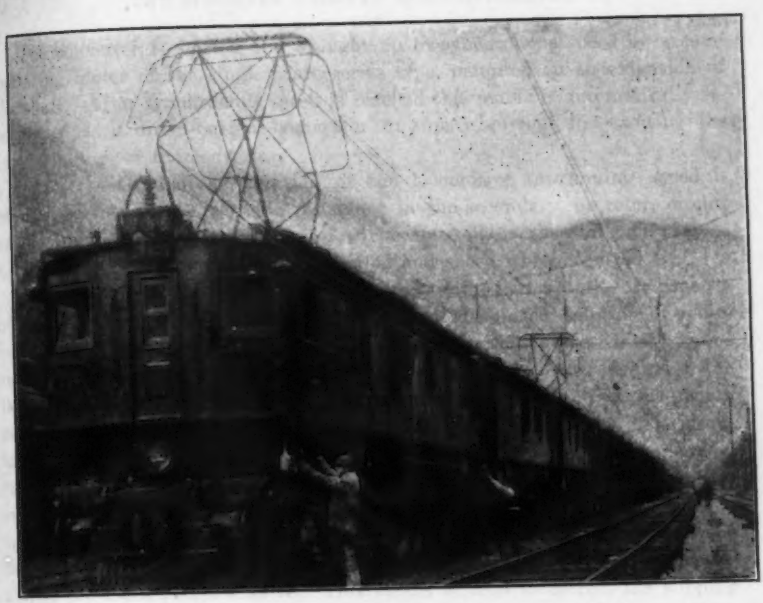

FIG. 24.—ELECTRIC LOCOMOTIVE, VIRGINIAN RAILWAY.

FIG. 25.—EMPTY TRAIN DESCENDING MOUNTAIN GRADE NEAR WEST END OF LINE.

The converter is started and brought up to synchronous speed by a commutating motor of the single-phase series type, mounted on an extension of the shaft. After synchronous speed is reached this motor is automatically reconnected as a direct-current generator to supply current for exciting the rotor windings of the converter.

Rheostat.—Gradual acceleration of the locomotive to running speed is effected by inserting a variable resistance in the secondary, or rotor, circuit of the traction motors by means of a rheostat. This rheostat can also be used to vary the locomotive tractive effort and speed when required.

The rheostat is of the electrolytic type, contained in a tank. It consists of metallic electrodes immersed in an unsaturated aqueous solution of sodic-carbonate. This electrolyte is controlled by an overflow valve which may be raised or lowered by a motor-driven mechanism to vary the height of the liquid around the electrodes and thus to vary the resistance in the motor circuit. As the electrolyte absorbs energy and thus becomes hot, it is circulated by a pump through a cooling tower. In addition to the main overflow valve, which regulates the height of the liquid, two auxiliary valves are provided, one for each electrode compartment. Either of these valves can be opened by a button in the motorman's controller to lower the level of the electrolyte rapidly in the compartment it controls, independently of the position of the main overflow valve. This means is used to correct the slipping of one set of drivers, or to reset the overload relays of one motor without affecting the tractive effort of the other.

Mechanical Construction.—The main backbone of each locomotive unit consists of two cast vanadium-steel side-frames, each in one piece, 42 ft. long, and tied together by end and intermediate castings which form motor supports and cross-ties. Between these ties a cast-steel bed is provided to form a continuous support for the heavy electrical apparatus, such as the phase converter, liquid rheostat, transformer, air compressor, etc., mounted on it. The whole frame assemblage is unusually strong in order to resist bumping and pulling shocks and any abnormal strains such as would be imposed if the locomotive should be lifted with the pedestal binders of the driving axle removed.

The frames and bed-plate carry all the driving mechanism and apparatus independently of the cab, or housing, mounted on it. This arrangement also provides means for supporting the cab rigidly on the substructure without the use of intermediary springs, and makes the cab, in effect, merely a box or shell to cover the apparatus and to carry the pantograph. Hatches are provided in the roof so that all apparatus may be lifted out by the shop traveling crane.

At each end of the frame is a two-wheeled pony truck. It is of the radius bar type with special suspension designed to give the desired resistance characteristics for tracking around curves and to distribute wheel-flange pressures properly between the truck and drivers.

No effort has been made to lighten the mechanical parts in order to obtain high weight efficiency of the locomotive as a whole. It was regarded

of importance, rather, to obtain ruggedness and durability in an extremely severe service.

For ready reference, a short summary of construction and operating data is given in Table 6.

TABLE 6.—CONDENSED DATA.

Dates	Engineering started	June 1, 1923
	Construction started	November 29, 1923
	Regular electric operation commenced between Mullens and Princeton	September 24, 1925
	Regular electric operation commenced over entire Division, Mullens to Roanoke	September 18, 1926
	Note.—Construction work suspended east of Princeton for three months, October to December, 1925, and resumed in January, 1926.	
Right of way	Route miles electrified	134
	Track " "	231
	Maximum grades, percentage	2
	Maximum curvature, degrees	12
	Percentage of line on curves of more than 2 degrees	54
Capacity	Tonnage of coal eastbound for which electrification was designed:	
	Per year	12 500 000
	Per maximum day	57 000
Train weight	Locomotives, cars, and lading on Clarks Gap Hill (two locomotives), in tons	7 285
	East of Princeton (one locomotive), in tons	9 640
	Westbound empty movement (one locomotive), in tons	3 440
Train speeds, running	Percentage of run at 14 miles per hour	53
	Percentage of run at 28 miles per hour	47
Maximum number of trains in motion and taking power	Simultaneous, eastbound	5
	" , westbound	2
	Total taking power at one time	7
	Total number of loaded cars moved eastbound on heavy day	2 200
	Total tonnage moved per heavy day eastbound and westbound (gross)	95 400
	Ton-miles (trailing) per month	160 000 000
Power demand	Starting 7 285-ton train, accelerating to 14 miles per hour on 2% grade, at train, in kilowatts	14 000
	Starting 9 640-ton train, accelerating to 28 miles per hour on 0.2% grade, at train, in kilowatts	11 000
Regeneration	Power, in kilowatts, regenerated down hill by 9 640-ton train	5 000
	Power regenerated in percentage of total consumed in an eastbound run over the Division	20
	Power regenerated in percentage of total power-house output	8

Power-house load	Normal day.	Congested day.
Average load, 24 hours, in kilowatts	14 500	20 500
2-hour peaks, in kilowatts	22 300	29 200
1-hour peaks, in kilowatts	31 300	31 500
5-min. peaks, in kilowatts	38 300	43 500
Total yearly power station output on basis of 12 500 000 tons of coal hauled eastbound, in kilowatt-hours	112 000 000	

INSPECTION AND REPAIR FACILITIES

Locomotive inspection facilities are required at the end of a run. At a turn-around point—such as at Roanoke—where it is undesirable to hold locomotives out of service for a considerable length of time, only minor routine inspection is done. The provisions made for this are: A track pit with housing over it, sanding facilities, and a supply of water for refilling the locomotive control rheostats. All these facilities are conveniently located for quick access by the locomotives.

The main repair shops for locomotives and cars and the Motive Power Department headquarters are at Princeton, 37 miles east of the Division terminus. These shops continue to be required for general equipment repairs for the road, other than for the electrified portion. It was deemed inexpedient to depend on the Princeton plant for all electric locomotive overhauling and repairs, as it was inconveniently located in reference to the end of the electric locomotive runs and the point where they are held for service. Therefore, it was decided to use the Princeton Shops for heavy and class repairs only of the electric equipment, and to build at Mullens a modern and well-equipped plant for general overhauling, minor repairs, and thorough inspection (Fig. 26).

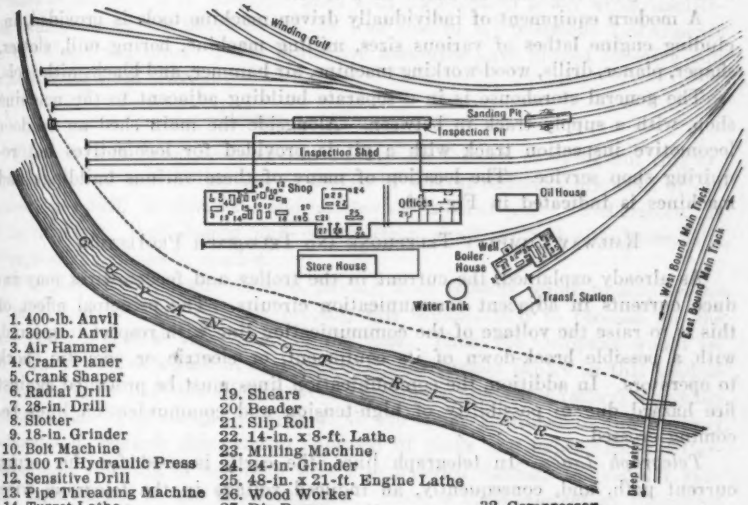

FIG. 26.—LAYOUT OF MULLENS SHOP, VIRGINIAN RAILWAY.

Mullens Shop.—The main building comprises a machine shop and an inspection track bay. It is a substantial steel framed structure, with curtain-walls of brick. The machine shop is 316 ft. long by 40 ft. wide. The front 50 ft. is fitted for offices, with a mezzanine for light machine work overhead. The rear 60 ft. houses the blacksmith shop, a foundry, and a welding shop.

A 15-ton traveling crane (hand-operated from the floor) spans the shop and travels the full length. Alongside the machine shop is a lean-to housing a carpenter shop, a dip-room, and two ovens for the impregnating and baking of motor coils. The ovens are electrically heated and are provided with automatic temperature recorders and control. The inspection shed part of the building is 206 ft. long by 70 ft. wide and covers three tracks, each long

enough to take locomotive cabs, with ample working space between each. An inspection pit is provided the entire length of each track, with a cross-pit at each end for dropping wheels; these cross-pits are equipped with hydraulic jacks. A 30-ton electrically driven traveling crane with a 10-ton auxiliary hoist spans the main shed and travels the full length.

The shop is heated by steam, supplied from a separate boiler and power plant. Electric shop power is obtained from the traction lines and is converted in this plant by a small transformer and motor-generator set from single-phase alternating current to 250 volts direct current for the shop machines. The building also contains electrically driven air compressors and service and fire pumps. The water supply is from wells and is pumped into a 125 000-gal. steel tank mounted on a tower.

A modern equipment of individually driven machine tools is provided, including engine lathes of various sizes, milling machine, boring mill, slotter, shaper, planer, drills, wood-working machine, air hammer, and blacksmith tools.

The general storehouse is in a separate building adjacent to the machine shop, with a supply track in between. Alongside the main shed an outdoor locomotive inspection track with a pit is provided for locomotives not requiring shop service. The location of many of these various buildings and machines is indicated in Fig. 26.

Railway Company Telephone and Telegraph Protection

As already explained, the current in the trolley and feeder wires may induce currents in adjacent communication circuits. The principal effect of this is to raise the voltage of the communication line with respect to ground, with a possible break-down of its equipment, or electric or acoustic shock to operators. In addition, the communication lines must be protected against fire hazard due to possibility of high-tension and communication lines becoming crossed.

Telegraph Lines.—In telegraph lines, the earth is used for the return current path, and, consequently, an induced voltage in the telegraph wire, with respect to ground, may cause disturbance in the proper functioning of the relay and interfere with normal telegraph dispatching. To prevent this, therefore, in the local circuits, a low-resistance relay of special design was introduced. This has a split circuit so arranged that the 25-cycle current passes through both parts in equal amounts and hence does not operate the relay or sounder. To protect the operator against coming in contact with high induced voltages, this special relay is enclosed in a wooden box, and insulated knobs are brought through the cover. Furthermore, an insulated telegraph key is provided.

On the through circuits, resonant shunts are introduced around standard relays in order to reduce the voltage to ground when the telegraph key is open. This shunt by-passes the greater part of the 25-cycle current, so that the operation of the relay is not affected. Anti-resonant shunts, or 25-cycle chokes, are also installed in all circuits to limit the flow of current to ground.

There are no protective devices used outside the zone of electric train operation, and hence means had to be provided to confine the induction to

the electrified section of the road. This was accomplished by installing special choke coils and resonant drainage coils at each end of the electrified zone, which drain off the 25-cycle current to ground. This arrangement, while it prevents normal induction from going beyond the electrified zone, does not afford protection in case of short circuits; it is, therefore, supplemented by low-voltage lightning protectors, which are designed to drain off any excess voltage.

Telephone Lines.—In the ungrounded telephone circuits the induction is about equal in both wires, and hence little disturbance is caused by normal operation. However, to provide against break-down of protection, and possible shocks to users (at times of short circuit), and also against possible crosses of the open-wire telephone lines with high-tension power wires, insulating transformers are provided on the line side of all telephone instruments in the electrified zone. These protective measures have proved effective and sufficient for good service.

Design and Construction

It is obvious from the foregoing description that, in carrying out this extensive project, a co-ordination of design in several different branches of engineering—civil, mechanical, and electrical—is involved. Furthermore, as it is necessary that design and construction shall proceed simultaneously, a large organization is needed.

The Railway Company decided, having these facts in mind, to employ the writer's firm to carry out the project, this organization to become for the time being a special department of the road. Thus, the Company would receive the benefit of a staff of designers and constructors skilled in this kind of work, and the entire installation would become a first-hand railway company undertaking. The engineers reported to the Chief Engineer of the Railway Company as regards the general approval of plans and expenditures. Purchases and auditing of accounts were also handled through the regular railway departments in the usual manner. Thus, a close contact of interested officials with the work in progress was maintained without burdening them with a multitude of detail.

Designing.—A heavy electric system cannot be applied to an existing property without a considerable number of changes in the steam railroad facilities, and, generally, a modification of certain operating methods is required to produce best results. As a basis, therefore, for preliminary information, the Company's records and plats of alignment and grade were used, and many conferences with the officials were had in order to determine the electric train sheets, and the additional operating facilities desired.

The roadway cross-sections, the tracks, tunnels, and viaducts were carefully studied, as well as the buildings and other facilities, which might affect the type and clearances of the catenary structures. All were separately checked in much detail, and supplementary surveying work was required both at the start and as designing progressed. Notes were also made of the nature of the sub-surface materials as an aid in determining the depth and character of column and guy-anchor foundations for the catenary spans. As

the transmission lines were to be run through a mountainous and heavily wooded country, extensive surveys were required, and protracted negotiations for the purchase of property or easements had to be conducted.

In order to deal with all designing problems promptly, a field organization, under the direction of a resident engineer, was formed and directed from a centrally located headquarters on the line. This official had charge of all surveying parties, and later, when construction was started, he organized and carried out the work, reporting to the home office in New York.

Many special problems in producing the designs have been mentioned. The design of the power house in itself involved much detail, but the plans for the electrical distribution system for 137 miles of railway, required the largest number of designers. Practically each catenary span had to be dealt with as a separate problem, because of the continually differing local situations as to foundations, track curvature, number of tracks, clearances, etc., all of which produce varying stress conditions. In the aggregate more than 3 000 drawings were made for the entire installation.

An important consideration in preparing designs is to reduce the amount of field cutting and fittings of parts of the catenary system during the process of erection. This was accomplished by securing accurate preliminary information as to track alignment and elevations, and by careful laying out and calculation in the drafting-room, notably of the curve and overhead special work, such as the turn-outs and section breaks. Schedules and tabular information were made up and furnished the field forces for each catenary span, including cable sags and hanger lengths, prior to the distribution of materials on the job. In this way a surprising amount of time and expense was saved in the actual erection work.

Construction.—Space admits the mention of only a few of the methods followed, principally those involved in the production of the transmission and distribution. Aside from the main construction headquarters at the Narrows Power Plant, secondary headquarters were established at several points along the railway. These were generally in camp trains, which furnished mobile living accommodations for the men. As many as five of these trains were used at times in the different operations. Certain of them carried tower cars which were used in the erection of the catenary wires and fittings. Tent camps were provided, especially for the surveying and erection forces on the transmission line, where this work was remote from the railway.

The entire work was so organized as to require the purchase of a limited amount only of special equipment to supplement the Railway Company's work-train and other construction or service apparatus and tools. A locomotive crane with a 50-ft. boom was used in erecting catenary poles, setting concrete anchors, etc. Extensive grading, where required at the sub-stations, was let to local contractors who had the necessary equipment.

The tower cars were built in the Company's shops by erecting wooden frames with extension tops on standard flat cars. A number of special automobile gasoline motor cars were used to haul air compressors for field

drilling and for the use of the adjusting and tensioning gangs; also for inspection and the transport of men and light materials. These cars were light and could be quickly removed from the track, to accommodate traffic. The aim was always to interfere as little as might be with regular train operation, with due regard, however, to a fair utilization of the time of men engaged in construction operations.

Transmission Line Erection.—The tower foundations were grillages with foot sections set in earth excavations and back-filled ready for setting up the superstructure. All this part of the work was laid out so as to require the minimum amount of handling of heavy pieces over a difficult country. The erection of tower sections was by means of a gin-pole carrying a block and tackle. Horse teams were used for haulage and for hoisting operations.

The stranded wire cable for the transmission circuits was delivered on reels, each containing about 2 600 ft. and strung through snatch-blocks attached to the tower cross-arms. The cable was afterward sagged, as called for by the engineering schedule, using block and tackle. The determination of the proper sag was by sighting through targets on the towers and on the cables at mid-span.

The rate of progress in this work was about one tower erected per day. Transmission cable was strung and sagged at the rate of 6 miles of cable per day.

Catenary Erection.—In conducting this operation, experience is especially valuable; the work must be done "under traffic", much is special to its location, and the adjustments required are many and precise.

As heretofore mentioned, the pole foundations are of a character that is not only economical in material and labor, but eliminates the necessity of requiring concreting work trains on the line and the consequent interference with revenue trains. The foundation holes were dug, or blasted out, as the case might be, fitted with corrugated steel casings, back-filled, and capped, ready for quickly placing the poles. These were placed in position by a locomotive crane attached to the work-train which rapidly carried a number of poles. In this way frequently as many as 35 poles were erected in a 10-hour day. The guy anchors were delivered and set in the same manner. At the time of placing the poles in the foundations, they were wedged plumb by wooden blocks, which were subsequently removed when the casings were back-filled. After an anchor and pole was set it was unnecessary to use the crane to complete the erection of guys or fittings.

The various wires of the catenary system were strung in the following order, by use of extension-top tower cars in a work-train: First the balancing transmission wire, then the cross-spans, the messenger cable, and, lastly, the trolley and auxiliary wires. Proper tension was given, in accordance with the drawings, by the use of a dynamometer installed at varying distances, depending on the track alignment. An average of four reels of messenger cable, each containing 4 500 ft., was strung and sagged per day; this amount, however, varied considerably, depending on traffic conditions.

Next, a separate gang distributed and erected the hangers, which had been previously cut to the lengths required by the tabulations of the designers and had been equipped with top and bottom fittings. The degree of accuracy of the designing calculations was such that little field cutting was required. The hangers were applied to the messenger cable by an employee riding the messenger in a "boatswain's chair". Subsequent operations were as follows: The erection of insulator strings, the clipping-in of auxiliary and contact wires, and the final adjustments. All these were done from light tower cars which could be quickly removed from the track, when required.

At points where special work, such as over-head switches, section breaks, deflectors, and pull-offs, occurred the operations were more complicated, and progress was slow.

Apparatus and Materials Used

All equipment was selected with due consideration of the service requirements and suitability. The electric apparatus throughout was of Westinghouse Electric and Manufacturing Company design and make. The mechanical parts of the locomotives were furnished by the American Locomotive Company. The powdered fuel combustion system is known as the "Lopulco" and was furnished by the Combustion Engineering Corporation.

Operating Results and Economies

The Virginian Railway has now (January, 1928) had full electric operation between Mullens and Roanoke for more than a year and on the section between Mullens and Princeton for approximately two years. The actual performance under electric traction has fully met expectations and the results have been satisfactory from the operating standpoint. The locomotives and the power system throughout have met the severe requirements of service. Trains of 9 000-tons trailing load are regularly operated over the line at 28 miles per hour on the low-grade sections and 14 miles per hour on the heavier grades, and are held by regenerative braking on descending grades without the use of air-brakes. The time of run between Mullens and Roanoke (134 miles), with full tonnage, as compared with steam, has been reduced 7 hours per trip, as anticipated.

The effect of electrification in increasing the capacity of the railroad, especially on the heavy grade section between Elmore and Clarks Gap, has been so pronounced that it is not anticipated that the ultimate capacity of the single-track railway will be reached, even with continued increase in business, for a long time to come.

It would be of much interest to present figures for the relative cost of operation, steam and electric, and to deduce the savings effected by the changed form of motive power, but the writer believes definite figures must follow very careful analysis covering a considerable period of time, and the conclusions cannot be safely used as a generalization in favor of electric traction elsewhere; they must be understood to apply only to the character of conditions, physical and operating, of the road in question.

It can now be safely stated that, as concerns the Virginian Railway Company's installation, savings have been very large and establish the fact that they will suffice to pay a very satisfactory return on the cost of the project, aside from a consideration of the indirect advantages secured. This result is largely due to the peculiar conditions of the service, that is, very heavy trains on a long division, operated at relatively high speed, such that the time of enginemen and train crews is greatly reduced over what is possible in a congested and slow steam operation.

Speaking in very general terms only, the main savings in operating costs on the electrified division of this road comprised reductions in three very large items, so that, on the basis of equal gross tonnage moved, the relative cost of electric operation and steam operation is as follows:

Enginemen and trainmen	One-third that of steam.
Locomotive repairs	One-third that of steam.
Fuel	One-half that of steam.

Engine-house expense, which is a comparatively small item, was reduced to one-quarter the amount required by steam service.

Personnel

This electrification was under the general direction of H. Fernstrom, M. Am. Soc. C. E., Chief Engineer of the Virginian Railway (now retired); Hugh Pattison, M. Am. Soc. C. E., Engineer of Electric Traction; John W. Sasser, Superintendent of Motive Power; and J. E. Sharpley, Electrical Engineer. The engineering, detail designing, and the construction work was carried out by Gibbs and Hill, Consulting Engineers, New York, in whose organization, in addition to the writer and E. R. Hill, M. Am. Soc. C. E., directly in charge of the designing and construction work, were Messrs. S. A. Spalding, Chief Engineer; Norman Litchfield, Mechanical Engineer; H. S. Richmond, Structural Engineer, and H. W. Hudson, M. Am. Soc. C. E., Resident Engineer, in the field.

DISCUSSION

W. B. POTTER,* M. AM. SOC. C. E. (by letter).—A substantial increase in tonnage capacity of the Virginian Railway with a material reduction in the number of locomotives and operating expenses is a result which speaks for itself. A comparison of the capital charges and operation under steam and electrification will be awaited with interest. A further comparative estimate based on a steam service equivalent to the heavier electric service might be even more interesting.

The electric system chosen with its constant speed characteristic appears to be well adapted to the particular requirements of this division of the Virginian Railway. It does not follow, however, that this is the only electric system capable of meeting the requirements.

Regeneration, as in this case, would seem to be a very desirable feature for any heavy grade operation. The return of energy thus made possible is in the interest of economy. However, is not the elimination of air-braking, with its consequent wear and tear on the rolling stock, an equal, if not greater reason for using regeneration? By attention to dispatching, the regenerated energy might be expected to reduce the fluctuation in power demand, but, after all, the purpose of a railroad is transportation and in an issue between power demand and train movement, it is likely that the trains would have the right of way.

Aside from conditions to the contrary, it would seem as if a power company having a diversity factor, and, therefore, a better load factor, should be able to sell power with profit for at least the same price as the cost of producing it in a station having only the railway load. The fixed charges, in particular, would be reduced by the better load factor.

The results obtained from pulverized fuel with the widely fluctuating demand for steam, appear fully to justify its use. It is an excellent showing for pulverized fuel under these extreme conditions. The diagram (Fig. 7), showing how uniformly the steam pressure is maintained under the operating requirement, is certainly an excellent record.

Successful current collection may be defined as the absence of sparking between the collector and the contact wire. With a system of overhead suspend wire having the essential "contact quality", it has been fairly demonstrated that several thousand amperes may be taken from a collector without visible sparking. In fact, current collection with more than four times the amperes per collector on the Virginian, has been in successful operation for a number of years. It is widely recognized that sparking between the contact wire and collector has a far more destructive effect than the wear resulting from mechanical friction.

The use of side-rod drive for electric locomotives would seem to be more of a special application, and although well suited to these particular locomotives, it seems probable that the trend of locomotive development will be more toward the use of rotary parts only. The requirements as to the strength of rods and side-frames in the motor-drive locomotive are considerably more severe than

* Chf. Engr., Railway Eng. Dept., General Electric Co., Schenectady, N. Y.

for a steam locomotive of corresponding tractive effort. That these electric locomotives have been so successful is to the credit of both those who designed them and those who built them.

The use of locomotives weighing 78 000 lb. per driving axle so far exceeds the general practice that the effect on the track is worthy of careful study. It may possibly be found that this weight, in an electric locomotive with a true running balance, will be comparable in its action on the track with a steam locomotive having less weight, but with an unbalanced rotating factor.

Every railroad electrification has successfully performed the service for which it was intended, and the Virginian is to be congratulated as a successful demonstration of the heaviest service yet undertaken.

MARCEL JAPIOT,* ESQ. (by letter).—Although the writer had the pleasure of investigating in detail several years ago the wonderful electrifications of the Pennsylvania Railroad and of the Norfolk and Western Railway, he did not find the opportunity to inspect the Virginian Railway electrification. Nevertheless, it may be of interest to know how the American situation in the matter of main-line electrification may be viewed from the other side of the water.

The most striking result of the Virginian Railway electrification is certainly the increased capacity of the line. It nearly doubled the speed of the heaviest trains in the world, on such severe grades as those prevailing in the Alleghany Mountains. That is enough to show that the decision to electrify was a most wise one, even if the direct savings had not paid a substantial return on the investment.

The writer agrees fully that, considering the magnitude of the problem, the single-phase overhead line was the best solution, and even perhaps the only one available at the present stage of development. That conclusion may seem strange, coming from a French engineer who advocates direct current for main-line electrification in his own country; nevertheless, it is very easy to justify it.

No system of electrification may be said to be the best in itself; each problem must be examined separately, and the engineer must look, in each case, for the system best suited to the special conditions involved in that individual problem. That was exactly the position that French engineers took when they selected the direct current at 1 500 volts as standard in France.

However, with such extremely heavy loads as those to be cared for in the Virginian Railway electrification, there is no doubt that it was necessary to raise the voltage on the contact line as much as possible, in order to bring down the amperes to be collected by the electric locomotives. Therefore, the single-phase overhead line, with its much higher voltage, seemed to be a necessity in that case. The Virginian Railway, with its heavy trains and its severe grades, was indeed the most appropriate field to be found anywhere for the single-phase system.

If the conditions of the problem are changed, the decision becomes reversed. Such was the case on the Illinois Central Railroad, where the scale turned, as it did in France, in favor of the direct current at 1 500 volts.

* Vice-Chf. of Motive Power, Paris, Lyons & Mediterranean Ry., Paris, France.

While the electrified lines in the United States are more important than anywhere in the world, they include only a small part of its vast system of railways. Moreover, there have been, until now, very few physical connections between electrified trunk lines using different types of current, alternating and direct. These two facts seem to explain why American engineers did not feel any urgent need for standardizing on a definite type of current for main-line electrification, as did several European countries.

With the unrestricted liberty still prevailing in the American field, engineers in the United States have the opportunity to give to each individual problem the most favorable solution. On the other hand, standardization must always be a compromise between the advantages and the drawbacks of the different systems of electrification for several various problems.

The necessity of such a compromise does not seem to be imminent in the vast territories of the United States. Nevertheless, it appears from the recent developments that, if any compromise had to be made at an early date (which does not seem to be probable), the single-phase overhead line might be adopted successfully in America.

That does not mean that the writer is ready to depreciate in any way the advantages of the direct current for many definite problems of electrification; but nobody can deny that the much higher voltage now allowed on the contact line by the single-phase alternating current is of the utmost importance for the average conditions prevailing on American railways.

Moreover, the flexibility of that system for electric motive power must be kept in mind, because it permits the use of either (1) the straight single-phase system, as on the Pennsylvania Railroad and the New York, New Haven, and Hartford; (2) the so-called "split-phase" system (single-phase to three-phase), as on the Norfolk and Western Railway and on the Virginian Railway; or (3), the motor-generator engine (single-phase to direct-current), as on the Detroit, Toledo, and Ironton Railroad, and on the Great Northern Railway. The motor-generator type may perhaps be further improved in the future by using some kind of static or rotating rectifier, instead of the somewhat cumbersome motor-generator set. In any case, the diversity of the solutions available for electric motive power with the same single-phase contact line gives to engineers great facilities to adapt that system to very different conditions, which is a most important quality for a compromise.

Nevertheless, from an engineering point of view, it is fortunate that the necessity for such a compromise has not yet become urgent in the United States, as it gives to American engineers an unlimited field of possibilities for other wonderful achievements.

L. K. Sillcox,* M. Am. Soc. C. E. (by letter).—One of the greatest disadvantages of the past for those endeavoring to present a proposition favoring electrification of an existing steam-operated railroad has been that their proposals were based on theory which made it possible of attack by contending that the theory would not be borne out in practice. Mr. Gibbs has been able

* Asst. to Pres., The New York Air Brake Co., Watertown, N. Y.

to avoid such a situation by reason of his long, valuable, and successful experience in connection with the electrification projects carried out on the Pennsylvania, Long Island, and Norfolk and Western Systems, as well as a number of other well known and important undertakings. His contribution to the art of electric railroading has always been worth while, and this paper covers the case accurately and fully.

About 1926, the writer was privileged to make a survey of this line and, therefore, can present some first-hand impressions gained at that time. In the first place this railway has a capacity for dumping 11 400 tons of coal per hour at the seaboard, which is equal to 273 600 tons per 24-hour day. It has always been recognized as a leader in the movement of heavy-tonnage trains, and in the operation of most powerful modern motive power. In May, 1921, all records of heavy trains handled were exceeded when there was a test run on the Third District, consisting of a train of 100 loaded cars, each with a capacity of 120 tons, aggregating 16 000 gross tons. To give some idea of the rapid expansion of the road's business, it is interesting to observe that, in 1911, a coal tonnage of 2 141 009 was handled; in 1920, this figure was increased to 7 621 555 tons; in 1925, it went to 8 250 000 tons; while in 1926 the total was 11 500 000 tons.

It is well, at the outset, to take seriously the author's remark that "it is obvious, however, that uniformity [in energy] demand cannot be secured, even approximately, in practical railroading", having due regard to the factors producing reasonable plant cost and economy of operation. When there is sufficient tonnage available, one of the principal features which limits the earning capacity of any railway system is the total amount of tonnage that can be handled over the line in a given time. The project under discussion was undertaken only after most careful consideration of all the comparable methods of successfully handling and expanding competitive traffic demand, and its greatest significance is an economic one.

The electrification of the Virginian Railway has, in general, enabled a much better use to be made of the capital expended in the construction and development of the property up to that time than would have been attainable under any other means involving an equal expenditure. This is mainly due to the more prompt movement of tonnage and greater utilization of the property as a unit than formerly was possible. Under electrified traction the section from the Elmore, W. Va., Yard to Roanoke, Va., a distance of 132 miles, is operated as a one-locomotive district. Under steam operation this was a two-engine district with turn-around runs between Princeton, W. Va., and Elmore. Trains of 6 000 tons are being handled from Elmore to Clarks Gap, W. Va., with one leading locomotive and one pusher behind, each composed of three electrical units. Under steam operation, trains of 5 500 tons were hauled by three Mallet engines, one in front, of the 2-8-8-2 type with a tractive effort of 101 300 lb., working compound, and two pusher engines of the 2-10-10-2 type with a tractive effort of 147 200 lb., working compound. The speed under electric operation is 14 miles per hour, while under steam it did not exceed 7 miles per hour. At Clarks Gap the load of the trains was increased to 9 000

tons, which was taken to Princeton with one locomotive. From Princeton to Roanoke, the train was assisted by a helper, from Whitethorne to Merrimac, Va., and also out of the Princeton Yard. Under electric operation this helper service is eliminated. The speed of the trains varies between 14 and 28 miles per hour, with a consequence that this line, which is of single-track construction (except from Mullens, W. Va., to Clarks Gap), is equipped for a handling capacity of 12 500 000 tons per year, and when this figure is reached the tonnage is to be carried by forty-eight electric units, or sixteen 3-unit locomotives. This same service, if it were handled by the existing design of steam power all of which was of modern construction, would require approximately twenty of the large 2-10-10-2 type Mallets, and forty-four of the 2-8-8-2 type Mallets, a total of sixty-four steam units as against sixteen electrical units; and, in addition, under steam operation, extra helper engines to assist trains out of the Princeton Yard and between Whitethorne and Merrimac would be required. The regenerative system of braking on grades, especially in the case of tonnage trains, is also of great value from a practical railroad-operating standpoint.

The electric locomotives have a 2-8-2 wheel arrangement, with a weight per unit of 212½ tons, so that the weight of the 3-unit road locomotive is 637½ tons. The maximum tractive effort of each unit, as limited by electrical capacity, is 92 500 lb., or 277 500 lb. for the 3-unit locomotive, which occurs at an adhesion of slightly less than 30 per cent. Computing the conservative starting adhesion at 25%, the tractive effort is approximately 77 000 lb., or 231 000 lb. for the 3-unit locomotive. This represents a starting force 57% greater than the compound rating of the 2-10-10-2 type Mallet steam locomotive (one of the largest steam engines ever built) and 31% greater than this engine when working simple. The continuous rating of the 3-unit locomotive is 135 000 lb. at 14 miles per hour and 78 800 lb. at 28 miles per hour. In the high-speed connection of the motors the three units exert 6 000 h.p. continuously. These engines operate on 2% grades and through a maximum line curvature of 12 degrees.

One feature of the project which is of unusual interest and needs to be especially commended has regard to the satisfactory location and thoughtful study given the design and equipment of the shop facilities at Mullens, which will enable the motive power to be kept in proper condition at a minimum of expense and to give a maximum of reliable movement. The greatest need under electrification, as compared to steam operation, is that of comprehensive inspection, since that requires much the greater part of the time of running maintenance forces; whereas with steam motive power, defects are relatively self-evident upon arrival at the terminal, or during the running inspection, and it is the time to make repairs which predominates and not that of inspection. For this reason, it is most unwise for any steam railroad, which may contemplate electrification, to attempt any lack of due consideration, required to maintain electric motive power efficiently, because the two types of operation do not lend themselves to similar treatment in this respect, and the facilities must be set up with a view to the peculiarities of the requirements

in each case. The ideal of attainment in transportation is to have all trains run at the same speed, and although that ideal is not fully realizable, it can be more nearly attained with electric than with steam traction.

I. ÖFVERHOLM,* ESQ. (by letter).—One of the reasons given for the 88 000-volt transmission line and the seven sub-stations is to make it possible to avoid the stub-end feed and its bad effects on the communication circuits along the railroad. As far as the writer is informed, the result of these arrangements is not fully satisfactory. It seems that, in any case, it has been necessary to make the telephone and telegraph circuits immune from the residual disturbances in these wires.

The writer, therefore, thinks that it would have been better to provide some other means in order to get a more desirable location for the communication circuits. According to Swedish practice, the transmission lines and the sub-stations would not have been designed for 88 000 volts. Swedish engineers would have used a trolley line with a potential of 16 000 volts and a balancing wire such as that used on the Virginian Railway, with a potential of 32 000 volts. Thus, they would have had a transmission potential of 48 000 volts, which seems to be great enough for the transmission along the electrified part of the Virginian Railroad.

The trolley wire and its catenary, according to current practice in Sweden, would have been made of copper with a section of 300 000 cir. mils for both together. The balancing wire would have been made also of copper and with the same section, and then a feeder line for 48 000 volts with two wires each with a section of 300 000 cir. mils would probably have been used. This causes a very severe stub-end feed, which is not to be feared with the precautions now used.

A fair comparison may be made with the most recently electrified line from Stockholm to Göteborg, where very satisfactory experiences were obtained with similar arrangements. On this line, the communication cable belonging to the railroad (which cable is placed in the roadbed), has a disturbance potential, under normal service, running up to a maximum of 10 to 15 volts, and at most severe short-circuits, 47 volts. For this reason there are no disturbances in telephone and telegraph circuits even at short-circuit. The telegraph circuits can be, and are, operated with a ground return on a single wire in the cable.

For such a case as the Virginian, Swedish engineers would have used feeder booster transformers inserted in the trolley wires and the balancing wire midway between the balancing transformers, which would have been spaced at distances of about 6 miles. In this way the arrangement of the transmission would have been much simplified, and the cost would have been reduced. Also, the residual disturbance voltages on the communication wires would not have amounted to such values as are reached on the Virginian Railway. However, these arrangements might give a somewhat greater potential drop in the contact lines.

* Chf. Engr., Swedish Govt. Rys., Stockholm, Sweden.

RALPH BUDD,* M. AM. SOC. C. E. (by letter).—The Virginian Railway is a good example of traffic and operating conditions which justify electrification purely for reasons of economy. The expedited movement of freight, the saving in fuel and in wages of trainmen and enginemen, and the avoidance of expensive additional tracks for increasing the capacity of the railway combine to make current economies which represent a large return on the investment. Undoubtedly, there are more instances in the United States where electrification of heavy traffic sections of steam railways is justifiable for similar reasons, and like action, therefore, may be expected to follow. On most of the railway mileage of the country, however, the traffic density is not great enough to pay a return on the cost of electrification sufficient to make the investment attractive.

The improved efficiency of the steam locomotive makes it more difficult to show great economy in electric operation, as compared with steam, than it was in 1918 and thereabouts. Of course, any study to be convincing to a competent and careful railway board of directors, must compare the estimated cost of operation after electrification with the cost of operation using the most modern and best adapted steam locomotives for the duty imposed, rather than the steam locomotive performance some years ago, or even that of the present. This is a point of some importance because, pending the final solution of a transportation problem, even the best railway company may wisely hesitate about replacing its old steam locomotives with strictly modern ones.

As Mr. Gibbs has stated, the Norfolk and Western electrification is so closely related to the Virginian, both in location and in operating requirements, that the very successful record of the former naturally influenced the adoption of the same system on the Virginian, thus giving convenience in detouring or the exchange of motive power, if desirable.

Whether or not rod-type electric locomotives are the most desirable does not seem to be demonstrated by anything in this electrification, nor indeed is there anything to show whether locomotive performance, and especially locomotive upkeep, is more favorable with this particular system of electrification than it would be with others. The limited speed control does not seem to be any particular handicap here as it might be under other and more varied conditions. The most striking differences the writer has seen in comparative data on heavy-duty electric railway operation have been in the cost of maintaining the motors, the best showing being made by direct-current motors. That item, of course, is only one, although a very important one, of many which go to make the total of operating cost. In any event, the Virginian Railway undoubtedly has a highly efficient and economical electrification.

GUIDO SEMENZA,† ESQ. (by letter).—The author is correct when he states that the electrified section of the Virginian Railway furnishes an example of the heaviest electric traction development to be found anywhere in the world. This is true for the amount of traffic hauled, for the magnitude of the locomotives, and for the power required by each unit. These features are of such

* Pres., G. N. Ry., St. Paul, Minn.
† Engr., Milan, Italy.

importance as to make this paper one of greatest interest, and the results obtained, both technically as well as economically, are so satisfactory that Mr. Gibbs and his collaborators are to be complimented.

In this clear exposition the author shows that the problems to be solved were quite unique—a very difficult profile of the line, with heavy grades; a traffic of such a character as to be called a "shuttle service"; a small number of very heavy trains, running at a relatively low speed; and a uni-directional movement of the charge. Therefore, if the methods, systems, and devices used in solving the problems of this large project appear to be justified and appropriate, one must be careful in extending them to other cases, in which the conditions of traffic are quite different.

The power of 11 000 kw. required by each train justifies the alternating high tension in the contact wire and, although at first it might seem a useless complication to transmit single-phase current when the motors are three-phase, one can only approve of having done away with the serious construction complications and the severe and costly operation of a 10 000-volt, three-phase contact line.

To one who has had occasion to follow closely a rather extensive system of three-phase traction, it seems rather queer that the three-phase motor was chosen in order to meet the severe starting conditions. The three-phase motor has many good qualities, but its drawback has always been considered to be in its starting characteristics, namely, a limited torque, that cannot be improved by slowing down, and that is highly influenced by the line voltage drop. It is only when the starting is difficult and when the track conditions are bad, that an abnormally high torque is required, with a corresponding increase of current, and the voltage drop then is maximum. Moreover, the starting conditions are likely to be altered by the heating of the water rheostats.

If, in spite of these structural features of the three-phase motor (and it does not appear that the phase converter can improve matters very much), the operation is satisfactory, that means that the dimensions of the motors and rheostats have been calculated so as to meet these special conditions. It would be interesting, however, to compare (as to weights, costs, and efficiencies) the actual use of three-phase to that of direct-current motors in these same locomotives.

F. H. SHEPARD,* ESQ. (by letter).—The paper shows, in a comprehensive way and in valuable detail, this important and successful railway electrification.

The institution of this undertaking reached its final stages in November, 1922, with the request from the Railroad Company for a tender upon and a recommended plan and method for electrification. This was required in the form of (1) a competitive bid for the apparatus and equipment involved (as manufactured by the Westinghouse Electric and Manufacturing Company); (2) an estimate on the other items going to capital expenditure; and (3) an estimate of cost of operation and savings. The contract was executed under date of April 18, 1923.

* Director of Heavy Traction, Westinghouse Elec. & Mfg. Co., New York, N. Y.

Subsequent to the signing of the contract, Mr. Gibbs and E. R. Hill, M. Am. Soc. C. E., took over the execution of the field work, the design and construction for the power house, sub-station, transmission, and conducting systems, all to suit the requirements for traffic movement as specified in the plan of operation.

A most gratifying part of the whole undertaking has been the confirmation of operating results and advantages which were predicted for this electric operation, all of which were realized with ample margin. The engineering and construction work undertaken by the consulting engineers was planned and executed with smoothness and despatch and in co-ordination with the regular operation of the road under steam.

From the initial run of the first train until the whole section was under complete electrical operation, the addition of electrical units was attended with a distinct and regular improvement in the movement of traffic. The members of the Operating Staff of the Railway Company were alert and responsive in their desire to learn the details of electric operation and had so far mastered the handling of the new motive power that little or no assignment, apart from the road's regular forces, was necessary for instruction of the forces required to operate and maintain the electric locomotives in this unprecedented train service.

As this operation now stands there has been realized an increase in capacity for moving traffic materially in excess of that claimed for the undertaking. Furthermore, the locomotives have capacity for service materially in excess of that required. They can make the run between Clarks Gap and Roanoke in approximately 1½ hours less time than that stipulated; they can handle the specified tonnage up Clarks Gap Hill even if the grade were 5 miles longer; they have demonstrated a momentary capacity for initial start equivalent to moving 6 000 tons on a 2% grade with a single locomotive; and, in addition, they have demonstrated the entire success of close regulation of tractive effort for these exceedingly heavy trains under all conditions of starting and running.

E. R. Hill,* M. Am. Soc. C. E.—The Virginian Railway, built in 1905-07, was planned and constructed in a far-sighted and broad-gauged manner, as a result of which grades were made as favorable as possible considering the region traversed. There were no unnecessary dips or other objectionable features, and only two pusher grades under steam operation and one under electric operation. The bridges were constructed for heavy engine and car loads and thus even before electrification the heaviest trains in the country, and, in fact, in the world, were operated on this line. In view of this and the physical limitations in strength of draft-geared cars in electrifying, it was not thought advisable at the outset to adopt maximum train weights (6 000 tons on Clarks Gap Hill and 9 000 tons elsewhere) materially greater than had been handled under steam operation, although these weights are about 50% greater than could be handled by steam in winter. It will be noted that provisions have been made to increase the trains to 12 000 tons at such time in the future as

* Cons. Engr. (Gibbs & Hill), New York, N. Y.

traffic conditions, construction of cars, and other considerations make this desirable or practicable.

The paper refers to the exacting conditions of the load and the probable difficulty of carrying such a load on a general power supply system. From the nature of the load it would be difficult to carry it on any ordinary power system except a very large one, a much larger system with a heavier power background than was available in that locality at the time.

The choice of the split-phase type of locomotive over the motor-generator type or the straight single-phase was somewhat influenced by the facts that there were two railroads in that same valley; that certain combinations of railroads were and are now permissible; and that mutual interests pointed to a uniformity of system and locomotive characteristics as being desirable in that territory. In fact, during the World War, these two roads were operated as one railroad. There were other considerations, of course, which led to the selection of the split-phase type of locomotive which it is believed was the right one under all the circumstances. Furthermore, at that time the motor-generator type of locomotive had not been developed to the point where it could safely be adopted on a large scale.

With regard to the sub-stations, it should be noted that all the power which goes to the trains passes through the main transformers, the balancing transformers being part of the distribution system and affecting the regulation. With this arrangement of transformers, less main transformer capacity is required than with a more frequent spacing of ordinary transformers, partly because of the necessity for having a "spare" at each location. The system was laid out in both ways, and the most economical and efficient one, all things considered, was selected.

The electrification of the line cost approximately $15 000 000,—the amount estimated. Allowing credit for the additional facilities that would be required to secure approximately the same capacity by steam, including double-tracking, locomotives, and other facilities, the net additional cost of electrification was about $5 000 000. The purpose of this electrification was to secure increased capacity of the railway, reduce operating costs, avoid expensive and difficult changes in the way of double-tracking, secure smoother, safer, and more reliable movement of trains, and, incidentally, to clarify the air in tunnels, especially the Merrimac Tunnel at the summit of the Alleghany Mountains, which is about a mile in length.

After 1½ years of electric operation it can be said that (1928) the expectations have been more than realized in all respects. The direct savings in operating costs effected by the change, as determined from carefully compiled steam-operating costs for this particular division prior to electrification and from actual results since, indicate a decrease in such items of cost per gross ton-mile of more than 50 per cent. This saving on the gross ton-mileage operated last year (1927) was sufficient to pay fixed charges on the gross cost of electrification, or three times that required to pay such charges on the net additional cost of electrification. The operating and the financial results, therefore, have been entirely satisfactory.

NORMAN LITCHFIELD,* ESQ.—The speaker has been closely associated with the Virginian Railway electrification throughout, and the following remarks are more in the nature of emphasis than discussion.

One of the outstanding features of the electrification is the rugged character of the country. Those who are unfamiliar with West Virginia can have little conception of the topography, for while the mountains are not of the height and grandeur of other great chains, nevertheless there are a great many of them, placed in such irregular groupings that it almost seems as if Nature had had a great convulsion there. This made the running of the transmission line a difficult matter, particularly in the delivery of materials to the site, new roads having to be cut in many cases.

The climate is more severe than is ordinarily associated in one's mind with railroads in that latitude, making winter work, although generally possible, at times, quite difficult. The "frozen fog" as its name implies is neither ice nor snow, but a sort of frost piled up on the wires, which sometimes attains the diameter of a man's arm. When the sun strikes such a coated wire in one spot, the frost drops off rapidly in the sunshine, but remains on the wire in the shade. This results in an unbalanced condition and the wire whips upward. To take care of this the lower wires are offset from the upper ones, as is shown in Fig. 12.

The diversified character of the problems encountered in a major electrification is apparent from Mr. Gibbs' paper. Virtually every branch of civil, electrical, and mechanical engineering is involved. One of the most striking features was the necessity for anchoring the power-house foundations to the solid rock to prevent possible dislodgment during river floods. The very patent question might be asked, "Why put the power house in the bed of a river?" The answer is obvious in view of the nature of the surrounding country, that this was the only flat place available, where condensing water could be had.

Some idea of the magnitude of the transportation problem which the Virginian Railway has to meet can be given by a more detailed consideration of the size of the train. Unless one is a railroader it is hard to conceive just what a 6 000 or 9 000-ton train is. As the cars average about 46 ft. in length and weigh (including contents) at an average about 100 tons, a 6 000-ton train contains 60 cars or more and is about 2 800 ft. long. Similarly, a 9 000-ton train has 90 cars and is about 4 100 ft., or nearly ¾ mile, long. If this were composed of the cars one finds in an ordinary freight train, averaging, say, 50 tons each, it would include about 150 cars and be about 6 000 ft. long. This gives some conception of what a Virginian Railway train really is.

To start a 6 000-ton train on the "hill" may require a tractive force of more than 500 000 lb. with one locomotive at the front of the train and another at the rear, pushing. At present, there are no means of communication between the front and the rear locomotive other than by whistle signals, which often cannot be heard because of intervening hills; hence, it is virtually impossible to start both locomotives at the same time without recourse to an indirect practice. The brakes are applied on the pusher locomotive, and the front

* Mech. Engr., Gibbs & Hill, Cons. Engrs., New York, N. Y.

locomotive backs the train down into the rear one. A train of this length will have a total slack in the couplings and draft gear of perhaps 50 ft., or more. Hence, the rear engine receives a relatively heavy bump when the slack has been taken up. This is the signal for the rear engineman to apply his power. Even then it is difficult to synchronize with the front locomotive, and some little time may elapse before the rear engine starts moving, in some cases as much as 1 min. This, of course, puts an exceedingly heavy electrical strain on the motor, which is one of the features that makes the induction motor a proper selection for this class of service.

Equally interesting is the action of the locomotive in descending the long 1.5% grade. An ordinary freight train hauled by a steam locomotive, going down grade sways back and forth both sideways and "fore and aft". This is largely due to the fact that it is impossible to keep the brakes applied continuously, because this would burn up the brake-shoes, crack the wheels, and cause havoc generally. With the exception of a few cars on which retainers are set up, it is necessary to release the brakes after the train has slowed down to as low a speed as possible without danger of coming to a full stop, then release the brakes again and let the train gain headway until the maximum safe operating speed is reached. This process is repeated again and again. Although the air-brake has been improved so that it is a marvelous mechanism, it is not perfect, and it takes a relatively long time for its action to be transmitted from the front to the rear of a long train; also, irregular braking action occurs and, in such a case, it is not unusual to break the train in two.

With the electric locomotive, after the train gets about on the crest of the hill, the engineman simply throws a lever, and the motors begin to regenerate, thus acting as a powerful and steady brake, so that the train proceeds down the hill at a practically constant speed, and with little irregular motion. This, of course, gives a very desirable operation, and one which is much easier on the rolling stock.

The electrification is popular with the rank and file of the railroad men (as shown by the expressed desire of the enginemen to obtain the electric runs) and has generally proved its worth.

SIDNEY WITHINGTON,* ESQ.—In presenting as full information as is possible within a brief space, of the large and important undertaking represented in the Virginian Railway electrification, Mr. Gibbs' paper is of great value as a matter of record.

One of the outstanding features of the Virginian electrification is the extreme variation of load over a short period of time, in swings amounting to nearly 50 000 kw., as indicated on the load curve in Fig. 4. Only very large commercial systems would be able to handle such great and extreme variations of load, and the wisdom of choosing pulverized fuel to obtain flexibility at the power plant is obvious. In a plant of this size, with such load characteristics, the consumption of 1¾ lb. of coal per kw-hr. net output is a creditable performance.

* Elec. Engr., N. Y., N. H. & H. R. R., New Haven, Conn.

In connection with the regeneration of power on descending grades, it is of interest to note that the only instances in the United States where such regeneration takes place occur in territories where, on account of the proximity to coal fields or availability of hydro-electric power, the unit cost of energy is relatively low and the money value of the regenerated power is of little importance. The advantage of regenerative facilities is not so much in the power saved as in the increased safety of operation and ease of handling trains. It is noteworthy that, in many instances abroad, regeneration as such has been discarded and replaced by simple electric braking wherein the traction motors operate as generators as in the case with regeneration, but the energy is absorbed in resistance on the locomotive itself and is thus not utilized.

Very much the same idea of balancing transformers was applied in 1913 on the New York, New Haven and Hartford Railroad between New Haven, Conn., and New York, and on the New York, Westchester and Boston Railway, a subsidiary. This type of transformer on the New Haven combines the benefits of 22 000-volt transmission with the balancing effect to reduce interference with telephone circuits. The plan has also been used abroad to some extent.

Poles of H-section were utilized on the New Haven, in 1914, in side-track construction, and, in 1925, on the main-line track between South Norwalk and Danbury, Conn. This type of pole, as Mr. Gibbs suggests, has great advantage in the use of the flanges in climbing, as the climbers or "skates" devised for the linemen eliminate the necessity for ladders or steps as in the case of tubular poles.

In connection with the electrification of the New Haven Line between South Norwalk and Danbury, a note on the foundation design for the catenary columns may be of interest. The poles or columns were the H-type, of normal sizes, 6, 8, 10 and 12 in., depending on the loads imposed. The foundations were poured in place, and embedded in the concrete of each pier were two channels, set back-to-back and separated by a distance equivalent to the dimension between flange faces of the pole to be set. These channels, and the lower end of the pole, carried holes for 1-in. bolts in sufficient number to develop the required strength of the connection. In the process of setting, the poles were slipped down between the channels and enough bolts installed to hold them, before the work-train with the crane moved on to the next pole. In spite of the fact that a considerable amount of both freight and passenger traffic was operated in both directions on this single-track line (which it was necessary to clear sufficiently in advance in order to avoid delays), as many as forty-nine poles were set in a single day in this manner.

Fig. 19 shows the limitation of the inclined type of hanger installed on extremely sharp curves. By laying a straight-edge along the contact wires between pull-off points shown in the photograph, it may be noted that the contact wire assumes nearly the same position which would be the case in chord construction mentioned by Mr. Gibbs, and it has been the experience on the New Haven that for curves sharper than 4°, the chord construction is as advantageous as the inclined hanger type in the matter of length of spans, is somewhat easier to install, and more economical to maintain.

In connection with the design of the catenary system, it is necessary to exercise care to insure that the cost of carefully developed details in the drafting-room, as suggested by Mr. Gibbs, covering all possible contingencies in the field for each catenary span, is not in excess of that which would be saved by a small amount of additional work done by the field gangs which might be necessary with standardization. It is probable even that some standardization of span details would be justified in actually saving money in the field both in construction and maintenance, by eliminating large numbers of odd lengths of hangers and consequent heavy storehouse expenses in handling material.

Under electric operation the engine-house expenses are noted as being about one-fourth of those accruing under steam operation. This seems a somewhat high ratio unless the Virginian Railway charges more to the account of engine-house expenses than some other railroads. The ratio is usually nearer 1 to 6, or even 1 to 10, on account of the simplicity of electric locomotive terminals. They eliminate the need of coal and ash-handling facilities, and the savings on this account may amount to a considerable sum in the aggregate.

GEORGE J. RAY,* M. AM. SOC. C. E.—The speaker wishes to add a comment as to the regenerating features of operating electric locomotives on heavy grades. The handling of heavy freight trains on steep descending grades is a difficult operation. On the road with which the speaker is connected there is one stretch of 17 miles of 1½% grade. On this grade it is necessary to restrict the speed of heavy freight trains to 15 miles per hour in order to avoid "runaways". The customary practice makes it necessary for the engineman to make approximately thirty-five brake applications and releases during the descent; that is, he must apply the brakes, bringing the speed of the train down to about 10 miles per hour, then release them again, and allow the train to run free until it reaches a speed of about 18 miles per hour and then apply them again. With this in mind, the great advantage in the regenerating feature under electrical operation is readily understood.

There has been much discussion about the feasibility of operating trains under automatic train control on such heavy grades. When the brakes are applied at low speed it is necessary to make a full stop before releasing them; otherwise, there might be a catastrophe. On a train of 85 or 100 cars it takes so long for the air to act from the engine to the rear of the train that if an engineer is permitted to release at slow speeds, especially with empties, he is almost certain to buckle the train or pull it in two. It is clear, therefore, that the introduction of an automatic brake application might be a rather serious matter where heavy trains are being handled down a steep grade. There would seem to be less likelihood of trouble with electric traction where the train is operated at a uniform rate of speed such as that indicated by the author. The speaker would like to inquire whether the question of automatic train control was given consideration in connection with either the Virginian or the Norfolk and Western electrification.

* Chf. Engr., D. L. & W. R. R., Hoboken, N. J.

JOHN P. HOGAN,* M. AM. SOC. C. E.—The speaker feels that if there were more knowledge of the advantages of electric operation among civil engineers there would be more electrification. Mr. Gibbs has gone a long way toward making this knowledge available and all civil engineers owe him a great debt of gratitude.

The Virginian Railway has a very heavy traffic; in fact, the maximum of 110 000 tons total weight, in both directions, over a single-track line in a single day, is very close to the maximum in the United States, and, therefore, in the world. Outside this Continent a 2 000-ton train would be considered a curiosity, yet here is a system planned for 9 000-ton trains and the speaker understands that even heavier trains have recently been hauled.

Mr. Gibbs has touched generally on the conditions which led to the construction of an independent power plant. While it is possibly true that, in the district in which the Virginian Railway operates, the existing utilities could not handle a load of this character, it may be stated in general that, in the more settled parts of the country, it should always be more economical to combine the railway load and that of the utilities. Whether it is possible to do so is always dependent upon the arrangements that can be made and whether a discussion of the relative costs can be brought about on a basis of perfect frankness and honesty. There is a great deal of misunderstanding between the power companies and the railroad companies on the question of power supply which is about equally distributed between the two and is generally due to misinformation.

The power companies do not often take the trouble to acquaint themselves with the load characteristics, nor do they do the necessary work to determine the effect of this load on their system, and the result is that uncertainty naturally causes high quotations.

The railroad people, on the other hand, frequently impose restrictions on power company supply far in advance of the service that they themselves can obtain from independent stations. This increases the cost of the service out of all proportion to the benefit that can be derived from such restrictions. The railroad companies frequently do not keep sufficient records of cost of power from their independent stations to enable them to determine the real cost of the service, and such figures as they do keep are usually shrouded in deep secrecy. In some cases, railroad companies, having independent power stations, later make connection with utilities and throw on the latter the service burden, power-factor correction, reserve capacity, etc., and then pride themselves that power from their own stations is cheaper.

An examination of Fig. 4 discloses the fact that the general shape of this curve would be very advantageous for combination with that of a utility with its maximum peak around 7 o'clock and its maximum hour between 8 and 9 o'clock. While the load itself is somewhat ragged and subject to violent fluctuation, it would be submerged in the daily load of a large utility with a good inherent system regulation. It is evident, however, that a power system with poor regulation would have difficulty in meeting the service demand of the railroad with a load of this character.

* (Parsons, Klapp, Brinckerhoff & Douglas), New York, N. Y.

Mr. Gibbs has stated, in part, as follows:

"Unfortunately, in the Eastern United States, available water powers are few, and such as exist are not generally near the consumer, and are often not dependable in capacity * * *."

This statement should not be applied to the entire Eastern United States because all through Northern New York and New England there are large districts which have excellent service from water power, and which are not normally supplemented by fuel-burning plants.

Mr. Gibbs also states, in part:

"As a matter of fact, the load conditions * * * are so exceptional that it is doubtful whether any existing local company * * * could afford to take on a load of this character, except by devoting special generators and transmission circuits to the railway supply * * *."

Was this entirely due to the deficiencies of the local utilities or was it partly caused by the desirability of single-phase generation?

Referring to the author's statement that "the alternating-current system is the nearest approach so far to a general one," the speaker does not think that any trend has developed toward any particular system. England, France, Holland, Belgium, Spain, Australia, South Africa, and South America are using direct current; Switzerland and Germany are using single-phase, alternating current; and Italy is divided between direct and three-phase current. European conditions do not apply to American railways and, in general, the street car and interurban systems in this country are using direct current at varying voltages, and such changes as have been made in existing systems, have all been from alternating current to direct current. The largest main-line electrification in this country is that of the Chicago, Milwaukee and St. Paul Railroad using direct current at 3 000 volts. The most recent electrifications (except that of the Pennsylvania Railroad) have been the Illinois Central at 1 500 volts direct current, and the Great Northern, with alternating-current distribution and direct-current locomotives. Most American terminal electrifications, including that of the Pennsylvania, have been at 750 volts direct current. On the other hand, the New York, New Haven and Hartford, the Pennsylvania, and the New York Connecting Railways are equipped with alternating-current distribution and single-phase motors; and, finally, the electrifications of the Norfolk and Western and the Virginian Railways are based on alternating-current distribution and contact wires and three-phase motors. It can hardly be said, therefore, that any system has been general, or that railroads are even approaching a general system.

The author states that the generators in the power-house are rated at 10 000, single-phase, continuous rating, and the speaker inquires as to what the equivalent rating of these generators would be if operated at three-phase. Was consideration given to the operation of motor-generator locomotives, or of single-phase motors instead of the split-phase motors, and, if so, what considerations led to their being discarded?

Mr. Gibbs has given an extremely interesting and clear description of the balancing wires and balancing transformers which are unique and useful

features of this system and for which he is largely responsible, if not for their actual invention at least for their practical application. The speaker would like to ask whether the balancing transformers, which are almost equal in total capacity to the main transformers, are not (to all intents and purposes) useful and necessary, and whether, in the event of their omission, it would not be necessary to put in equivalent capacity in the main transformer stations? Would it have been possible to space the transformer stations 20 miles apart if it had not been for the addition of these balancing stations?

In addition to these questions, the following are also submitted:

(1) What normal pressure is maintained between the trolley wire and the pantograph as used on the Virginian Railway?

(2) Mr. Gibbs states,

"Under these conditions the motors are subjected to high-current inputs and may be damaged unless they are of a type which will meet this severe requirement."

Can a single-phase motor be constructed that will meet these requirements?

(3) The speaker notes the connection of two driving wheels to a single motor. Is any difficulty experienced in the distribution of the load between the two motors included in each unit?

(4) The split-phase motor is limited to two speeds except when operated in connection with a rheostat. This would seem to limit its use to heavy freight traffic where a comparatively low rate of speed was sufficient and would not make it suitable for general railway operation under varying conditions. How much is the rheostat used in ordinary operation other than in acceleration?

(5) Rheostatic operation is presumably rather expensive in power consumption, and in this connection the speaker would also like to know how much the speed limitations influence the character of the load curve, since it would appear that a train might be required to go up a heavy grade at a higher speed than was absolutely necessary.

The speaker wishes to congratulate Mr. Gibbs on the accuracy of his preliminary power estimates and on the very brief but satisfactory statement of the general results.

R. D. N. SIMHAM,* ASSOC. M. AM. SOC. C. E. (by letter).—The author describes the broad engineering features of the railway electrification problem quite completely and concisely. There is little more that can be said except to make a few remarks as to the merit or usefulness of a few of the details mentioned. The paper must be of immense practical help to engineers who are engaged in designing such electrification projects, particularly the data given in Tables 3 and 5.

The electrification of the Virginian Railway is one more illustration of the economy that would be possible by changing the motive power from steam to electricity. The power then comes from a central common source; that is, the generating unit is large and comprehensive. That is the reason

* Town Planning Asst., Madras, India.

why, from the points of view of economy of power, equipment and operation costs, and efficiency, electrification projects invariably prove successful and beneficial both to the Company and the public. The author states that the Virginian electrification project has effected considerable savings by the changed form of motive power. Such conclusive evidence is very encouraging to engineers engaged in other electrification projects and should certainly stimulate engineering activities throughout the world in establishing, with confidence, electric plants in the place of steam, oil, or other forms of power plant.

So far as India is concerned, it has great prospects for developing very cheap hydro-electric power and already several undertakings of great magnitude have been started. Hydro-electric power should be cheaper than steam turbo-electric power, at least so far as the conditions of India are concerned, where good, cheap coal is scarce and natural water power is plentiful. Another advantage of water power is that it requires only the single transformation from the energy of water into electricity; whereas in steam turbo-generators a double transformation is required. The first transformation is to convert the latent energy of the fuel into heat energy as stored in steam. The next transformation is to convert the steam energy into electrical energy.

Besides the loss involved in the double transformation one of the great disadvantages of the steam-driven station is the large amount of space required for the boiler equipment and the condenser plant. In the case of the Virginian Railway plant (see Table 3), the turbine room occupies 11 440 sq. ft., whereas the boiler-room space is 13 454 sq. ft. That is, much more space is allotted to the steam-raising plant than to the generating plant. The ratio of the turbine-room space to the boiler-room space is as 100 to 118. It is usual to find the boiler occupying as much as three times the ground space required for the generators. Again—and this is especially important—boilers cannot be over-loaded 50% like turbo-alternators, so that, if advantage is to be taken of the overload capacity of the generators at any time, the necessary extra boiler capacity must be secured.

In countries like America and England there are, perhaps, several reasons for the slow development of railway electrification. As stated* by H. P. Gillette, M. Am. Soc. C. E.,

"Resistance to change, which usually is stronger in an old and powerful institution like the railroads than in a young and struggling one, probably has been the most serious single cause of delay; and as might be expected, it appears to have operated more effectively in England than in America."

In India, however, where railroad projects are just beginning to be developed, there is no reason for delay. All the present railway projects (which may be counted on the fingers of one hand) are capitalized by outside enterprise, and certainly the financiers would not start experimenting and would always postpone so radical a step as electrification in the hope that some other capitalist would bear the first expense of the experiment.

* *Engineering and Contracting*, February 20, 1924, p. 385.

There is great prospect, however, that the problem of electrification will be influenced by the growth of the great power systems in India. It is recognized that the cost of power is becoming more and more important, since civilization is requiring increasingly larger amounts of cheap power per capita. It will become still more important to utilize all possible sources of natural power, which is plentiful in India and is now going to waste. Cheap fuel is scarce and the cost of transportation is high. Therefore, this problem is becoming more important and more serious each year. The development of hydro-electric power would relieve the situation tremendously. To India, electricity is indeed the only practical source of economical power. It is inexhaustible, and should displace all the old forms of motive power.

The considerations that should generally be the basis of any power plant design are well illustrated in Fig. 4. The somewhat sharp peaks and sudden falls in the curve indicate that it must be very difficult to maintain economical operation of the station. Quite contrary to what might be usually expected in a railway load curve, the paper shows that, on two occasions within a period of twelve hours, the entire station load was taken off; but the sudden falls are not necessarily so serious in the economical running of the plant. The sharp peak loads, especially those of very short durations, are, however, very disadvantageous. For the sake of supplying power just for the abrupt peak loads, all the generators must operate and thus there is a great deal of idle power which is not being utilized. In other words, by underloading the plant, the average output would have supplied the whole of the daily demand had that output been constant. In this respect the author seems to think, for obvious reasons, that it is impossible to secure, in practice, any such uniformity of load; but if it is possible to relieve the station of such peak loads by drawing the excess power from a secondary source of accumulated power supply, or by creating some form of special boosters whereby temporary high drafts for power may be made, it would mean, for the Virginian Railroad plant, the running of not more than three turbo-generator sets at a time.

The problem of meeting the demands of excessive peaks that occur for short periods must be carefully considered. Assuming that such a thing is possible, the maximum demand of the generators would be reduced from 48 000 kw. to 30 000 kw. during the peak intervals. This would make it possible to shut down one generator throughout the day. It is with an idea of meeting the highest peak loads that the extra plant is made necessary. This extra plant is a measure of the increase caused by the capital charges for the running plant and incidentally for buildings and other equipment. From the data given by the author one may note that the average load for a normal day is only about 30% and on a maximum congested day not more than 43% of the full capacity of the generating plant. The effect of this low ratio and of allowing the extra plant to run idle is noticeable in the actual output in kilowatt-hours per pound of coal consumed. The station coal rate has averaged even less than 1¾ lb. per kw-hr. of net output, or about 14½% efficiency, which is poor.

In referring to the use of pulverized fuel, it must be said that, although combustion would be better and firing easier, the fuel cannot constitute the source of energy by itself. It would be useless unless there was practically an unlimited supply and a sufficient circulation of air. It is invariably necessary in every plant to make careful calculations and provide suitable arrangements for the supply of oxygen to the combustion chamber. Perhaps the provisions made on the Virginian Railway are adequate. The author has shown all the principal merits of location and planning of the Virginian Railway power plant in a way that should open the eyes of designers to the conditions that must be satisfied, in order that a project shall be a financial success. The choice of site and other details of planning are decidedly problems for the engineer as distinct from the designer and inventor of machinery and apparatus.

A noteworthy item concerning the transmission arrangement is the decision to secure a separate right of way intersecting with the railway only at the sub-stations. In places where such a plan is practicable without future trouble and other public inconveniences, direct transmission routes should always be adopted, as far as possible. As a matter of fact the economy effected by reducing the transmission circuit in this project is very great. The saving in 34 miles means nearly 770 tons of steel in the towers, 136 miles of transmission cables, and other incidental expenses.

The choice between direct and alternating current is a matter of the very foremost importance. This will depend on the distance to which the electric current is to be supplied and the purpose for which it is to be used. It seems to have been agreed that, where there are no other conditions affecting the choice of current, the high-tension alternating system is best for larger supplies. It is also a fact that transformers for alternating current offer great advantages over those for direct current. They are stationary, require perhaps little or no attention, and can be constructed for any amount of power; and their efficiency may be as much as 96 or 98 per cent. From the point of view of economy in the electric mains or conductors, however, three-phase current is best; next is direct current; and last, alternating current. For railway traction itself three-phase motors are the best and most economical.

At present (1928), there are about fifteen locomotives on the Virginian Railway. Assuming that they are all moving in one direction in a day of, say, 12 hours, the time headway per train would be 1 hour per locomotive. At an average speed of 20 miles per hour, this would give an actual space headway of 20 miles between any two trains. The ordinary spacing of sub-stations with a much lower voltage arrangement would be 20 miles. From Table 6, it is found that, at present, the maximum number of trains either way (say, eastbound) is five. This would mean presumably an actual headway of 2.4 hours per train. Taking the lowest average of 14 miles per hour, the actual space headway would be 29.6 miles, instead of 20 miles. To satisfy the latter requirements five main sub-stations would have been sufficient under ordinary conditions of close sub-station spacing; but in this case the operation is done at a very high voltage. Taking full advantage of the balancing wire system

it would have been sufficient to increase the sub-station capacity and reduce the number of main sub-stations.

Referring to the main operating costs, the results given by the author are very encouraging. Generally, by electrifying the road, only in a few items, such as cost of engines and maintenance of equipment, are considerable savings to be expected because these would be about 45% of the total expenses. A 30% saving in these items would mean nearly 14% reduction in the total operating cost; but the enormous increase in the capitalization and the very large incidental increase in the item of maintenance of way and structures (including the trolley and other contract system and the supporting structures) is the main handicap against electrification. Sometimes these larger expenses would go a long way toward neutralizing the 14% saving; but however small the savings may be, electrification is an up-to-date development and will displace other kinds of power in the future. It can perform a service beyond the possibilities of the steam engine and it can effect greater operating economies than are possible by steam propulsion, so that in the future these may be sufficient to pay a reasonably attractive return on the new capital charge incurred. This has proved to be the case in the Virginian electrification.

GEORGE GIBBS,* M. AM. SOC. C. E. (by letter).—The discussion is confined chiefly to comments on electrical and power matters. None has been made on the purely civil engineering details of design or on methods followed in the construction and application of the peculiarly electrical devices to the railway right of way. The writer hoped to have had suggestions from engineers who have the care of the physical plant of railways as to the effect of the presence of structures and appliances upon clearances and operating procedure. It is evident that the presence, everywhere, over or along the tracks of conductors designed to secure continuous physical contact by a device on the locomotive means an invariable location (within narrow limits) of these conductors with respect to the tracks and adequate supporting structures alongside. All these restrictions raise difficult problems of accommodation between right of way and electrical construction and it is important that they should be adjusted in the best possible manner between the interested parties in order to produce economy in first cost and maintenance.

The paper, presented to a Society which has not been especially interested in electrical devices, was intended primarily to stimulate interest and inquiry into a method of railway traction which is becoming increasingly important and which is, therefore, a matter of concern to engineers having to do with the design or care of every department of a railway. The writer hopes that, in spite of the absence of comment from members engaged in maintenance-of-way work, the paper will be found helpful to them and will assist in the further development of details best suited to the physical conditions and limitations of railway location.

While the contact devices of an electric traction system impose obstructions on the permanent way of a railway, electric operation permits steeper grades

* Cons. Engr.; Chf. Engr., Elec. Traction, L. I. R. R.; Cons. Engr., P. R. R., New York, N. Y.

than are allowable with steam haulage, especially in the case of motor-car passenger trains on which can be concentrated an almost unlimited motive power. Similarly, trains hauled by locomotives can be grouped for multiple control from one point when it is necessary to furnish increased tractive effort; in the case of steam traction the dual control of two locomotives is open to objection, as is well known.

Mr. Hogan has raised a number of interesting questions in connection with heavy electric traction systems and methods. Some of these are rather outside the scope of the paper, but may be answered briefly.

He is interested in the "system" controversy. This is not the place to enter into a discussion of the relative merits of different electric systems, for the reason that the paper was intended to cover only the considerations and conditions which led to the adoption of a certain system as best adapted for the Virginian Railway. He takes exception to the remark that the "alternating-current system is the nearest approach so far to a general one". The writer made this statement only in connection with a brief explanation of the trend of development of systems, beginning with appliances for light or comparatively short-distance haulage and leading up to those required for the heaviest character of trunk-line work over long distances. The distinction was made in order to show the reason for using high voltages in the transmission and the current-collecting devices at the trains for the latter services.

Some systems are limited in respect to the working voltage and are, therefore, most suitable for light or short-distance work; but the alternating-current system, being flexible as regards working voltage, is adaptable for any character of traction. The word, "general", used by the writer, has no reference to the extent of present usage of systems, which is really a factor of little significance in determining on a system for a particular case. Many of the installations cited by Mr. Hogan can be considered only as examples of the progressive steps followed in the development and application of heavy electric traction. Therefore, to draw any conclusions from a catalog of such installations it is necessary to take into account both the dates at which they were installed and the local railway conditions surrounding each. As matters now stand, there is no one system in exclusive use, and this is as it should be. Developments should be allowed to continue along different lines and by different systems before being tied down to a standardization on one, which would preclude further useful advances in the art.

This point has been well brought out in the discussion submitted by M. Japiot, who is one of the French railway officials responsible for the selection of a system for the French railways. He is a man of broad railway experience, a keen student of electric traction, and is unusually familiar with what has been done in the United States as well as elsewhere in this field. He recognizes that European railway conditions are quite different from those in America and may require different methods for their solution. He brings out the important point, moreover, that the need for standardization on one system is not as great in America as it is in Europeon countries, stating that,

"With the unrestricted liberty still prevailing in the American field, engineers in the United States have the opportunity to give each individual problem

the most favorable solution. * * * standardization must always be a compromise between the advantages and drawbacks of the different systems of electrification for several various problems."

He goes on to say that "if any compromise had to be made at an early date (which does not seem to be probable), the single-phase overhead line might be adopted successfully in America." The writer is not arguing that question now, and merely wishes to state that the reasons in favor of the system which was adopted on the Virginian Railway were controlling for that case. Furthermore, it can be safely stated that no one connected either with the design of the installation or its successful operation on that particular railway, has found any reason to regret the decisions made.

Mr. Hogan refers at some length to the consideration which led to the construction of an independent power plant by the Railway Company. The problem of power supply for the road was most carefully studied for the particular situation and character of load. All outside local sources of power were examined and it was found that no existing power company in that particular field was willing to submit a proposition which could be considered.

These definite facts, therefore, should dispose of the question for this particular case, and in stating this there is no intention of reflecting unfavorably on commercial power supply in general or in particular. As stated in the paper, "doubtless, there is a field for commercial power companies, especially large networks, in the supply of power for heavy railway traction, * * *".

As an example, the Pennsylvania Railroad Company has closed a contract on satisfactory terms with an independent power company for its present and future single-phase power requirements, which contemplate very large energy demands for an extensive electrification plan. This power company, the Philadelphia Electric Company, has a large generating capacity from a number of plants, both steam and hydro-electric, tied together in a great distributing network of lines. It was in an unusually favorable position to take on a railway load, which contemplates electrification of both freight and passenger services with a high daily load factor. None of these conditions applies to the case of the Virginian Railway.

Further, Mr. Hogan objects to the statement that "in the Eastern United States available water powers are few, and such as exist are not generally near the consumer, and are often not dependable in capacity." He thinks that this does not apply to the entire Eastern United States. This may be true for certain locations in the East and for near-by and, as a whole, rather limited power demands. However, the point is that the extension of electric traction generally should not be predicated on the availability of hydro-electric energy, and it is not necessary that it should. Water is often said to be a "free gift of Nature", but electric energy produced from it is far from being "free" and may, in fact, be very expensive at the point received. Doubtless railway electrification will grow in extent by reason of its advantages and economies, in certain cases, over steam haulage. It is from these viewpoints that it should be examined. Fuel-burning, however, to produce electric energy must, in the nature of things, be depended on for the majority of these enterprises.

Mr. Hogan asks a number of questions relating to details of the electrical apparatus of the Viriginian Railway installation. He refers to the capacity of the generator sets, stated as 10 000-kw., continuous, single-phase rating; the capacity of this generator would be greater, of course, if loaded three-phase. The turbine, however, is built to suit the load. Therefore, to state the case more accurately, if the output were three-phase the generator would be smaller and the power plant otherwise would be the same.

As to the type of motor used, Mr. Hogan asks whether the single-phase motor can be constructed so as to meet the requirements of this service. This is best answered by stating that on the Pennsylvania Railroad (where similar service as to grades and heavy trains and starting conditions will obtain on the Pittsburgh Division when electrified) the straight single-phase type of motor has been adopted, built, and tested, and the conclusion is that it will satisfactorily meet such service conditions.

There has been no difficulty experienced in the distribution of load between the driving-wheels that are coupled to the different jack-shafts of the Virginian locomotive units. Of course, there are times when one motor will slip its coupled wheels and the other coupled unit will not, but there is no difficulty in a practical way in starting and hauling trains on that account.

As to the necessity of using the rheostats in the handling of trains, other than during acceleration periods, this is, in point of fact, not a necessity and is a very small practical factor anyway. Occasionally, an engineman may cut in the rheostat descending light grades when he wishes to operate at more than 15 miles per hour (the normal speed being 15 miles per hour descending grades). In such case, by using resistance, the motors will operate above synchronism, and a speed of 18 to 22 miles per hour can be secured. Under these conditions almost no energy is returned to the line, either at 15 miles per hour or at the higher speeds.

The question is also asked as to how much the two-speed characteristic of the locomotive influences the system load curve. It does affect it to some extent, but the difference is not controlling in its effect on the general character of the load curve or in the power plant capacity. Other considerations, such as definitely limiting maximum running speeds to a safe figure in handling these very heavy trains over the division in the desired time, are of more importance. It is unsafe, in this as in many other matters, to generalize from an incidental factor in establishing a desirable over-all solution for a particular case. As to the normal pressure maintained between the trolley wire and the collecting device on the locomotive, each pantograph carries two shoes 4 in. wide having centers 10 in. apart; the pressure of each shoe against the wire is set at 10 lb. Answers to other questions submitted by Mr. Hogan will be found in Mr. Hill's discussion.

Mr. Potter speaks of the great desirability of "regeneration" in moving down heavy grades, and refers—aside from energy savings secured thereby—to the difficulties attending the use of air-brakes on these heavy trains at such times. He also mentions that when the issue is between the question of power demand and train movement, the latter is the important one, inasmuch as "transportation is the purpose of the railway". All this is true and well

expressed. In the paper, the writer mentions that the regenerated energy on the Virginian was found to be more than 8% of the total used to operate the road. The latest figures, covering 12 months' operation, show that the actual value was 9.1%, as taken from the watt-hour meters on the locomotives. This is obviously an important amount of energy saved, but does not express all the advantages secured by "electric braking". Safe and smooth control of the 9 000-ton train on the 12-mile Kellysville Hill (1.4% average grade) has been found to be a most important result.

Mr. Ray refers in an interesting way to the experience of his road, the Delaware, Lackawanna, and Western, in handling heavy freight trains by steam on a certain steep descending grade 17 miles long, where it is necessary to restrict movement to a speed of 15 miles per hour. This requires thirty-five brake applications and releases during the descent. In contrast to this complicated operation, J. W. Sasser, Superintendent of Motive Power of the Virginian Railway, states* that, under electric operation on his railway, brakes are only regularly applied once during the 131-mile run from Elmore to Roanoke (the entire electrified division). He also states that 100% increased life has been secured from brake-shoes over that previously obtained under steam operation, and that slide-flat wheels are of rare occurrence. It naturally follows that the car as a whole receives reduced wear and tear over the division, and that train delays, accidents, and derailments on account of defective brakes are rare. A prominent Western railway official, on a recent inspection of the Virginian installation, commented on the remarkably smooth handling of these electrically operated trains over an undulating division, and the absence of surges and jars in starting and while in motion. Also, the absence of jar in stopping, due to it being unnecessary to apply the automatic brakes, is noted; final stop is made with the straight air-brake on the engine only.

Mr. Litchfield refers to a contributing cause of smooth operation from the constant-speed characteristics of the locomotives. By riding on the trains observers cannot fail to be impressed with this result.

Mr. Semenza is interested in knowing the relative weight and cost efficiencies of different types of electric locomotives. This is, in the writer's opinion, really a question for determination at a future time. The effort on the Virginian was to adopt initially a locomotive of tried capabilities and of rugged construction. Other reasons for the locomotive design adopted are given in the paper. Refinements in type, details, and weight reduction will naturally follow further experience here and elsewhere. It would seem that foreign engineers have been more interested than those in America in developing locomotive designs to secure maximum weight efficiency. In the writer's opinion, some European locomotives show undeniable complication and a paring down of weights of parts to an extent which would be inadmissible under American railway conditions.

Mr. Öfverholm comments on certain differences between Swedish and American practice in the design of the distribution systems of electric railways and in the provisions adopted to prevent disturbances in near-by telephone and telegraph wires. The information he gives is interesting, but it is

* *Bulletin*, Am. Railway Assoc., June, 1928.

unsafe to conclude from the particular to the general for the preferred solution of complicated cases. Swedish electrifications are quite extensive and have been planned to conduct, successfully, traffic which in some cases is heavy compared with general European practice, but is always light as compared with American practice. It is especially very light as compared with the train loads dealt with in the Virginian Railway electrification. The treatment adopted by foreign engineers, therefore, for details can hardly be expected, in all cases, to fit in with American ideas and the radically different traffic conditions here.

Mr. Budd is undoubtedly correct in stating that "on most of the railway mileage of the country * * * traffic density is not great enough to pay a return on the cost of electrification sufficient to make the investment attractive". He refers to the constant improvement made in the efficiency of the modern steam locomotive, both in capacity and economy, which makes it difficult to show the same advantages for electric locomotive operation over steam as was the case some years ago. This is a true statement and emphasizes the importance in making a thorough investigation of all factors governing a proposed use of electric instead of steam operation as applied to the particular case in hand and the danger of drawing the conclusion that if electric traction has been found advantageous in one location it would be equally so in another. An analysis of the individual problem, therefore, should always be made beforehand and by competent authorities in railway operation generally and in the special technical features connected with the two methods of operation. The Virginian Railway Company was confronted with the necessity of a very extensive physical rehabilitation of its property in order successfully to conduct its rapidly increasing business, and it became a question of whether it would be better to secure the increased capacity by a continuation of steam haulage with expensive additions to the main tracks, to get the best obtainable road capacity from steam locomotives; or, on the other hand, to make its present single main track adequate for a long time by using electric locomotives of unlimited capacity at a greater running speed. Electing to do the latter, the Company obtained a form of motive power which insured maximum hauling capabilities and sufficient for present needs. It still has the possibility of obtaining, when needed, additional road capacity by double-tracking.

Mr. Budd's questions regarding the type of electric locomotive used are answered elsewhere. The Virginian is not tied down to any one particular type. If in the future it should be found advantageous to use another, it can be done without in any way changing the main and expensive features of the electrification, namely, the power plant, the transmission lines, and the distribution system over the tracks.

FLOOD CONTROL WITH SPECIAL REFERENCE TO THE MISSISSIPPI RIVER

INTRODUCTION

By Edgar Jadwin,* M. Am. Soc. C. E.

The importance of controlling the floods of the Mississippi River is now generally recognized. It is a National problem. The Mississippi Valley contains the largest area of rich soil in the country. It must be inhabited and used to as great an extent as practicable.

This valley is about 600 miles long and 50 miles wide. The entire area is generally considered to have been formed by the river itself. It is the natural bed of the river in time of flood. In its natural state it was flooded practically annually. This rendered intensive cultivation of the land too uncertain for practical purposes.

It has been compressed or narrowed in recent years to an increasing extent. This work has been done by levees, which have kept the water off the land so that it can be cultivated on an average of at least four out of five years. Some parts of the reclaimed land have not been flooded for much longer periods.

How much further can the river be compressed without having it break out at intervals and do even greater damage than it would have done if the works had not been constructed? The population in the valley is increasing and a crevasse is now of greater threat than formerly. In the further control of the river, to what extent shall levees, dredging, reservoirs, spillways, floodways, and other safety measures be used? Will it be possible to reclaim the entire valley permanently? Or must some part of it be permanently or intermittently dedicated to the service of the river?

In watching some piece of machinery, such as the steam shovel, probably every one has commented upon its likeness to a living thing. The steam shovel is guided by a man, expresses his aim, and has good reasons for appearing lifelike. The Mississippi River, without human aid, comes as near being lifelike in its own right as any inanimate object in the world. It consists of water and dirt aided by gravity. Some one has calculated that its volume in flood would fill the great Lake Erie in two weeks; some one else, that its energy when in flood would, if expressed in pounds and the square of its velocity, be measured in quintrillions. It tears the dirt from its banks and bed. Some one else has calculated the dirt carried annually as equivalent to a cubic mile in volume. A large part of this dirt was formerly deposited on the alluvial valley, re-fertilizing the ground and slightly raising it. The works along the river and at its mouth so concentrate the flow of this dirt that the mouth of the river is being extended into the Gulf of Mexico 5 miles per 100 years.

* Maj.-Gen., U. S. A.; Chf. of Engrs., U. S. A., Washington, D. C.

In talking with those who have given the best part of their lives to the river, the speaker was impressed with their admission of the results obtained by levees and equally by the shake of the head when there is talk of raising them much higher. They know the power of the river, and they know that work to be successful must reckon with this power. They know the danger of the crevasse and that the higher the flood-plane and the greater the population behind it, the greater the threat of the crevasse. The first three papers presented herewith describe largely the history of the river, the work done on it, and fundamental data needed for the solution. In the other papers, various phases of the problem are considered. The authors may not all agree, but if one will follow through, he cannot fail to acquire a greater and broader comprehension of the subject.

RESUME OF THE MISSISSIPPI RIVER FLOOD PROBLEM

By C. McD. Townsend,* M. Am. Soc. C. E.

Introduction

The problem of flood protection is one which has vexed mankind for ages. In Genesis VI, 12, 20, 24, a flood is described, which was caused by a rainfall of 40 days and 40 nights and which raised the waters 15 cubits, covered the earth for 150 days, and destroyed all animal life in its path. This description of the Deluge would not be a very exaggerated account of the flood of 1927 in the Mississippi Valley. Moreover, there is an analogy between the Ark that Noah constructed as a means of flood protection and the boats and barges used in 1927 for the same purpose.

The Chinese appear to have records of floods extending over a period of 4 000 years, and "thirty-five years ago more than 1 000 000 people (some say 7 000 000) perished by drowning and starvation, resulting from one flood which came from a break through the south dike of the Yellow River, about 20 miles above Kai-feng City."† The annals of the countries of Europe also record disastrous overflows with a loss of life far greater than that from any which have occurred in the United States. The loss of life from floods in Europe during three months in 1927, largely exceeded the deaths in the United States from the same cause during the entire year.

The most fertile portions of the earth's surface are the valleys of streams that are periodically subject to overflow, and, therefore, enriched by the alluvium brought down and deposited from the mountains. This fertility induces a settlement of the country, and the farmer who first tills the valley is prepared to lose an occasional crop by flood, relying on the increased yield in other years to recoup him for his losses. In fact, in certain regions, the difference in yield between hill land and bottom-land is so great that the farmer reaps a greater profit by tilling the bottoms, even if he loses his crop every third or fourth year, as is demonstrated by the high prices that are paid for land along the banks of the Missouri River even when unprotected by levees.

The early settlers usually adopted Noah's method of flood protection. They built their huts on the high ground along the river bank, and constructed a boat into which they moved with their few household goods whenever the waters invaded their dwellings. It is the method used by the trappers and lumbermen living along the bayous in the Atchafalaya Basin at the present time.

A second method of flood protection adopted at an early date was that of building a mound of earth or of erecting a platform above the flood waters,

* Colonel, U. S. A. (*Retired*), Washington, D. C.

† "Flood Problems in China," by John R. Freeman, Past-President, Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1405.

on which the home was located. The numerous Indian mounds found in the Mississippi Valley were probably built for that purpose.

If it is only necessary to provide for the population, this method of flood protection is economical and efficacious, and is adapted to rivers which overflow their banks at periods of the year when vegetation is not injuriously affected thereby. Thus, in the Valley of the Lower Nile, irrigation is necessary to produce a crop. It is only after flood waters have covered the land that vegetation will grow. Its floods are caused by rains originating in the tropics, and occur early in the spring before the period of planting. The problem in Egypt is not to prevent floods, but to impound their surplus waters so as to utilize them for a further flooding of the land during periods of drought while the crops are growing. In the Lower Mississippi Valley conditions are reversed. The floods caused by rains falling in the temperate zone through which the river flows, inundate the valley after the crops begin to mature, and they will be frequently destroyed unless protected from the overflow.

The occasional loss of a crop or even the destruction of his habitation was of little consequence to the aborigine, but as civilization progresses man becomes more firmly bound to the soil. It was a natural development from the mound of earth on which the dwelling was placed to a ridge of earth surrounding the area that was being cultivated, and so long as the area of land which was being tilled was a small percentage of that of the valley, levees could be constructed cheaply by the property owner, which would protect his crops from ordinary floods. If he was energetic and far-sighted, he insured his property from even the occasional overflows, which overwhelmed the remainder of the valley, by building his levee a little higher than that of his neighbor.

As the population increased and a larger proportion of the river bed was used for agricultural purposes, a mysterious increase in the heights and frequency of floods was observed, which was attributed by scientists in olden days to the wrath of the gods and by those of the present generation to the cutting down of forests which are assumed to have heretofore prevented rainfall or held in place soil which is now raising the river bed. A much simpler solution of the mystery occurs to the engineer, that is, that the same quantity of water can only be made to flow through a contracted channel by increasing the head or height and thus creating a greater velocity.

In narrow river valleys with small flood discharges, this increase in flood heights is not excessive, but when it is attempted to remove from the Mississippi River about 30 000 sq. miles of its flood channel, and contract a flow over an original width exceeding 40 miles to a channel less than 1 mile wide, the problem is a serious one. The nations of Europe have solved the problem for such rivers as the Rhine, Seine, Loire, Rhone, Po, and the Danube under the conditions which exist in that region, but it is to be noted that the flood discharge of any of these rivers is approximately that of a large crevasse during the 1927 Mississippi River flood.

The Legal Status of Flood Protection

When the French under Bienvielle settled the Lower Mississippi Valley, they had a knowledge of the methods of flood protection then adopted in Europe, and the original grants of land contained a proviso which required the grantee to construct and maintain a levee line along the river-front of his property. This servitude on the land was maintained in Louisiana after it was admitted into the Union, and only ceased by reason of an amendment adopted by the State within the past five years, which transfers it to the levee district in which the land is located.

This servitude was not oppressive so long as the plantations to be protected were limited to those in the State along the river bank, as only an insignificant part of the river bed was being occupied. It was only after settlement extended to the neighboring States of Arkansas and Mississippi that an appreciable increase in floods was observed. The lands of these States were originally a part of the public domain, but the "Swamp Act" passed by Congress, September 28, 1850, ceded those subject to overflow to the States in which they were situated, with a proviso that the cession to the State was to enable it "to construct the necessary levees and drains to reclaim the swamp and overflowed lands therein." The States of Louisiana, Arkansas, Mississippi, and Missouri organized offices for the sale of the swamp lands, and appointed commissioners for the location and construction of levees.

There had already been an appreciable increase in flood heights, which led to the passage of an Act approved September 30, 1850, directing "a topographical and hydrographical survey of the delta of the Mississippi River with such investigations as may lead to determine the most practicable plan for securing it from inundation", etc. The results of this survey were published in the report of Humphreys and Abbot on "The Physics and Hydraulics of the Mississippi River." This immortal work contains a scientific analysis of nearly every suggestion of flood relief which is being advocated at the present time (1927), and when the limited data which were then available are taken into consideration, it is a marvelously accurate forecast of the work necessary to protect the valley securely. Fig. 1 shows the average dimensions of the levee that existed in the vicinity of Arkansas City, Ark., in 1882, twenty-one years after they submitted their report, the levee profile recommended by them, and that suggested by the writer in 1893, and practically adopted by the Mississippi River Commission in 1913.

During the Civil War, the levee lines were cut by the contending forces, and seriously damaged by floods. After the Civil War local levee boards generally replaced the State organizations, originally appointed under the Swamp Act, although in Louisiana, a State Board of Engineers continued to exercise supervision over the local levee boards which had replaced the riparian owner in levee construction. Although the construction of levees by local boards gave more satisfactory results, than when the riparian owner was the sole judge of the dimensions, this method of construction was also objectionable. While one district was constructing levees of relatively large size, a neighboring district, either from a lack of funds or from erroneous

views of the height which floods would attain, would provide a weaker section, and crevasses would occur in levees beyond the jurisdiction of the more provident residents, which would overflow their lands.

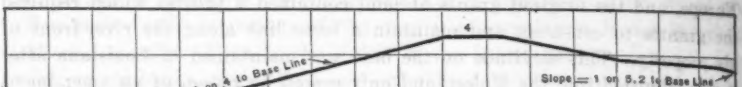

FIG. 1.

By an Act of Congress approved June 22, 1874, a commission was appointed to "make a full report to the President of the best system for reclamation and redemption of said alluvial lands from inundation." By an Act approved June 28, 1879, the Mississippi River Commission was created, and the duty of completing the survey authorized by the Act of June 22, 1874, was transferred to that body, and it was also directed "to take into consideration and mature such plan or plans, and estimates as will correct, permanently locate and deepen the channel, and protect the banks of the Mississippi River; improve and give safety and ease to the navigation thereof, and facilitate commerce, trade and the postal service." The Act also contained a proviso that "the Commission shall report upon the practicability, feasibility, and probable cost of the various plans known as the jetty system, the levee system, and the outlet system, as well as upon such others as they deem necessary."

The Act of March 3, 1881, making appropriation for the work of the Commission contained, however, the proviso that "no portion of the sum hereby appropriated shall be used in the repair or construction of levees for the purpose of preventing injury to lands by overflow, or for any purpose whatever except as a means of deepening or improving the channel of said river."

The Act of March 13, 1892, modified the wording of this proviso and directed that the funds appropriated "shall be expended for the general improvement of the river, for the building of levees and for surveys, * * * in such manner as in their opinion shall best improve navigation and promote the interests of commerce at all stages of the river."

The Act of March 1, 1917, contains a proviso that "no money appropriated under the authority of this Act shall be expended in the construction or repair of any levee unless and until assurances have been given satisfactory to the Commission that local interests protected thereby will contribute for such construction and repair a sum which the Commission shall determine to be just and equitable, but shall not be less than one-half of such sum as

may have been allotted by the Commission for such work." The same Act extended the jurisdiction of the Commission over levee construction to Rock Island, Ill. The Act of March 4, 1923, further extended its jurisdiction to the tributaries and outlets of the river so far as they may be affected by its flood waters.

It will be noted that in all these Acts of Congress while the authority of the United States over levees and its financial assistance has been progressively increased, there has been considerable care exercised to preserve a servitude on the lands which are to be benefited. As Comptroller General McCarl has stated, "the primary obligation for protection of private property adjacent to the streams for which co-operation between local interests and the Government has been provided, rests upon the individual States or subdivisions within which the private property is located, the Government's part being to assist financially in connection with the maintenance and development of the river as a navigable stream only in proportion to the amount made available by such State or subdivision."

Under this construction of the law, the question of servitude becomes the most important problem which Congress must consider in any project for an extensive development of flood protection. The States have transferred it from the riparian owner to the various levee districts. Shall it now be assumed by the State or by the Federal Government? It is evident from the results of the 1927 flood, that the cost of any project for absolute security will far exceed the capacity of the riparian owners to meet their portion of the expense provided by existing law. It is also apparent that the farmer tilling the less fertile hill lands of Arkansas and Mississippi will never consent to an increased taxation for the purpose of further increasing the value of the plantations in the delta region, and insuring the maintenance of such values.

The Mississippi River Commission

It will be noted that while Congress in the Act creating the Commission directs it to investigate various methods of flood protection, yet in the Act appropriating funds to carry on its work, it is expressly prohibited from using them for the purpose of protecting land from overflow. This apparent inconsistency in legislation had its effect on executive action and, therefore, merits explanation.

Most levee engineers in the Mississippi Valley had not accepted the conclusions of Humphreys and Abbot that levee construction would largely increase flood heights. There was a general belief that the concentration of the flood discharge would enlarge the river bed and that this enlargement would materially reduce the levee grade, and would greatly improve low-water navigation. These views had Congressional support, and as General Humphreys was then Chief of the Corps of Engineers, U. S. Army, it was considered advisable to appoint a commission of which the majority would not be connected with that Corps, and thus insure a more liberal policy in determining the effect of levees on channel improvement. As a majority of Congress

did not approve of appropriating public funds for the protection of private property, it was considered advisable to limit the powers of the Commission thus created by the proviso of the Act of 1881.

As a majority of the Commission which was first appointed believed that levees would improve low-water navigation, a liberal allotment of funds for levee construction was assured, but the proviso mentioned rendered it necessary that the levees thus improved should be located where they would produce the greatest influence on the low-water channel, instead of where they would best preserve the land from overflow. As low-water navigation was notoriously bad in the upper reaches of the river, there was a tendency to concentrate the allotments for levee construction along those sections, and particularly in the sparsely populated levee districts where the inhabitants did not have sufficient funds to protect themselves. A great impetus was given to levee construction, and a marked increase in flood heights resulted, so that not infrequently the protection afforded to the weaker districts caused crevasses in those more densely populated.

Levee construction from 1881 to 1891 not only largely increased flood heights, but it also failed to produce any appreciable improvement in low-water navigation. The Commission then investigated the effect of dredging on river bars, and came to the conclusion that a low-water navigation of 9 ft. could be obtained temporarily by this means and could be maintained more economically than by either levee construction or bank revetment. Congress then authorized the construction of dredges for that purpose, and permitted the allotment of funds for levee construction whenever it would facilitate high-water navigation of the river. Federal funds were allotted for levee enlargement under this proviso, and the weaker levee districts continued to derive a greater relative benefit.

The Act of 1917 caused a radical change in the methods of making allotments by providing that at least one-third the cost of levees constructed by the United States should be borne by local authorities. Under this method of making appropriation the more populous districts became the greater beneficiaries, as they could more readily raise the funds required to obtain Federal assistance. The weaker districts had difficulty in keeping pace with their more fortunate neighbors. The result is clearly shown in the record of crevasses during the recent flood, which most vividly emphasizes the Biblical saying that "unto every one that hath shall be given, and he shall have abundance; but from him that hath not shall be taken away even that which he hath." The levee districts which escaped overflow owe their immunity to the poverty of their less fortunate neighbors.

In compliance with the provisions of the organic act, the Commission has made extensive surveys and investigations for the purpose of determining the practicability, feasibility, and relative cost of the various methods of flood protection that have been proposed. The results of its investigations are scattered through its annual reports for the past forty-seven years, and have been summarized in papers and reports submitted by the writer from time to time. The gist of its conclusions was invariably that levees afforded the

most practical, feasible, and economic method, although its processes of reasoning varied with changes in the membership of the Commission.

So long as a majority believed that only an increase of flood height of 3 ft. should be provided for, which was the provisional grade for many years, the question was hardly worthy of serious argument. The crudest estimates of cost conclusively demonstrated that levees were so much cheaper than either reservoirs, the diversion of tributaries, or spillways, that a further discussion of the practicability or feasibility of these methods was merely an academic compliance with the law. It was only after a majority of the Commission endorsed Humphreys' and Abbot's views, and attempted to make provision for the greatest flood which had then occurred, that a careful analysis of the various methods of flood control became imperative.

After the flood of 1912, such an attempt was made. The Commission assumed as a major premise that the flood of 1882 was the greatest to which the levee system would be exposed, but based its estimates on the flood of 1912 which, while of shorter duration, had the same estimated maximum discharge, and had been more accurately gauged and measured. The Commission unanimously agreed that levees were the most economical method of flood protection, and that reservoirs were impracticable; but there was such a diversity of opinion with regard to the feasibility of spillways and the diversion of tributaries that the discussion of these subjects was omitted from the report. The views of individual members, however, were printed as Commission documents.

Effect of an Increase in Discharge on the Conclusions

When Humphreys and Abbot submitted their project for the protection of the Mississippi Valley from overflow, they based their computations on the flood of 1858 which was the largest flood through the entire valley of which there was then any record, although the flood of 1844 exceeded it above Cairo, Ill., and that of 1785 had similar characteristics to that of 1844. As stated, the Mississippi River Commission based its estimates of levee grades on the flood discharge of 1882, which largely exceeded that of 1858, and has only been exceeded since 1785 by that of the flood of 1927.

While both Humphreys and Abbot and the Mississippi River Commission came to the conclusion that levees were the most practicable and most economical method of flood protection, they based their argument on an assumed flood discharge, and it by no means follows that such flood discharges as are now being discussed as possibilities can be more cheaply controlled by this method. Any project which contemplates increasing the heights of existing levees at certain localities about 15 ft., not only affects the item of cost, but raises the question of the practicability and feasibility of maintaining such a levee line after it has been constructed. Whenever the Mississippi River flows in a channel 30 or 40 ft. deep, it has a powerful erosive force, and to expose levees in concave bends or across points to such a force would invite their destruction.

The cost of the existing methods of levee construction increases as the square of the height, and, if absolute protection is demanded for such levees as indicated, the cost over existing methods will probably approach the cube of the height. The cost of a weir is independent of the height of the water flowing over it, and the cost of a dam is approximately a direct function of the quantity of water which it impounds. If possibilities instead of probabilities are to control future levee construction, the cost will become so enormous that the economic solution of the problem will be found in other methods of flood protection.

The problem of flood control by reservoirs has been much simplified by the record of rainfall during the flood of 1927. It is self-evident that a reservoir which will reduce flood heights must be constructed in a locality where it can receive the waters which create the flood. This eliminates from consideration all reservoir sites in the Missouri Valley above Kansas City, Mo., in the Mississippi Valley above Rock Island, and in the Ohio Valley above Pittsburgh, Pa., as the rainfall in those regions did not exceed a total of 6 in. during the months of March and April. It practically limits their location to those portions of the States of Illinois and Indiana which drain into the Wabash River, the streams of Southwestern Illinois and Southeastern Missouri which discharge into the Mississippi River below St. Louis, Mo., the drainage area of the Tennessee River below the Wilson Dam, and the rivers of Arkansas, Mississippi, and Louisiana which empty into the river below Cairo. In this area there was a rainfall exceeding 12 in. in 60 days. The prairie country of Illinois, Indiana, and Southeastern Missouri is not adapted to the construction of large reservoirs. The flood of 1927, therefore, clearly demonstrates that the only reservoir or reservoirs capable of controlling the waters which created it must be located in the delta region below Cairo, that is, in the area which it is desired to protect by their construction.

It is theoretically possible to create in either the St. Francis, the Yazoo, or the Tensas Basins reservoirs which would have sufficient storage capacity to retain the surplus waters of the flood of 1927, but the cost would be excessive. Humphreys and Abbot suggested the utilization of the Tensas Basin to reduce floods, and the Mississippi River Commission has had before it propositions to utilize the St. Francis Basin for the same purpose. In the days of Humphreys and Abbot, the greater portion of the land needed for such a purpose was a part of the public domain and could have been acquired at a nominal cost. When the utilization of the St. Francis Basin was being considered, the State authorities were having difficulty in collecting the nominal taxation levied upon it. Levee construction, however, has enormously increased the value of property in both basins, and it is extremely doubtful whether the area for the reservoirs could be acquired by the Federal Government at the present time for $100 per acre, when the cities and villages which have sprung up in this region are taken into consideration, notwithstanding the reduction in values of real estate which must have resulted from the overflow.

The fact that it is estimated that more than 600 000 were made homeless by this flood and that it is one of the great catastrophes of the century is striking proof of the development of the delta from levee protection. Other floods have overflowed a greater area, but it was then so sparsely settled that the disaster did not create much comment beyond the Valley. If, to the cost of condemning about 6 000 sq. miles of reservoir sites, is added the cost of embankments for retaining the water higher than the levees which would be required, reservoirs can not be recommended as an economic proposition.

With spillways, conditions are reversed. For years, the writer has maintained that the existing Commission grade for levees below the mouth of Old River is the limiting line for their economical use. In a paper on spillways* presented before the Louisiana Engineering Society in 1925, he invited attention to the fact that a reduction in the flow of the Atchafalaya Outlet by the closure of Old River would necessitate the construction of a spillway to compensate for the increased discharge down the main river which would result therefrom. He also advocated the construction of a spillway below New Orleans, La., which would reduce flood heights at that locality, considering it a cheaper solution of the overflow problem for that city than raising its docks and the walls of the Industrial Canal to the Commission grade. He was then discussing the problem of lowering flood heights about 1 ft. The question ceases to be open to discussion, when it is proposed to provide for a discharge in the lower river 30 or 40% greater than that assumed by the Commission.

Although favoring a spillway which spills the water, and allows it to flow unrestrained to the Gulf, the writer also invited attention to the danger which arises from contracting the flow. The spillways required to reduce the discharge now considered possible to that assumed by the Commission, must have a flow exceeding that of the Yellow River in China or that of the Po River in Italy. The proposed flow in the spillway will exceed that of the South Pass of the Mississippi River, and approximately equal that of Southwest Pass, or Pass à Loutre, the other mouths of the river. Both South Pass and Southwest Pass have been successfully deepened by confining their flood discharge between parallel jetties. There are, however, hydraulic engineers who assert that the same discharge can be confined between parallel levees in a spillway without producing scour. It is a curious coincidence that the width proposed after the flood of 1922, for a spillway emptying into Lake Borgne, corresponds to the distance between the shore ends of the jetties at Southwest Pass recommended by noted levee engineers and adopted by Congress as the original project for its deepening to 35 ft., although a Board appointed by the Chief of Engineers in 1916 reduced this width from 6 000 ft. to 2 400 ft. because the excessive width as first approved was unable to maintain a channel depth exceeding 25 ft. The slope in Southwest Pass during floods is about 0.2 ft. per mile, while that in the proposed spillway would have exceeded 1 ft. per mile.

* *Proceedings*, Louisiana Eng. Soc., Vol XI, 1925.

A deep hole is invariably excavated in the contracted section of a crevasse, and the material thus scoured is deposited approximately on the arc of an ellipse enclosing the hole, and at a distance from it determined by the reduction in velocity caused by the dispersion of the flow. This action is similar to that which creates a bar at the mouth of the river. The forces which create the hole at a crevasse will exist in a spillway, and if not reduced by allowing its water to expand will be propagated its entire length. Some accidental cause, as an abandoned ditch or even a line of fence posts, will induce a local scour and when such a channel starts, it will enlarge. By such means both the Po and Yellow Rivers have created channels through which the entire river now flows.

In providing for possibilities which have not yet arisen, it is rash to ignore probabilities which have already occurred. The diversions of the Po and Yellow Rivers are historic facts while the excessive discharges now being discussed may be mere flights of a vivid imagination. The extension of the spillway at Point La Hache a sufficient distance up stream, will produce the same lowering of flood heights at New Orleans as the one proposed at Poydras, and at less cost. It will also reduce to a minimum the danger of river diversion.

An Act of Congress approved April 17, 1926, provides,

"* * * that the Secretary of War be and he is hereby authorized and directed to cause a survey to be made, and estimates of the cost of such controlled and regulated spillway or spillways as may be necessary for the diversion and control of a sufficient volume of the excess flood waters of the Mississippi River between Point Breeze and Fort Jackson in Louisiana in order to prevent the waters of the river exceeding 16, 17, 18, 19 and 20 ft. on the Carrollton gauge at New Orleans, and of approximately 46, 47 and 48 ft. on the gauge at Simmesport on the Atchafalaya Outlet. * * *"

Section 2 of the Act, however, contains a proviso "that no spillway shall be constructed as a result of the survey authorized by this act whereby the waters of the Mississippi River would be diverted into Mississippi Sound". A Board of Engineer Officers has been appointed in accordance with the terms of this Act, and will presumably submit its report before the next session of Congress. The Congress could never have contemplated the occurrence of the flood of 1927 when it passed the Act, and a strict compliance with its provisions under existing conditions would thwart its intent.

The river attained a height of 15.9 ft. on the Carrollton gauge during the flood of 1867, and of 46.3 ft. on the Red River Landing gauge. The levee line had been neglected during the Civil War, and practically annihilated by the floods of 1862 and 1867. A continuous spillway existed on both banks of the river from Baton Rouge, La., to its mouth, with the exception of the area occupied by the City of New Orleans. To assume that any spillway can be constructed in a semi-controlled river having a discharge at least 50% greater than that of 1867 which will only raise the gauge at Carrollton 0.1 ft. is absurd. Moreover, the proviso that no spillway constructed under the law shall divert water into Mississippi Sound precludes the construction of any spillway discharging into Lake Pontchartrain or Lake Borgne, and sug-

gests as a solution of the problem, a further extension up stream of the spillway recently built below Point La Hache, where the escaping waters flow into Breton Sound. The removal of the entire levee line on the east bank of the river below the Lake Borgne Canal could not be expected to reduce flood heights at Carrollton much below 20 ft. with a river discharge as great as has been recently estimated.

The gauge at Simmesport, La., can only be maintained at 46 ft. by closing Old River and preventing the discharge of the Mississippi River from entering it, and even then the existing reservoir at the lower end of the Tensas Basin will have to be maintained to reduce the maximum discharge which it is assumed flowed in the Ouachita and Red Rivers during the 1927 flood. The provisions of the Act which limits the survey to that part of the river between Point Breeze and Fort Jackson, La., also prevents the Board from investigating what gives promise of being the most satisfactory solution of the theoretical problem which is now being considered.

The disastrous results of the flood of 1927 are not primarily due to the floods of the Ohio and Upper Mississippi Rivers, but to the rainfall of 18 to 25 in. which occurred in the Lower Valley during the flood. Early floods in the rivers of Arkansas created such stages in the main river from Helena, Ark., to Vicksburg, Miss., that it destroyed what is termed the river's reservoir capacity, so that later moderate floods from the upper rivers created gauge heights through this section far exceeding any that had been heretofore recorded for the same discharge.

When the flood of 1927 is compared with that of 1912, on which the Commission based its estimates, it is noted that at Helena a discharge 300 000 sec-ft. less in 1927 than in 1912 increases flood heights 2.6 ft.; at Arkansas City, a reduction of 300 000 sec-ft. is accompanied by an increase in flood heights of 5.5 ft.; while, at Vicksburg, the same flood discharge increases flood heights 6.9 ft. When in addition to this disastrous condition of affairs, the crests of the floods of the Arkansas and White Rivers poured their waters on the crest of the main river flood, the question arises whether the cheapest solution of the problem would not be to separate these rivers entirely from the Mississippi and provide a separate channel for them across the Tensas Basin.

The Commission estimated that these rivers would only add to the maximum flood discharge of the Mississippi about 200 000 sec-ft. at their mouths, relying on the reservoir capacity of the main river and the lack of coincidence of the crests of the floods to reduce their reported maximum discharges to this quantity. If provision must be made for adding about 1 000 000 sec-ft. to a river the reservoir capacity of which has been exhausted, the grade of the levee line becomes excessive. If these rivers were diverted the reservoir capacity of the main river would be much greater than that estimated by the Commission and the flood of 1927 would have been propagated through the lower river, without the necessity of building spillways even if Old River was also closed. The cost of the proposed levee enlargement, and of spillways, would largely exceed the cost of such diversion.

It must be admitted, however, that this solution of the flood problem will not reduce flood heights at Simmesport to 46 ft., and that the determination of flood heights along the diversion channel would be a problem difficult of solution for the next twenty years, during which time the diverted flow would be excavating its bed. While the cost of this project may be many hundred million dollars less than that of any other project that will afford complete protection from any possible flood, it is still so great as to raise the question whether the increase in value of the land to be benefited would justify the expenditure.

The practicability of flood control by reforestation, by straightening the river, by enlarging its low-water channel with dredges, and by increasing its reservoir capacity by placing the levee lines at a greater distance from the channel, is not affected by a variation in the discharge. The only one of these propositions that is now being seriously considered is a further increase in the reservoir capacity.

For every mile that the levee line is moved away from the river bank, the reservoir area during floods will be increased by about 1 000 sq. miles, but the area capable of being cultivated will also be reduced by the same amount. The land along the concave banks of the river is the highest land in the delta, the most highly cultivated, and the location selected for the houses and barns of the inhabitants. Many levee districts would be bankrupt by a change of 1 mile in the location of the levee line. A large proportion of the productive land which now pays the taxes, would be left unprotected. While the Commission places levees in bends at a considerable distance from the bank, it is solely to protect them from river caving and insure a levee life of about twenty years.

The practicability of the project also merits consideration. If the flood of 1927 is to be an annual occurrence, it would adjust its channel to its discharge, but if it does not again occur during the next 100 years, the minor intermediate floods will tend to build up the river banks just as they have for ages, and by the time the second flood occurs, this fill will have largely reduced the reservoir depths.

It has also been suggested that complete protection necessitates a change in the standard levee section adopted by the Commission. In a discussion of the paper by the late William Starling, M. Am. Soc. C. E., entitled "The Discharge of the Mississippi River", presented to the Society in 1896,* the writer stated that,

"* * * the forms adopted for the levee section differ materially from those which obtain in reservoir construction. The causes of this difference arise from the impracticability of finding in an alluvial valley the foundation impervious to water that is an essential condition in reservoir construction. The material for constructing the puddled core is also not readily obtainable, and its value is not so evident when it can be flanked by water passing through a permeable foundation into the embankment beyond.

"The essential condition of levee construction is a mound of earth of sufficient height so that water cannot flow over its top; of sufficient mass so

* *Transactions*, Am. Soc. C. E., Vol. XXXV (1896), pp. 341–343.

that surfaces of saturation cannot be formed through it on which the superincumbent material will slide; of sufficient width of base, so that the water flowing through the permeable foundation will not have sufficient force to remove any material, it being assumed that the earth has been placed with care so that there are no channels left across the embankment through which the waters can directly flow. This mound of earth must be protected from the eroding action of rains, and its river surface from erosion by river currents and waves during floods. The grade must be somewhat higher than the highest flood to afford protection from wave action during storms.

"With the extreme variations in permeability which are found in the soils of which levees are constructed, variations in form become necessary, but practical experience with the soils of the Mississippi bottoms has developed certain forms which are of general application. A slope of 1 on 3, when well sodded with Bermuda grass, has been found to resist the action of rain, of river currents, and of minor waves. In localities exposed to the full force of waves through long reaches of the river, it is necessary either to reinforce the sod with some more permanent form of revetment, or to adopt a gentler slope.

"A width of crown varying from 6 to 10 ft. generally exists. The width to be given to the crown is interdependent with the slope to be given the land side of the levee. An 8-ft. crown affords convenient space for patrolling the levee line during floods, and storing such material as may be required to repair any damage which may be inflicted by storms. With a width of crown of 8 ft., a land slope of 1 on 2 can be safely employed until the levee attains a height of 6 ft.; with higher levees unless the soil is especially adapted to levee construction, there is a tendency to form a surface of saturation through the mass on which the upper portion is liable to slide. Levees not exceeding 12 to 14 ft. require a land slope of 1 to 3; above these heights in the upper basins of the river, trouble begins to be experienced with the foundation, and still gentler slopes are necessary, or the same result can be attained by adding to the base a mound of earth termed a banquette. * * * While these levee sections have resulted from practical experience rather than from theoretical considerations, it may be noted that the sections most generally employed in recent years insure an angle of repose of dry earth on wet clay of 14° when water is at the top of the levee, the limiting angle of such materials."

From these suggestions by the writer was evolved the standard levee section of the Commission (Fig. 1) which has been used on a levee line more than 1400 miles in length during a period of more than 30 years, and without a failure from weakness of section until the flood of 1927. During this flood, a disastrous crevasse occurred at Mounds, Miss., in a levee of standard section. A succession of rains converted the earth composing the parts of the levee above the banquette into a mud which could not withstand the static pressure due to a head of water of 6 ft., and it is natural to assume that the material placed in that part of the embankment was unsuited for levee construction.

When the writer was Assistant to the Commission and found material of such a character, he did not hesitate about enlarging the levee section which he had recommended. Such a course of action was so self-evident that he did not even consider it necessary to obtain the approval of the Commission for this change in form. It is illustrative of the hysteria that is sweeping over the country as a result of the flood that it is now proposed to prohibit the Assistant from exercising such a discretionary power, and to enlarge the

entire levee line to a section which will resist the water pressure, even if composed of poor material, notwithstanding the fact that more than 1 400 miles of levees of standard section, or weaker, successfully resisted the flood of 1927. This proposed reform will cost about $40 000 000.

Before making such an expenditure, however, it is advisable to make a further investigation of the causes of the conversion of this levee into mud. Several other levees, while not failing, showed similar signs of weakness, but it is a peculiarity of this flood alone. In all previous floods a mound of earth 6 ft. high, with an 8-ft. crown and slopes of 1 on 3, properly compacted and covered with a layer of Bermuda sod, could resist the water pressure no matter how porous the soil might be, of which it was composed, and if not protected by a revetment of Bermuda sod, rains eroded its slopes, instead of soaking into the mass and destroying its cohesion. During the flood of 1892, the writer, who was then Assistant to the Commission, had to hold a levee line 40 miles long in the Tensas Basin in Arkansas, a great part of which had a crown of 4 ft. and slopes of 1 on 2, not only until the water attained the top of the levees, but, by means of sand-bags and other devices, to still greater heights, and the only material that was converted into mud by rains was the fresh earth used in topping.

The Commission has passed strict regulations about allowing vehicles on the levee crown. If, however, during the excitement of flood protection, employees ignored those regulations and used automobiles for inspection purposes, the Bermuda sod would be rapidly destroyed during rainy weather, and longitudinal ruts formed from 6 in. to 1 ft. deep. With a 14-in. rainfall in 24 hours, these ruts would become veritable reservoirs for retaining water which could seep into the levee, and convert the best material into a mud. The excessive sloughing of the land slope of levees during this flood may also be due to this cause.

While the writer has no knowledge that such was the practice, before expending $40 000 000 on the levee line to enlarge the section, he would try the experiment of giving steep slopes to the crown, which would not only facilitate the run-off of the rainfall, but render it physically impossible for automobiles to violate the Commission's regulations. It is noted that the various projects for enlarging the levee section invite a greater use of the crown for travel in vehicles by widening it.

Conclusion

Congress has been extremely liberal in its appropriations for the Mississippi River since the creation of the Commission, but any one who assumes that Congress while limiting the expenditures for all the other rivers and harbors in the United States to $50 000 000 per year, can be persuaded to appropriate for the Mississippi alone $50 000 000 to $100 000 000 per year during a period of 10 years, has little knowledge of the workings of the Congressional mind.

Attention has been called officially to seven great projects of water development which will cost from $1 500 000 000 to $2 000 000 000, and there are numerous other expensive river and harbor projects which have local support. The American people will most liberally contribute a vast sum to the

Red Cross for humanitarian purposes, but when it is a question of expenditure from the United States Treasury, every community will demand consideration of its local needs. An equitable distribution of the funds over the entire country is necessary to insure the passage of a river and harbor bill.

The Mississippi River Commission has always been embarrassed by a lack of funds, and the fundamental principle governing its actions during the past 45 years has been to benefit the people of the delta as much as was possible with the appropriations made by Congress and under the limitations prescribed by that body. It is probable that it will have to pursue the same course in the future. If the attempt to establish a grade line which would be above all probable floods, as recommended by the writer when he was President of the Commission, should be abandoned, and the original Commission grade of 3 ft. above the stages that have occurred at the different stations along the river be substituted for it, there would be a probability of carrying out such a program with the funds which can be anticipated. Such a project not only would meet the economic situation, but would be in accordance with normal engineering practice.

The city engineer who designs sewers to carry off the rainfall has to solve the question, "What is the maximum run-off for which provision must be made?" The *Transactions* of the Society contains a number of discussions of this subject, and curves have been constructed showing graphically the probability of run-offs extending to periods of several hundred years. It is, however, generally recognized by the Engineering Profession that provision of a sewer system for a city, which will prevent the flooding of the streets under the most adverse conditions, is an unwarranted extravagance. For example, if the City of New Orleans had constructed a sewer system to provide for the rainfall which occurred during the recent flood, it would have been compelled to expend on it, funds which could have been more profitably diverted to street pavements, to a water supply, and to other essentials to a city's progress. The occasional over-taxing of the sewer system is less injurious to the city's development than the curtailment of other prime necessities.

When the problem is expanded from drainage of a city to that of a continent, its complexity increases and the determination of future possibilities becomes more uncertain. Such possibilities are not then determined by mathematical computations, but by the imagination. When it is stated that a flood like that of 1927 will not probably occur again in 100 years, the engineer must take into consideration probabilities instead of possibilities, and consider the interest on investment for a period of 100 years. If the interest is computed at 4% on the cost of some of the proposed projects, it would be greater in 15 years than the estimated damage caused by the flood. A disaster which will not probably occur once in 100 years is in the same category as an earthquake or cyclone. It is an Act of God for which the philanthropist should make provision. Because an earthquake formed Reelfoot Lake opposite New Madrid, Mo., 100 years ago, engineers do not make the buildings in the Mississippi Valley earthquake-proof.

It is suggested, however, that the engineer who attempts to solve the problem must make a definite decision whether he will be governed by probabilities or by possibilities. To submit a project which in one part provides only for what will probably occur, while in another makes provision for a possible increase, will be trying to serve two masters, with the usual result.

The final suggestion is also submitted that no matter how much money is expended on the levee line, it will still be at the mercy of the combination of a muskrat, a dark night, and a careless levee inspector. A burrowing animal can create a hole in the finest levee that has been devised, which, if not closed within a few moments, will insure its destruction. Perfection is difficult in all engineering enterprises. To try to construct a levee line which will resist the river flow under all the imaginary conditions which now fill the public mind, is to attempt the impossible.

RAINFALL CHARACTERISTICS OF THE MISSISSIPPI DRAINAGE BASIN

By H. C. Frankenfield,* Esq.

The Mississippi Basin

The drainage basin of the Mississippi River comprises about all that portion of the United States lying between the Alleghany and the Rocky Mountains except the Great Lakes and Hudson Bay drainages, with a total area of 1 250 900 sq. miles, about two-fifths of the total area of the United States proper. Some water from 31 of the 48 States passes into the Gulf of Mexico. For convenience of study it has become customary to divide the entire area into six major sub-divisions, or sub-basins, as follows: the Missouri, the Upper Mississippi, the Ohio, the Arkansas-White, the Red, and the Lower Mississippi. The drainage areas of the sub-basins, together with their percentages of the entire area, are as given in Table 1.

TABLE 1.—Drainage Area of the Mississippi Basin.

Sub-basin.	Drainage area, in square miles.	Percentage.
Missouri	528 850	42.3
Upper Mississippi	187 850	15.0
Ohio	203 900	16.3
Arkansas-White	186 000	14.9
Red	90 000	7.2
Lower Mississippi	54 300	4.3
Total	1 250 900	100.0

Barometric Pressure Distribution and Precipitation

Having these proportions in mind in a general way, consider the precipitation that occurs over each of these sub-basins, its form to a certain extent, the peculiarities of its distribution, and the reasons therefor, so far as one may be able to give them. Without going deeply into the subject, begin with the ordinary weather chart. Certain relative distributions of barometric pressure will be followed by fair weather, and others by rain or snow. These different distributions have long been grouped into types that officials of the U. S. Weather Bureau have classified according to their regions of inception so far as they have been able to determine them. The types that are principally concerned in precipitation over the Mississippi Drainage Basin are known as the North Pacific, the South Pacific, the Central Rocky Mountain, and the Southwestern. Reference is had now to low-pressure types only, or, technically, cyclones, as these are directly concerned in precipitation causation, although influenced in greater or less degree by the high-pressure types, or anti-cyclones.

Low-pressure areas have warm and moist southeast and south winds on their eastern and southern sides, and the warm and moist masses of air rise until they come into contact with other masses of air which are sufficiently cold to cause condensation of some of the water vapor in the warm masses, and rain

* Senior Meteorologist, U. S. Weather Bureau, Washington, D. C.

or snow results. The amount of resulting precipitation will depend upon the velocity and direction of movement of the cyclone and attendant anti-cyclone, the amount of available water vapor, and the difference in temperature between the warm cyclone and the cold anti-cyclone.

The great general and never failing type of rain producer, whatever its origin may be, is a well-defined low-pressure area moving in some easterly direction—usually northeast or east-northeast—with a relatively cold high-pressure area to the northward or northeastward. This is true for the entire Mississippi River Basin, notwithstanding the varying amounts of precipitation that are normal to the different sub-basins. As a matter of fact the four types previously mentioned are neither more nor less than modifications of the great general type, but with different points of origin and different velocities of progression.

Normal Precipitation Over the Mississippi Basin

The figures in Table 2 show the normal precipitation by seasons for the States comprised in the Mississippi Basin. The data are given for the States in each of the six major sub-basins, and wherever a State extends over portions of adjacent sub-basins, the figures cover only that portion of the State within that particular sub-basin. For instance, Kansas would appear in both the Missouri and Arkansas Sub-Basins, etc.

TABLE 2.—Seasonal Normal Precipitation by States, Mississippi Basin.

State.	Drainage area, in square miles.	Precipitation, in inches.				
		September-November.	December-February.	March-May.	June-August.	Total.

Entire area	54 300	9.85	13.33	14.10	12.59	49.87

Table 2 has virtually been brought down to date (1927), an always desirable condition for those who are interested in the study of normal precipitation, and, furthermore, so far as the writer is aware, the data have not previously been presented in similar form, the usual practice having been to confine the com-

ponent data within the exclusive limits of State boundaries for which river drainage basins have no respect whatever. Table 3 gives the data in Table 2 arranged to show the normal annual precipitation for the sub-basins weighted in accordance with the ratios between their respective drainage areas and the area of the entire basin.

TABLE 3.—Weighted Normal Precipitation, Mississippi Basin.

Sub-basin.	Drainage area, in square miles.	Normal precipitation, in inches.	Percentage.
Missouri	528 850	9.62	30.9
Upper Mississippi	187 850	4.78	15.4
Ohio	203 900	7.29	23.4
Arkansas-White	186 000	4.36	14.0
Red	90 000	2.88	9.3
Lower Mississippi	54 300	2.17	7.0
Total	1 250 900	31.10	100.0

It is readily apparent from even a casual inspection of Tables 2 and 3 that the precipitation over the Mississippi Drainage Basin is at a minimum at its extreme northern and western boundaries, and increases steadily, although by no means uniformly, to the eastward, southeastward, and southward. The meteorological reasons for this distribution are not intricate, and are undoubtedly familiar to the majority of engineers.

Barometric Pressure and Geographical Distribution of Precipitation

As previously stated, low-pressure areas, or cyclones, or storms, as the U. S. Weather Bureau terms them, if they have assumed definite and pronounced formation, as they move eastward over the country, are attended by warm southeast winds on their southeastern and southern sides, or in their southeastern quadrants. These masses of warm air, coming as they do from the Atlantic Ocean, or the Gulf of Mexico, carry with them large quantities of water vapor, and as the air rises higher and higher in the atmosphere, it finally becomes cooled through loss of heat by expansion and by contact with cooler air masses. The ascending air, as it cools, of course loses its capacity for retaining vapor, the saturation point is soon reached, and condensation, or precipitation, sets in. The land nearest the original water supply naturally receives the largest quantity of precipitation, and as the air continues to move farther inland toward the northwest, the available supply of moisture becomes less and less, until the water supply available at the existing temperature has been precipitated, generally at a considerable distance from the Northwestern Rocky Mountains. This is the usual occurrence, although not without exception so far as the surface weather chart shows. At times, there are heavy rains, occasionally torrential, that attend the summer thunderstorms between the Missouri River and the Rocky Mountains. The surface pressure distribution preceding these heavy rains does not always present an orderly arrangement, but aerological observations by kite and balloon will generally show a

mass of cold air, unusually cold for the season, to the westward and northwestward, close to the warm air masses, which will soon under-run them with resulting heavy precipitation.

The Far Northwest then does not receive much moisture from the Atlantic Ocean and the Gulf of Mexico, as the available supply is exhausted farther to the eastward and southward, and its precipitation is due to other types of pressure distribution. One of these is the presence of a warm low-pressure area over Southeastern Wyoming, or Eastern Colorado, with a cold high-pressure area over Saskatchewan, and precipitation, either of rain or snow, will result from the cold northerly and northeasterly winds. This precipitation is usually heavy. Aside from this type precipitation over the Far Northwest generally results from the cold air of the high areas following the movement of low areas across that section. Over the great central valleys the precipitation precedes and accompanies the low area, with little or none following, but in the Far Northwest the southeasterly and southerly winds blowing into the eastward-moving low areas carry but little moisture, not enough to condense until the cold from the following high area reaches it, and precipitation will set in behind the low area and with west and northwest winds. Precipitation from this type of pressure distribution is uniformly small.

Finally, the one great rain-producing type for the entire Central and Southern Mississippi Basin is the "Southwestern." By "Southwestern" is meant a low-pressure area from Mexico, Arizona, or New Mexico (sometimes originating in the Central Pacific Ocean), moving northeastward through Texas and the Ohio Valley, with the usual high area to the northward. The moisture supply is virtually unlimited, and the precipitation is abundant, sometimes in the form of heavy snow in the Ohio and Middle Mississippi Valleys. These storms afford a sufficient explanation of the heavier precipitation over the central and southern portions of the basins and incidentally a partial reason at least for flood behavior in the Lower Ohio and Lower Mississippi Rivers. The rains begin first over these sections, and by the time they reach the Upper Ohio Valley the rivers below have risen decidedly, so that the waters from the great and prolific tributaries of the Ohio and from the upper river itself are added to the already swollen streams below. Sometimes these southwestern storms move in series with intervals of three or four days, and when this happens a severe flood follows. In 1912 there was a series of six of these storms, separated by intervals of only a few days, and the resulting flood was one of the greatest in the history of the Lower Ohio and Lower Mississippi Valleys.

Seasonal Distribution of Precipitation

A study of the seasonal distribution of precipitation over the Mississippi Basin discloses a number of points of difference when the sub-basins are examined separately. In the Missouri and Upper Mississippi Basins the minimum amount occurs during the winter months, December to February. Nearly all the precipitation is in the form of snow which produces comparatively little water when melted. There is a decided increase during the spring

months, March to May, and a still further but less decided increase during the summer months, June to August, a large part of the summer rains coming from thunderstorms. During the autumn months, September to November, there is a sharp decrease as the thunderstorms become less frequent and storm activity is usually at its lowest ebb. In the Ohio Basin there is a steady increase from season to season, beginning with the autumn, although in Illinois and Indiana the winter precipitation is lower on account of the snow effect. The spring and summer data do not differ greatly, the summer thunder showers supplying slightly more rain than the spring storms. In the Arkansas-White Basin the tendency is the same as in the Missouri and Upper Mississippi Basins. The winter decrease from snow effect is not so marked, as it is mostly limited to the western portion of the drainage area, and, furthermore, the rains over the States of Missouri and Arkansas are abundant. In the Red and Lower Mississippi Basins the minimum amount of precipitation is recorded during the autum months, and the maximum during the spring months, the season of the most effective rain-producing storms. The summer months have less rain than the spring months as summer pressure conditions are usually more or less stagnant, and thunderstorms, while frequent, are often local and spring rains are general. Table 4 shows the seasonal amounts for each sub-basin and the percentage of the total fall.

TABLE 4.—NORMAL SEASONAL PRECIPITATION, IN INCHES, AND PERCENTAGES OF NORMAL ANNUAL AMOUNTS, MISSISSIPPI BASIN.

Sub-basin.	September-November.		December-February.		March-May.		June-August.		Total.	
	Amount.	Percentage.	Amount.	Percentage.	Amount.	Percentage.	Amount.	Percentage.	Amount.	Percentage.
Missouri	4.81	21	2.39	11	6.77	29	8.84	39	22.81	100
Upper Mississippi	7.43	23	4.44	14	9.10	29	10.85	34	31.82	100
Ohio	8.81	20	10.99	25	12.14	27	12.76	28	44.70	100
Arkansas-White	6.47	22	4.43	15	8.80	30	9.60	33	29.30	100
Red	8.47	21	8.76	22	12.39	31	10.38	26	40.00	100
Lower Mississippi	9.85	20	13.33	27	14.10	28	12.59	25	49.87	100

SNOWFALL

The correct measurement of snowfall has never proved to be an easy problem. It is true that improved apparatus and methods have resulted in very much greater accuracy during the last thirty years so far as individual places of observation only are involved, but when attempts were made to co-ordinate these individual data over areas of any considerable extent, difficulties arose. Sometimes it was found that the total measured run-off of a stream was greater than the total recorded amount of precipitation of rain

and snow combined, while at other times the percentage of run-off was less than could be reasonably expected. In both instances the trouble was due much more to deficient data than to defective methods of observation. Over broad expanses of comparatively level country this objection could sometimes be waived, but in mountainous regions and in others of diversified topography it is ever present.

For many years it was impossible, except in a few isolated instances, to obtain snowfall data for the high mountain altitudes, although in later years the U. S Weather Bureau, ably assisted by the U. S. Forest Service, has been able to reach some of the high places. Nevertheless, there remains the impossibility of accomplishing satisfactory co-ordination of the data on account of the limited areas covered and the numerous and abrupt changes in topography. If the work of snowfall measurement and its translation into water equivalent is to be properly performed there must be made first a topographical survey of the mountain areas and perhaps some others. Once the survey is made it will stand for all time. Then must come the location of a number of measuring stations that will be sufficiently representative of the entire area; that is, located where they will afford a true index of the snow depths, and entirely without any idea as to uniformity with respect to relative location. The imperative need is for more data properly obtained. During recent years several attempts have been made to secure funds from Congress for a few experimental surveys, but without success. However, there are hopes of the future, especially in view of the fact that the great floods of 1927 appear to have nationalized the water problem, at least to a very large extent. The results of a computation of the normal annual snowfall by the ordinary method of averages are given in Table 5, for the States of the Mississippi Valley, with the small areas of North Carolina, Maryland, Western New York, Michigan, Texas, and New Mexico omitted.

TABLE 5.—Normal Annual Snowfall, Mississippi Basin.

State.	Normal annual snowfall, in inches.	State.	Normal annual snowfall, in inches.	State.	Normal annual snowfall, in inches.
Eastern and Central Montana	55	Missouri	20	West Virginia	34
Eastern Wyoming	59	Kansas	17	Virginia	18
Eastern Colorado	72	Oklahoma	8	Kentucky	16
North Dakota	32	Wisconsin	45	Tennessee	10
South Dakota	36	Illinois	23	Northwest Georgia	4
Nebraska	30	Indiana	26	Northwest Alabama	4
Minnesota	39	Ohio	32	Mississippi	2
Iowa	30	Western Pennsylvania	47	Arkansas	8
				Louisiana	1

As would be expected, the greatest snowfall occurs over the Rocky Mountain districts, with the maximum of about 72 in. in Eastern Colorado. From the mountains eastward and north of the 35th Parallel there is a decrease to the Middle Mississippi Valley, except in Minnesota and Wisconsin, which are partly under the influence of the Great Lakes. Then follows an increase until

the Alleghany Mountains are reached, with a maximum of about 47 in. over Western Pennsylvania. Snowfall below the 35th Parallel is not of consequence.

Roughly, the assemblage of the figures in Table 5 into normals for the individual sub-basins is, as follows:

Basin.	Depth, in inches.
Missouri	39
Upper Mississippi	31
Ohio	26
Arkansas-White	13
Red	6
Lower Mississippi	5

On the usually assumed arbitrary basis of 1 in. of water for each 10 in. of snow, the precipitation of the entire Mississippi Basin, using the data in Table 2, may be divided as shown in Table 6.

TABLE 6.—NORMAL RAIN AND SNOW, MISSISSIPPI BASIN.

Basin.	Rainfall, in inches.	Snowfall (melted), in inches.	Total, in inches.
Missouri	18.91	3.90	22.81
Upper Mississippi	28.72	3.10	31.82
Ohio	42.10	2.60	44.70
Arkansas-White	28.00	1.30	29.30
Red	39.40	0.60	40.00
Lower Mississippi	49.37	0.50	49.87
Entire basin	28.31	2.79	31.10
Weighted	(91%)	(9%)	(100%)

METHODS OF COMPUTING NORMAL PRECIPITATION

The normal values in Table 2 were computed in accordance with the time-honored procedure; that is, by dividing the sum of the normal values at as many units of observation as possible by the total number of units. Little objection could be offered to this plan were it not for the fact that, except in rare instances, the aggregate quantity of data for any considerable area is not sufficient to insure a true and dependable normal. Every hydraulic engineer knows that the amount of precipitation that occurs over so small an area as several hundred square miles is far from uniform, even under virtually identical conditions of topography and meteorological influence. In other words, under the system that has universally prevailed—a system that economic conditions, if nothing more, has rendered compulsory in this country—the data have always been insufficient to serve in the most efficient manner the interests for which they were recorded.

If the number of stations of observation could be multiplied by three or four, or if the stations could be located on the basis of one for not more than each 50 or 75 sq. miles of area, a solution of the problem of questionable normals would be obtained. In mountainous sections, especially in high moun-

tains with their abruptly diversified topography, the stations of observation should be more numerous than one for each 50 or 75 sq. miles, and arranged so as to have proper regard for rapidly changing topography. The Weather Bureau has long realized this situation, but thus far it has been helpless through inability to finance the undertaking. No criticism of other Governmental agencies is implied in this statement, as the Weather Bureau has probably received all the consideration that has been due and in keeping with the requirements of other services of equal importance. Therefore, with a view to the better utilization of the available data in connection with the discussion of flood problems, the Weather Bureau began about 1922 to compile precipitation data by another method which, if laborious, at least possesses the merit of being more accurate, so that the results obtained were very probably as nearly correct as they would have been had the number of stations of observation been multiplied by three or four.

If a planimeter is not available, the plan suggested to the writer by Professor C. F. Marvin, Chief of the Weather Bureau, may be used. It is as follows: Monthly data for a large number of stations were charted and isohyetal lines carefully drawn. These lines were then traced upon sheets of cross-section paper, together with the outlines of the six drainage areas.

The isohyets divide the drainage basins into various small sub-areas, over which the precipitation may be assumed to be uniform and of an amount represented by the mean between the two adjacent isohyetals. Therefore, the number of squares in each sub-area was counted. This number was then multiplied by the average precipitation for the sub-area in question and the product divided by the sum of the counts for all the sub-areas, which latter, of course, is the number of squares in the whole drainage basin being studied. Finally, the sum of the quotients found in the manner described gives the depth of precipitation which, spread uniformly over the whole basin, would represent the same quantity of water as fell in the irregularly distributed precipitation.

This method of discussing precipitation permits the consideration of actual quantities of water over large areas with the certainty that inequalities of rainfall distribution and the uncertainties arising therefrom have been largely eliminated. The method was used in the computation of precipitation data for the great Mississippi floods of 1922 and 1927, and for purposes of comparison the data for the floods of 1882, 1912, and 1913 were computed on the same basis. Monthly seasonal, and unusual normals for the sub-basins and for the different States were also computed, and the sub-basin data are given in Tables 7 and 8.

Analysis of Distribution of Precipitation

General Distribution.—Table 7 shows that the maximum water-fall over the Mississippi Basin occurs in May and June and in equal amount for each month; also, that the minimum fall occurs from November to February, with a maximum difference of only 0.15 in. between any two months.

Considering the sub-basins individually, the same general arrangement is found in the Upper Mississippi, the Missouri, and the Arkansas-White Basins,

those that have the greatest amount of snowfall. The distribution in the Ohio Basin is different in that the maximum fall occurs in March and July and the minimum during October and November, instead of in the winter. In the Red Basin the maximum fall occurs in April and May and the minimum in February, while in the Lower Mississippi Basin the maximum occurs in March, April, and December, and the minimum in October, although, as a whole, there is little variation in monthly values, except during the autumn months.

TABLE 7.—WEIGHTED MONTHLY MEANS OF PRECIPITATION OF THE INDIVIDUAL BASINS OF THE MISSISSIPPI DRAINAGE AREA.

(Precipitation, in Inches.)

Basin.	Percentage of area.	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.	Annual.

Lower Mississippi...	4.3	0.21	0.19	0.22	0.22	0.19	0.18	0.20	0.18	0.14	0.12	0.15	0.22	2.22
Total.....	100.0	1.75	1.64	2.26	2.88	3.63	3.63	3.22	2.94	2.58	2.09	1.68	1.79	30.09

TABLE 8.—WEIGHTED SEASONAL PRECIPITATION OF THE INDIVIDUAL BASINS OF THE MISSISSIPPI DRAINAGE AREA.

(Precipitation, in Inches.)

Sub-basin.	Ratio to whole basin.	FALL.	WINTER.	SPRING.	SUMMER.	Annual.
		September to November.	December to February.	March to May.	June to August.	
Upper Mississippi.....	0.150	1.13	0.61	1.34	1.68	4.76
Missouri.....	0.423	1.79	0.95	2.63	3.36	8.73
Ohio.....	0.163	1.44	1.76	1.96	2.02	7.18
Arkansas-White.....	0.149	0.98	0.67	1.35	1.44	4.44
Red.....	0.072	0.60	0.57	0.86	0.73	2.76
Lower Mississippi.....	0.043	0.41	0.62	0.63	0.56	2.22
Total	1.000	6.35	5.18	8.77	9.79	30.09

It will be noticed that the Upper Mississippi and Arkansas-White Sub-Basins differ but little as to drainage area and water depth, whereas the Missouri Basin, with nearly three times their drainage area, has less than twice the quantity of water on account of the long snow season. The Ohio Basin,

with a drainage of a little less than two-fifths that of the Missouri Basin, has 82% as much water, the winter season showing an excess over the Missouri Basin. The Red Basin, with about one-half the drainage area of the Arkansas-White and Upper Mississippi, has about 62% and 58%, respectively, of the quantity of water of the two latter basins, while the Lower Mississippi Basin, with about 10% of the drainage area of the Missouri Basin, has about one-fourth as much water, but the Ohio Basin, with a drainage area about two and one-fourth times as large as that of the Red, has nearly three and one-fourth times as much water on account of the smaller precipitation over the Upper Red Basin.

Seasonal Distribution.—The seasonal distribution will conform, of course, closely in character to that previously outlined in the discussion of actual precipitation. A comparison of the annual normals and their percentages of the total basin precipitation by both methods of computation is given in Table 9.

TABLE 9.—Comparison of Precipitation Normals.

Sub-basin.	Actual Precipitation from State Normals.		Computed Precipitation.	
	Inches.	Percentage.	Inches.	Percentage
Missouri	9.62	30.9	8.73	29.0
Upper Mississippi	4.78	15.4	4.76	15.8
Ohio	7.29	23.4	7.18	23.9
Arkansas-White	4.36	14.0	4.44	14.7
Red	2.88	9.3	2.76	9.2
Lower Mississippi	2.17	7.0	2.22	7.4
Total	31.10	100.0	30.09	100.0

The small difference between the two totals is due to the fact that the State normals, after their reduction to the sub-basin normals, were then weighted according to the area ratios. Had the actual precipitation figures been used throughout, the difference would doubtless have been greater, but it was not feasible to undertake the work at this time, and the data were not obtainable from any other source.

Floods

So much for the causes, character, and distribution of precipitation over the great Mississippi Basin. It is in order now to discuss what becomes of this precipitation when at times its normal characteristics undergo decided changes, that is, become abnormal as to quantity, time, and distribution, and manifest themselves in the form of the floods that have become so distressingly and destructively frequent during the last sixteen years, and especially during 1927. The subject of floods will not be discussed herein by the writer, except in connection with the precipitation that caused them.

Before taking up the Lower Mississippi floods, the floods of the Missouri and Upper Mississippi Basins will be touched upon briefly.

Severe or even ordinary floods in the Missouri River above the mouth of the Kansas River are rare. The greatest general flood of which there is record occurred in the spring of 1881 and extended to the mouth of the river, merging there with an Upper Mississippi flood of fair proportions. However, it was not very severe east of Kansas City, Mo. There was also a severe flood in March, 1887, in the North Dakota portion of the Missouri River, but the flood stage was not reached as far south as Omaha, Nebr.

These Upper Missouri floods are spring floods, and are due usually to a combination of melting snows in upper reaches, high temperatures, and rain. The melted snow factor is not of importance unless in large quantity, and supplemented by substantial rains, and the rain is the essential factor. It is not necessary to discuss the floods caused by the formation and subsequent breaking of ice gorges, and, incidentally, it is very probable that the flood of 1881 was largely an ice flood. From Kansas City eastward, Missouri River floods are quite frequent, although as a rule not great. They are essentially rain floods and occur usually in late June and in July. By far the greatest of these floods occurred in June, 1844, a season of torrential rainfall that also extended over the Middle Mississippi Valley causing stages that have not since been reached between the mouth of the Illinois River and Cape Girardeau, Mo.

Upper Mississippi Floods, that is, floods above the mouth of the Missouri River, are more numerous. They are almost entirely spring floods, and, unless caused by ice gorges, they are rain floods, although the rain may be considerably augmented at times by melted snows. Owing to the flat contour, these floods are likely to be destructive below the mouth of the Wisconsin River.

The floods of the Ohio, Arkansas-White, Red, and Lower Mississippi Valleys are virtually of annual occurrence, and great floods are not infrequent, as witness those of comparatively recent occurrence, 1912, 1913, 1915, 1916, 1920, 1922, and 1927. These floods are pre-eminently rain floods, although at times considerable assistance is lent by melting snows in the winter or early spring from the Ohio River and its many large mountain tributaries.

The Flood of 1927

As the flood of 1927 overshadowed all others from Cairo, Ill., southward it will hardly be necessary to discuss the precipitation conditions for any others except the flood of 1922 which was next in magnitude to that of 1927. All data will be expressed in terms of water depth over the entire area.

In Table 10 will be found the data for the floods of 1922 and 1927, together with the departures from the normals. The normals are of recent determination and are the product of the combined labors of Messrs. Montrose W. Hayes and Walter J. Moxom, of the U. S. Weather Bureau Office, at St. Louis, Mo., and engineers of the office of the Mississippi River Commission, also of St. Louis.

The total depth of water more or less contributory to the flood of 1927 was 10.79 in., and 12.38 in. if the last two weeks of December, 1926, are included, as they really should be. The excess of 1927 over 1922 for the entire period, December 18 to April 30, was 1.80 in., but for the four months, January to April, 1927, only 0.21 in., or a little less than 2 per cent. The excesses

above the normal amounts in both years are significant. The water depths for January were below the normal amounts in both 1927 and 1922, and February, 1927, was also deficient, while February, 1922, shows an excess. Taken together, January and February, 1927, show a deficiency of 0.22 in. against a deficiency of 0.15 in. in 1922, a difference so small that during the two months both years were virtually on even terms. The month of March shows a decided excess for both years, but with 1922 still in the ascendancy, the figures being + 0.72 in. for 1927 and + 1.24 in. for 1922. Both values are quite large and indicate a severe flood. In April, the month of greatest water depth over the entire area, conditions became decidedly reversed with an excess of 1.75 in. in 1927 against 0.94 in. in 1922.

TABLE 10.—PRECIPITATION FOR THE FLOODS OF 1922 AND 1927, IN TERMS OF INCHES OF WATER OVER THE ENTIRE MISSISSIPPI DRAINAGE AREA, AND DEPARTURES FROM NORMAL.

Lower Mississippi	0.16	—0.05	0.18	—0.01	0.37	0.15	0.33	0.11	1.04	0.20	0.27	—0.17	1.31	0.03
Total	1.70	—0.06	1.48	—0.16	2.99	0.72	4.62	1.75	10.79	2.25	1.59	—0.08	12.38	2.17

Comparison of the data as a whole for 1922 and 1927 does not disclose any particular reason why the magnitude of the flood of 1927 should have exceeded

that of 1922. In fact, the behavior was much the same in both. The months of January and February differed but little, and, taken together, both were deficient. In March, 1922, the excess precipitation was large and the maximum flood occurred in that month, while in April, 1927, the excess was nearly twice as great as in April, 1922, and the maximum and greater flood occurred in that month. Therefore, it is obvious that the distribution of precipitation, as to intensity, time, and locality, is almost as important as the amount thereof. In both 1922 and 1927 a reasonable additional amount in January and February and an equivalent lesser amount in March and April would have lowered the flood crests materially, while the reverse occurrence would have resulted in still higher crests, assuming that levees had remained intact. In 1912, another year of great March and April flood, the excess water in February and March amounted to 1.57 in., with a slight deficiency in January, and the total quantity of water for the three months was 8.24 in., 2.34 in. less than in 1922, and 2.55 in. less than in 1927. The 1912 flood was caused by a series of six storms of the "southwestern" type, the best rain producers, as stated previously, for the Middle and Lower Mississippi Basins. These six storms were separated by intervals of only a few days, a period entirely too short to check the rate of rise materially, and another inch or so of water from the storms would probably have resulted in a flood as great as that of 1922 had the levees remained intact. It should be stated, also, that during the flood of 1912 neither the Upper Mississippi, Arkansas, nor Red Rivers was in severe flood.

In the floods of 1882, 1903, and 1913, the total quantities of water, January to March, inclusive, were 7.68, 6.11, and 6.44 in., respectively. These figures appear to justify the assumption, partly at least, that a water cover over the Mississippi Basin of about 10 in. in 3 or 4 months between January and April, will probably result in a great flood from Cairo southward, and that under the most favorable conditions for flood formation, a somewhat less amount will answer.

All data thus far given have been based upon precipitation and water depth over the entire Mississippi Basin, although it is a recognized fact that the Missouri River above the mouth of the Platte, and the Mississippi River above the mouth of the Wisconsin do not contribute materially to Lower Mississippi floods. If these upper areas, amounting to approximately one-third of the total drainage, were to be excluded, the precipitation over the remaining two-thirds would have amounted to 16.28 in. of water over the latter area in 1927, whereas in 1922 the total water depth was 13.70 in., 2.58 in. less than in 1927. If the data for the last two weeks in December, 1921, and 1926, were included, the 1927 excess would be still larger.

Possible Maximum Flood Crests in 1927

A question frequently asked the U. S. Engineer Corps and the Weather Bureau was this: What would have been the maximum crests reached during the flood of 1927 had all the main levees remained unbroken? Each organization considered the question independently and by somewhat different methods, and opportunity was afforded to make informal comparison of the Weather Bureau figures with those of the Engineer Corps in Washington.

It is gratifying to be able to state that differences in the two groups of figures were insignificant. The stages reached at key stations and the estimated possible stages under most favorable conditions are given in Table 11.

TABLE 11.—ACTUAL AND POSSIBLE CREST STAGES, FLOOD OF 1927.

Station.	River.	Flood stage, in feet.	Crest, 1927, in feet.	Possible stage, 1927, in feet.	Difference, in feet.
St. Louis, Mo.	Mississippi	30	36.1	36.1	0.00
Paducah, Ky.	Ohio	43	47.2	48.0	+0.08
Cairo, Ill.	Ohio	45	56.4	57.7-58.0	+1.3—+1.6
Memphis, Tenn.	Mississippi	35	46.0	47.2-47.5	+1.2—+1.5
Helena, Ark.	Mississippi	44	56.8	58.2-58.5	+1.4—+1.7
Arkansas City, Ark.	Mississippi	48	60.5	68.5-69.0	+8.0—8.5
Greenville, Miss.	Mississippi	42	54.7	61.5-62.0	+6.8—7.3
Vicksburg, Miss.	Mississippi	45	58.7	64.5-65.0	+5.8—6.3
Natchez, Miss.	Mississippi	46	56.5	64.5-65.0	+8.0—8.5
Baton Rouge, La.	Mississippi	35	47.8	54.5-55.0	+6.7—7.2
New Orleans, La.	Mississippi	17	21.0	27.2-27.7	+6.2—6.7

The processes of reasoning through which the figures in Table 11 were evolved were basically alike, and perhaps a single example will suffice to illustrate them.

At Cairo the crest stage of 56.4 ft. occurred on April 20. The crevasse at Dorena, Mo., on the right bank, 30 miles below Cairo, occurred at 4:00 A. M., April 16, and after that time the river at Cairo rose only 0.7 ft., notwithstanding the fact that the Mississippi River at St. Louis was at a stage of 34 ft., or 4 ft. above the flood stage, and continued to rise steadily for a week thereafter. The Ohio River, at Paducah, Ky., also continued to rise for a few days after the crevasse. The rises at St. Louis and Paducah after the Dorena crevasse were about 2.0 and 0.9 ft., respectively, with an increase of only 0.7 ft. on the Cairo gauge. It is apparent, therefore, that if the crevasse had not occurred at Dorena, and making the usual allowance for the additional rise that would ordinarily have resulted from the high stage at St. Louis, the crest stage at Cairo would have been approximately 58 ft. about, but not after, the end of April. Incidentally, with the stages at Cairo and St. Louis as they were on the morning of April 16, and no crevasse at Dorena, but with the Upper Ohio in flood equal to that of March, 1913, the crest stage at Cairo would probably have approximated 62 ft.

Finally, it is within the bounds of possibility that the indicated stages in Table 11 could be exceeded. It can be shown, for instance, that stages of 65 ft. at Cairo, and of 73 ft. at Arkansas City, are not entirely removed beyond the limits of possibility under the most favorable conditions of precipitation distribution and synchronization. However, the probability is so very remote that its complete realization can perhaps be disregarded, as the sequences of the proper meteorological combinations that would be necessary to produce the extreme conditions as computed, while not absolutely impossible, are almost beyond belief.

RUN-OFF CHARACTERISTICS OF THE MISSISSIPPI RIVER DRAINAGE BASIN

By Nathan C. Grover,* M. Am. Soc. C. E.

Flood problems in general can be presented most satisfactorily to engineers and the interested public in the simple terms of quantities of water and capacities of channel. In such simple terms the flood problems of the Mississippi may be said to consist in determining the quantities of water to be expected in various stretches of the river and in making ample provision in channel and temporary storage capacities for conveying those quantities to the Gulf. If these problems are to be thus set forth, it is necessary that reliable continuous records of discharge be collected for the critical stretches of the Mississippi River below Cairo, Ill., and for its major tributaries. Unfortunately, such records, covering the crests of floods and showing the possibilities of their synchronization, have not been made, and this basic information is, therefore, not now available.

A few approximate figures may serve to make the situation clearer. A typical flood at Cairo, consisting of the combined discharges of the Ohio River and of the Mississippi River above the Ohio, is 2 000 000 cu. ft. per sec., more or less. The tributaries below Cairo may add to such a flood enormous quantities of water, amounting in 1927 to more than 1 500 000 cu. ft. per sec., according to the best estimates that have been available to the writer, making an apparent flood discharge of more than 3 500 000 cu. ft. per sec. for which channel and storage capacities must be provided so far as they do not already exist. The maximum capacity of the channel at New Orleans, La., with the levees intact is about 1 500 000 cu. ft. per sec. Any satisfactory plan of flood control must afford the means for handling the water in the lower river in excess of the channel capacity at New Orleans by providing either additional channels to the Gulf, definitely set aside for that purpose, or sufficient lateral storage capacity to detain the excess water until it can be discharged through present recognized channels, or, more probably, channel capacities to carry the major part of the floods and supplementary lateral storage to take care of the remainder.

The writer does not wish to be understood as stating that the discharge of the Mississippi in 1927 reached in any stretch at any time the enormous total of 3 500 000 cu. ft. per sec.; some channel and lateral storage had been left available to the river, many crevasses were made whereby the river re-occupied its natural lateral basins that had been closed by levees, and there was a great quantity of water that broke through the artificial barriers that had been constructed, and re-occupied the natural channels across the delta to the Gulf, all of which, by returning in part to Nature's plan, tended to decrease the crest discharges in the lower river, which have been aggravated

* Chf. Hydr. Engr., U. S. Geological Survey, Washington, D. C.

by the very works designed to control them. In spite of these mitigating conditions, however, the waters in this flood covered nearly 20 000 sq. miles, situated in seven States, an area approximately equal to that of New Hampshire and Vermont combined.

A comparison of the Mississippi with other great rivers of the Continent will serve to emphasize the magnitude of the quantities of water to be controlled in a Mississippi flood. Available estimates indicate that the total run-off in a great flood of the Mississippi, covering a period of six months or more, may exceed 500 000 000 acre-ft.—a quantity equal to the average annual run-off of that river or to the total run-off of either the Columbia or the St. Lawrence for three years, or of the Colorado for more than thirty years. The seven largest reservoirs constructed by the U. S. Bureau of Reclamation in the Western States have an aggregate capacity of 7 280 000 acre-ft., or about 1½% of the estimated 500 000 000 acre-ft. in a single Mississippi River flood. The proposed Boulder Canyon Dam, with a capacity of about 25 000 000 acre-ft., would store the total run-off of the Colorado for nearly 1½ years, and yet this capacity, great as it is, is equivalent to only 5% of the run-off in a single flood of the Mississippi.

The area from which the water of the Mississippi is derived, aggregating 1 240 000 sq. miles, is widely diversified in topography, geology, vegetation, and climate. It constitutes the great central basin of the country, extending from the crest of the Alleghanies to the crest of the Rockies and from the Great Lakes to the Gulf of Mexico, and includes mountains and plains, forests and grasslands, fields that are cropped annually, and remnants of the great public range. This great area includes all or parts of 31 States and of 2 Provinces of Canada, and is equivalent to nearly 41% of the area of the Continental United States. It is pre-eminently a great food-producing region and contains about 42% of the population and 39% of the wealth of the country. No other river basin on the globe combines topography, soil, and climate to make attractive living conditions for so many people as that of the Mississippi. It has within its borders many cities, railroads, highways, and farms with artificial or modified drainage conditions. These works of Man, which have certainly affected the rate and probably the total quantity of discharge of the Mississippi, cannot be decreased, however desirable it might be in the interest of flood control to restore the basin to the conditions of Nature. In fact, to restore it to such conditions would eliminate the need for flood control, because no one would be there to be damaged. Rather, it is certain that such works will be continually increased with the growth in population, industry, transportation, and wealth of the country. It may be possible, however, to improve present conditions by a reasonable program of forestation and by the construction of reservoirs in head-water streams, but, in the writer's opinion, it is vain to hope for a material reduction of the flood flows of the Lower Mississippi by such methods. Although it is recognized that vegetation, including forests, affects run-off and that reservoirs on head-water tributaries may be operated so as to decrease in a small way the floods in the lower

river, the quantities of water in a Mississippi flood are so great that these two influences, which will always be considered beneficent, can probably never have a major effect and at most can only add some small amount to a reasonable factor of safety which should be contained in any plan of flood control.

The Mississippi above the mouth of the Missouri and the four principal tributaries—the Missouri, Ohio, Arkansas, and Red—drain 96% of the total area of the Mississippi Basin. There are gauging stations which will yield continuous and reliable records at all stages of discharge from about 86% of the area drained by rivers above Cairo. Below Cairo, however, the run-off from only 18% is fully measured, and this 18% does not include any appreciable part of the valley that is subject to torrential rains.

There are several long-time records of the stage of the Mississippi between Cairo and the Gulf, and many measurements of discharge have been made by current meters and floats whereby some of the gauges have been fairly well rated for conditions of unbreached levees. There are, however, in this part of the basin no records of stage that can be satisfactorily converted to records of discharge for the varying conditions of slope and of flow through lateral flood channels resulting from crevasses. In other words, there are no reliable records of crest discharge of either the main river, or of its tributaries below Cairo, and the existing voluminous records are scattered through hundreds of reports, in part out of print, and are too lacking in adequate analysis, interpretation, and co-ordination to be reasonably usable.

The eastern and northern tributaries drain regions of moderate precipitation that accumulates in part during the winter in the form of snow and ice, which thus form the source of the characteristic spring freshets that occur when the rising temperatures release the water. The head-water feeders of the southern, western, and northwestern tributaries drain large regions of semi-aridity, in which the precipitation decreases gradually toward the west. More than one-third of the basin of the Mississippi lies west of the 100th Meridian which passes through the middle of the Dakotas, Nebraska, and Kansas. This part yields considerably less than 5% of the water of any flood. By contrast, the Ohio, draining 17% of the basin, may yield 50% or more of a Mississippi flood, and the lower basins of the southern tributaries and the lower valley of the Mississippi itself, which are subject to heavy rains that may occur in any month with the intensity of cloudbursts, yielding several inches of rain in 24 hours, may furnish a considerable and critical part of the flood waters.

An illustration of the differences in run-off between the humid and dry parts of the western and southern tributaries is afforded by the recorded run-off of the Missouri River for the year October 1, 1925, to September 30, 1926, at Leavenworth, Kans., and at Boonville, Mo. At Leavenworth, with a drainage area of 428 000 sq. miles, the run-off was 26 400 000 acre-ft.; at Boonville, with a drainage area of 508 000 sq. miles, or only 20% more than that at Leavenworth, the run-off was 40 900 000 acre-ft., or nearly 55% more.

The foundation or base of every great flood in the Mississippi comes from the Ohio. Starting with at least a reasonably large flood in the Ohio, the

building up of a great Mississippi flood depends on the synchronizing of that flood with floods from other tributaries as the crest progresses toward the Gulf. The peaks of the Ohio floods generally pass into the Mississippi between January 1 and May 31. They frequently join with high water from the Upper Mississippi at Cairo, as the records of stages at St. Louis show that April, May, June, and July are the months in which crest stages generally occur at that place. Fortunately, however, for floods at Cairo, the crest stages from the Ohio are generally ahead of the crest stages from the Upper Mississippi, but as crest stages may occur in either river in April and May, there is a possibility that in some years the crests of an early flood from the Upper Mississippi and a late flood from the Ohio may reach Cairo simultaneously. Nevertheless, it is probable that the climatic conditions that cause early floods on the Upper Mississippi also cause them on the Ohio—in other words, that climatic conditions make the possibility of a combination of crests of floods from the two rivers at Cairo rather remote.

If there were no influx of flood waters below Cairo, the flood problems of the Lower Mississippi would probably be relatively simple, because the natural channel and flood-plain storage would so flatten the crests of the floods passing Cairo as to permit the water to pass without causing damage through those stretches of channel in the lower river that have smaller capacities than the channel just below the mouth of the Ohio.

The yield of the lower tributary basins and especially of the parts of those basins that lie within 200 miles on either side of the Mississippi, in the path of the big storms, is, therefore, of great importance in any study of floods, and it is just this part of the run-off that is largely unknown. The contribution of the lower part of the basin to the disastrous floods of the Mississippi is caused exclusively by heavy rains that occur most frequently from October to March, but that come occasionally in the late spring and early summer. The rate of local run-off is dependent on the magnitude and intensity of the precipitation over this southern part of the basin. The probability of floods in the Ohio synchronizing with floods in the lower tributaries of the Mississippi appears, therefore, to be much greater than that of floods in the Ohio synchronizing with floods in the Upper Mississippi.

The floods of the Mississippi are thus caused in the first instance by floods in the Ohio to which melting snows in the head-water tributaries contribute, but with which must be combined high water from the Mississippi above Cairo or floods in the southern tributaries due to heavy rains over broad areas of the lower basin, or by some combination of these conditions. The combination of climatic conditions that produces floods has occurred periodically for countless ages and will be repeated again and again as years go by, and floods will surely recur with those conditions. De Soto experienced a great flood when he visited the Mississippi, but it caused no great damage because there was little to be damaged. Future floods may be no greater than that of De Soto's time, but if they are uncontrolled they will be increasingly destructive in lives and property as the use of the great flood-plains of the delta increases.

The flood-plains of the Mississippi and its delta have been built by its floods. The lands that are now protected by levees from overflow owe their very existence to floods. The process of valley and delta building involves periodic inundation and the deposition of silt. River channels through the flood-plains and delta do not normally have sufficient capacities to carry within their banks the floods that occur. A change from this fundamental condition of overtopped banks and temporary lateral storage of water is, therefore, man-made and represents a radical departure from the natural processes of a silt-bearing river that is constantly building its delta. It must be recognized that such an artificial change in the regimen of a great river is always attended by difficulties and dangers and that to be adequate, it must be on a scale commensurate with that of the natural forces.

In Nature's process of flood-plain building, a Mississippi flood, after leaving Cairo, would normally spread out over several thousand square miles of bottomland included in the St. Francis, Tensas, Yazoo, and other basins, and would be drained therefrom over a period of several months at a fairly uniform but lesser rate than the maximum inflow to those basins. Consequently, the channels leading from the basins to the Gulf would be formed with smaller capacities than the channels discharging water into the basins. So long as the great overflow basins were available for temporary storage of excess flood waters, the smaller channel capacities across the lower delta were ample. As Man has gradually shut off these natural regulating basins by building levees, thereby depriving the river of their effects in equalizing flow, the floods below the basins have inevitably increased in magnitude, and greater channel capacities have been required. Available records of stage show clearly this situation, which should have been expected as surely as increased fluctuations in the stage and discharge of the St. Lawrence would follow if river channels were to be constructed through the Great Lakes so as to eliminate the equalizing effects afforded by the natural storage of those wonderful natural basins.

The run-off characteristics of the Mississippi Basin above Cairo are fairly well known and are not being changed radically by man, but those below Cairo have been and are being gradually changed with progress in the construction of levees, and there are no satisfactory records of the resulting changes in crest rates of discharge. The run-off characteristics will continue, of course, to change until stability has been reached in a system of levees, spillways, and overflow basins that will carry uniformly the successive floods of the river.

Students of hydrology have long realized that a flood like that of 1927 was inevitable. They know, too, that similar and even larger floods will occur in the future. To the end that the magnitude and periodicity of these certain great floods may be known within reasonable limits of error, it is necessary that the yield of water by the tributaries shall be definitely known over a period of years, not only in total quantities, but in distribution throughout the year and in variations from year to year. On no other basis can satisfactory forecasts of future floods be made as a necessary first step in designing control works.

The re-occupation of leveed basins and the breaking of barriers to natural overflow channels to the Gulf cannot, of course, be longer left to chance, but such capacities of channels and overflow basins must be provided in advance of flood as to remove the danger of disastrous breaks in levees. It may be stated, as a self-evident truth, that the nearer the methods of flood control conform to Nature's way the less will be the difficulty in maintaining the control works, and, conversely, the greater the departure from Nature's way the stronger will be the tendency for the river to return to natural conditions and the more difficult will be the maintenance of these works.

It is the writer's opinion that an adequate determination of the necessary channel and storage capacities can be made only on the basis of reliable estimates of the quantities of water for which provision must be made in the several stretches of the river, and such estimates must rest on continuous reliable records of discharge. Similarly, the problem of selecting the best locations for temporary storage of the flood waters in lateral basins and the most practicable auxiliary channels to the Gulf cannot be intelligently studied or correctly solved until the area subject to floods has been topographically mapped. As less than 8% of this area is now mapped, the problem is, indeed, difficult.

It is fortunate that the same records and maps will serve as a basis for both flood control and general development. The problems arising in connection with the utilization and administration of surface waters in the Mississippi Valley are constantly increasing. The best solution of many of these problems can be reached only on the basis of adequate data in regard to quantities of run-off and its distribution with respect to both time and drainage areas. As utilization progresses, these data are becoming more essential and are increasingly in demand by a wide range of users, including Federal, State, and municipal officials, corporations, and individuals. Definite plans for flood-control works and for important structures to utilize rivers, or to be built on their banks or flood-plains, should not, in the interest of safety and economy, be adopted in the absence of adequate hydraulic investigations and hydrologic data, or of complete topographic maps.

The many failures of enterprises developed on the basis of insufficient records of water supply show conclusively that it is unsafe to proceed with developments involving the use of rivers except on the assurance afforded by adequate records of discharge. That estimates of water supply made from records of rainfall and comparisons of drainage areas may be unreliable and misleading has been demonstrated repeatedly, and the Mississippi Valley is no exception to the general rule. The wise development of this valley must rest on adequate data in regard to the discharge of its many rivers. Because of the diversity of interests, of which flood control is doubtless the most pressing, and the complexity and interrelation of the many problems involved, provision should be made for the collection of these necessary data on a continuing basis, and for their analysis, correlation, and publication promptly, in order that they may be available for use by engineers and the public.

The floods of the Mississippi affect the development and prosperity of a region that is of major importance, not only to the United States, but to the world. As population increases and development progresses, the resources of this vast region must ultimately be completely utilized in the production of foodstuffs and textile raw materials needed by the world. Whatever effects the levees and other works for controlling floods may have on the run-off characteristics of any part of the basin, the control must be accomplished in the interest, not only of the flooded regions, or the entire Mississippi Basin, but of the whole country. Full justice cannot be done if the situation is approached with a narrow-angle view and near-sighted vision.

THE WORK OF THE MISSISSIPPI RIVER COMMISSION

By C. W. Kutz,* M. Am. Soc. C. E.

The Mississippi River Commission was created by an Act of Congress approved June 28, 1879. It consists of seven Commissioners, three of whom are selected from the Corps of Engineers, U. S. Army; one from the U. S. Coast and Geodetic Survey; and three from civil life, two of whom must be civil engineers.

The basic law required the Commission to "mature a plan or plans as will correct, permanently locate and deepen the channel, and protect the banks of the Mississippi River; improve and give safety and care to the navigation thereof; prevent destructive floods; promote and facilitate commerce, trade and the postal service."

It also called for a report in full on the practicability, feasibility, and probable cost of the various plans known as the jetty system, the levee system, and the outlet system, as well as on such others as the Commission deemed necessary. Before presenting the conclusions of the Commission as embodied in its first report, it seems desirable to describe briefly the physical characteristics of the Lower Mississippi Valley and the work that had been done prior to the creation of the Commission and, particularly, to refer to the prior Federal investigations and surveys, as on the results of those studies the plan of the Commission was largely based.

Physical Characteristics

The Mississippi River and its tributaries drain an area of 1 240 000 sq. miles, including all or portions of 31 States and about 20 000 sq. miles of Canada.

The natural divisions of the basin are as shown in Table 12.

TABLE 12.—Divisions of the Mississippi Basin.

Designation.	Area, in square miles.	Ratio to entire basin.
Upper Mississippi Basin	165 900	0.13
Missouri Basin	527 100	0.43
Ohio Basin	201 700	0.16
Arkansas Basin	186 300	0.15
Red Basin	90 000	0.07
Central Valley	69 000	0.06
Total	1 240 000	1.00

The alluvial valley, with which the Commission is chiefly concerned, begins at Cape Girardeau, Mo., 52 miles above Cairo, Ill. This flood-plain of alluvial deposit varies in width from 20 miles just north of Natchez to 80

* Colonel, Corps of Engrs., U. S. A., Honolulu, Hawaii.

miles at Greenville, Miss., the average width above Plaquemine, La., being 45 miles. Below Plaquemine it spreads out into a broad delta, the general shape of which is a semi-circle having a radius of about 80 miles.

Through this valley the river winds its way to the Gulf, generally following the bluffs on the east from the mouth of the Ohio to Memphis, Tenn., touching the west bluffs at Helena, Ark., and hugging the east bluffs closely from Vicksburg, Miss., to Baton Rouge, La. The air-line distance from Cape Girardeau to Head of the Passes is about 600 miles; the river distance, 1 102 miles.

The river flows in a well-defined but unstable channel, the natural banks of which are from 3 to 12 ft. above the general level of the plain. These banks are highest nearest the river and have an average slope away from the river of 7 ft. per mile in the first mile. The river is constantly eroding its banks in unprotected bends and forming new land on points. This caving is accentuated in many places by an underlying strata of sand which washes out and causes the bank to fall by its own weight as the river subsides.

Above the mouth of Red River on the right bank, and above Baton Rouge on the left bank, the drainage of the valley finds its way into the river through tributaries. Below these points the drainage is carried away from the river and into the Gulf of Mexico through numerous bayous and streams.

The minimum measured discharge of the river at Columbus, Ky., below the mouth of the Ohio, is 71 000 sec-ft.—the maximum at this point, 2 015 000 sec-ft. having occurred in 1912. The carrying capacity of the natural channel at bank-full stage is about 1 000 000 sec-ft.

The building of levees on the banks of the Mississippi River began with the first settlements in the lower alluvial valley (as early as 1717), and as a measure of economy they were built on the highest ground, that is, near the river bank. The extension of levees kept pace with the establishment and growth of settlements along the lower river, each planter being required to complete the levee along his own river-front. In 1812, when Louisiana was admitted to the Union, the levees extended on both sides of the river, to Baton Rouge on the left bank and to Point Coupee on the right bank. By 1844, they were almost continuous from 20 miles below New Orleans to the mouth of the Arkansas River on the right bank and to Baton Rouge on the left bank.

The floods of 1849 and 1850 caused widespread damage in the valley. National interest was aroused and, in response to a plea for Federal aid, the Swamp Land Act was passed in 1850. By this Act the Federal Government granted to the several States in the Lower Mississippi Valley all unsold swamp lands and overflowed lands within their limits to provide funds to reclaim the districts subject to overflow. The States of Louisiana, Mississippi, Arkansas, and Missouri organized offices for the sale of swamp lands and appointed Commissioners for the location and construction of levees. Due, however, to differences in laws governing levee construction, to differences between counties and parishes within a State, and to a total lack of co-ordination and co-operation, but little effective protection was secured from the proceeds of the sale.

In the same year, Congress appropriated $50 000 "for a topographical and hydrographical survey of the delta of the Mississippi with such investigations as may lead to determine the most practical plan for securing it from inundation * * *". This work was placed in charge of Capt. A. A. Humphreys, Corps of Engineers, U. S. A. Field work was started in 1851, but suspended in the fall of that year until 1857 when it was resumed by Lieut. Henry L. Abbot, Corps of Engineers, U. S. A., who had been detailed as Assistant to Captain Humphreys. The final report on this survey was submitted jointly by these officers in 1861.*

This report, which is very comprehensive, discusses, as plans for protection, a system of cut-offs, the diversion of tributaries, a system of head-water reservoirs, and a system of outlets as alternatives for levees. Its conclusions were that no advantage could be derived from diverting tributaries or constructing reservoirs, that the plan of cut-offs and new or enlarged outlets to the Gulf were too costly and too dangerous to be attempted, and that levees could be relied upon for protecting all the alluvial bottom-lands liable to inundation below Cape Girardeau. It noted, however, the possibility of reducing levee heights near Lake Providence, La., by constructing near that town an outlet leading to Bayou Tensas and the Black River, but its approval of this alternative was conditional upon further investigation.

The Humphreys and Abbot investigation included measurements for the determination of the quantity of sediment in suspension in Mississippi River water. These observations were begun at Carrollton, La., in 1851, and continued for two years, and the results, combined with similar measurements made by other agencies, led to the following conclusions:

(*a*) "* * * the Mississippi water is not charged to its maximum capacity with sediment; * * * A most important practical deduction may be drawn from this fact, namely, the error of the popular idea that a slight artificial retardation of the current, that caused by a crevasse, for instance, must produce a deposit in the channel of the river below it.

(*b*) "* * * the sediment of the Mississippi is to the water, by weight, nearly as 1 to 1 500, and by bulk, nearly as 1 to 2 900; provided long periods of time be considered. * * * and if the mean annual discharge of the Mississippi proper be correctly assumed at 19 500 000 000 000 cubic feet, it follows that * * * sedimentary matter, constituting one square mile of deposit 241 feet in depth are yearly transported in a state of suspension into the gulf.

(*c*) "Besides the amount held in suspension, the Mississippi pushes along into the gulf large quantities of earthy matter.

"No exact measurement of the amount of the annual contributions to the gulf from this source can be made, but from the yearly rate of progress of the bars into the gulf * * * it appears to be * * * which would cover a square mile about 27 feet deep.

"The total yearly contributions from the river to the gulf amount, then, to a prism 268 feet in height, with a base of one square mile. * * *"

The next milestone in the history of the Lower Mississippi was an Act of Congress (1874) appointing a Joint Civil and Military Commission to make a full report upon the best system of permanent reclamation and redemption of the alluvial valley from inundation. The report of this Board, submitted in

* "Report upon the Physics and Hydraulics of the Mississippi River," 1861.

1875, was based upon the results of the Humphreys and Abbot survey, and upon additional data secured subsequent thereto. Its conclusions were: "No practicable aid can be derived from any diversion of tributaries or by artificial reservoirs; that cut-offs are very pernicious and that outlets, though correct in theory, find no useful application to the Mississippi". A general system of levees was recommended.

The Mississippi River Commission was created four years later. In its first report to the Secretary of War (1880), it advocated as the best means of securing the needed improvement in its navigation, a plan which would concentrate, rather than disperse, the waters of the river. In this report it also condemned the outlet system as a means of flood control, expressing the belief that "no surer method of ultimately raising the flood surface of the river can be adopted than by making lateral outlets for escape of its flood waters."

Asserting that the bad navigation of the river was produced by the caving and erosion of its banks, the excessive widths, and the bars and shoals resulting directly therefrom, it proposed to narrow the river, where too wide, by contraction works and to protect the caving banks by bank revetment. This was assumed by the Commission to be the plan referred to in the Act as the "Jetty System". As a means of protection against floods, it recommended levees as essential to prevent destruction to life and property by overflow. The Commission was not agreed as to the value of levees as an auxiliary to a plan of channel improvement.

The first appropriation for the improvement of the Mississippi River in accordance with the plans of the Commission was made in March, 1881, and work continued for several years, but several facts were soon developed, namely, that the light contraction works originally designed were much too weak; that the cost of the improvement would be much greater than had been originally estimated; that one of the first results of contraction work was to increase bank caving; and that generally bank revetment was of greater relative importance than had at first been considered.

The work was interrupted in 1885 by a legislative proviso that no works of bank protection or revetment should be executed until it was found that permeable contraction works would not secure the desired stability of the river banks. This prohibitive clause was not revoked until late in 1888 so that four successive working seasons were practically lost. After that date, bank protection became of prime importance, contraction works being restricted to the repair and completion of work under way.

Although the Commission in its report of 1880 had recommended levees as a means of protection against floods, Congress was then unwilling to expend Government funds in protecting the land of private owners, for the first Appropriation Act contained the following proviso:

"That no portion of the sum hereby appropriated shall be used in the repair or construction of levees for the purpose of preventing injury to land by overflow or for any other purpose whatever except as a means of deepening or improving the channel of said river."

In taking this position Congress was apparently influenced by the fact that in 1850 it had, through the passage of the Swamp Land Act, conveyed to the States a free title to all the unsold swamp and overflow lands in the delta basin with the understanding that they would be sold and the proceeds used to protect them against overflow. In the Appropriation Act of 1882 it was again provided:

"That no part of this appropriation shall be expended for repair or to build levees for the purpose of reclaiming land or preventing injury to land by overflows; provided that the Commission is authorized to repair and build levees if in its judgment it should be done as a part of its plan to afford ease and safety to the navigation and commerce on the river and to deepen the channel."

Under the strict prohibitive clause in the Act of 1881 no part of the appropriation was allotted to levees. Under the Act of 1882 which gave somewhat wider discretion to the Commission, a large part of the appropriation was allotted to levee construction. From that time on the policy of allotting money for levee purposes was followed, but it was not until 1890 that the prohibitive clause was removed.

From 1890 to 1917, the periodic appropriations made by law for expenditure by the Commission were divided between levees, revetments, and dredging, but the work on the levees was looked upon as an adjunct to river improvement. It was not until the Flood Control Act of 1917, that flood control became by law as definitely a part of the Commission's work as is river improvement. That Act provided for co-operation by local interests, they to provide the necessary right of way and to pay not less than one-third of the cost of levee construction, and to assume the entire cost of maintenance after completion. The cost of river improvement (revetment and dredging) was to be paid for entirely out of Federal funds.

Considered as an adjunct to river improvement, it was natural that levees should be placed fairly close to the bank. This placed them on the highest ground, thereby reducing their cost, it prevented cross-currents and consequent fill within the river banks during flood, to the detriment of the low-water channel, and helped to stabilize the main channel of the river. Even from a flood-control standpoint there is much to be said in favor of placing the levee line fairly close to the river bank.

Levees

The levee section of 1882 was a modest earth embankment with an 8-ft. crown and slopes of 1 on 3, with practically no free-board above the flood of that year. At Lake Providence this resulted in a section that contained 161 sq. ft., or 31 000 cu. yd. per mile. As the levee lines were extended and the flood flows more and more confined, it became necessary to raise the levee grade and correspondingly increase the section so that, in 1896, there was at Lake Providence a cross-sectional area of 530 sq. ft. and a yardage of 103 000 per mile, and, in 1914, a cross-sectional area of 2 158 sq. ft. and a yardage of 422 000 per mile.

This gradual building upward, toward the levee grade required to confine a given flood completely, is believed to be responsible for the widespread fallacy that when a sedimentary stream like the Mississippi is confined between levees, levee grades must be steadily raised to keep pace with a rise in the river bed. In some instances it has been asserted that the bed of the Mississippi River, due to the levees, has risen until it is above the surrounding country. This view, that there has been a marked change in the elevation of the river bed, is not borne out by the results of surveys made at many different points over a long term of years.

In 1924, a study was made of a reach of the river along the Lower St. Francis Basin in Missouri and Arkansas. This basin has a river frontage of 236 miles, from New Madrid, Mo., to Helena, Ark. The construction of modern levee systems in that section was not begun until 1893, except for about 60 miles on the east bank of the river. The period considered was from 1882 to 1921, inclusive, a period extending from no levees to complete levees. The low-water troughs of each year passing the gauges in the reach were tabulated to show the elevations of such troughs at the various gauges, all of which had been established prior to 1882 and had been read regularly since that date. This comparison showed a decided lowering of the low-water plane.

Recently, more than 2 000 measured cross-sections at different points on the river were compared to show the changes that had occurred between early surveys and those of recent years, and the results show uniformly a moderate but well-defined increase in width, depth, and cross-sectional area. It is a well-recognized fact that Mississippi River bars do build up on a rising river and scour out on a falling river, but these are seasonal changes and the effects are not permanent. Bars also travel down stream, diminishing the depth on one section and increasing it on another; but there is no evidence whatever in the records of the Mississippi River Commission to support the view that the bed of the river is being raised due to the construction of levees.

Prior to the flood of 1927 the major flood of record was that of 1912, and, as a result of that flood, the Commission established levee grade lines along the main river computed to be high enough to contain with a 3-ft. free-board a flood of equal magnitude. At the same time it established new standard levee sections defined as follows:

"Levee: Crown to be 8 ft. wide—reduced to 6 ft. above mouth of Missouri River; front slope to be 1 on 3 to intersection with natural ground (or bottom of old borrow-pits where enlargements have thrown the toe of the levee so far forward); and back slope to be 1 on 3 to intersection with top of banquette, which will be from 5 to 8 ft. below the levee crown.

"Banquette: Top to be 20 ft. wide for levees from 10 to 13 ft. high, 30 ft. wide for levees from 13 to 16 ft. high, and 40 ft. wide for levees exceeding 16 ft. in height; top to have slope of 1 on 10 away from the levee; and rear slope to be 1 on 4 to intersection with natural ground. In cases of extreme height —crossing sloughs or bayous—a false berm may be required beyond the rear slope of the banquette."

Subsequently, slight modifications were authorized by the Commission in both grade and section but, generally speaking, both were substantially unchanged at the time of the flood of 1927. Although work had been in progress

for thirteen years, two more years would have been required for completion of the levee project at the rate at which funds were being appropriated.

The Annual Report of the Commission for 1927 shows a total expenditure to date for levees by the United States from Federal funds of $71 000 000 and an expenditure by the United States from funds contributed by local levee districts of $15 000 000. In addition to this expenditure of $86 000 000 by the United States, State and local organizations, prior to and since the creation of the Mississippi River Commission, expended approximately $152 000 000 on levees and in expenses incident thereto, such as rights of way, repair work, high-water expenses, etc. This combined expenditure of $238 000 000 is represented by 1 880 miles of levees containing approximately 500 000 000 cu. yd. of material. This shows an expenditure of slightly less than 50 cents per cu. yd. of material now in the levees; the difference between this and actual cost per cubic yard being represented by lost or abandoned levees, by expenses for maintenance and repair, and by the cost of closing crevasses and fighting floods.

When Commission reports are consulted, progress toward completion of the 1914 levee project seems slow and the amount of levee lost or abandoned seems large. One reason for the rate of progress lies in the fact that the Commission's jurisdiction on tributaries has been gradually extended, so that, while in 1918 the estimated final contents of the levee line was 473 000 000 cu. yd., in 1927 it was 534 000 000 cu. yd., although no change in grade or section had been made.

In six years, from 1918 to 1924, the lost or abandoned yardage amounted to 15 800 000, about 0.7% per annum of the average annual contents of the system. The losses have been due partly to the necessity of abandoning old lines where threatened by caving banks and partly to changes in alignment in order to secure better foundations. The caving of banks is much the greater cause of losses, and bank revetment is the only remedy for this evil.

Bank Revetment

A number of years ago it was estimated that, of the 2 000 miles of bank-line between Cairo and the Head of the Passes, more than 700 miles were in need of revetment. The funds available for such work, however, have never been sufficient to justify undertaking the work on a large scale or in a systematic manner. Each year it has been necessary to confine revetment work to cases of the most urgent necessity, such as threatened cut-offs or endangered levees that could be replaced only at excessive cost. Even if the work has of necessity been prosecuted in this haphazard manner there was in place, at the end of the fiscal year 1927, 128 miles of revetted bank.

The revetment in most common use is made of small willow trees from 2 to 6 in. in diameter and from 30 to 50 ft. long, which grow rapidly and in abundance on the sand-bars along the river. In the earlier forms, the revetment was composed of these small trees, laid diagonally, in two layers, and the mass was given a certain rigidity and strength by means of large "poles", below and above, tied together by galvanized wire. This type has given way to the

"fascine" mattress, composed of small bundles of young willows bound by galvanized wire. These fascines are placed side by side to make up the length of the mattress, and are held in position by being tied underneath by means of galvanized "sewing strands" running over and under the bundles to longitudinal cables. In the earlier forms of mattress, these fascines were made complete, and were bound in the circular form by short lengths of wire, before being placed in the mattress. In the present mattress, the two processes are combined. Longitudinal wire cables and larger trees or "poles" give the requisite strength and rigidity.

These mattresses are built on floating ways in lengths of 1 000 ft. and of varying widths depending upon the character of the bank to be revetted. The mattresses are sunk in position by stone dumped from barges. In certain places where rock was costly, concrete ballast blocks weighing about 65 lb. were used instead of rock.

A number of different types of reinforced concrete mattresses have also been used, one of them, developed in the Third Mississippi River Commission District, having been in use about five years. This type of revetment is fabricated in units 4 ft. wide by 25 ft. long and 3¾ in. thick, each unit consisting of 25 concrete slabs 1 ft. by 4 ft. by 3¾ in., reinforced and held together by wire reinforcement. These units are cast on deck barges and, as soon as the concrete has hardened sufficiently, a second layer is cast on top of the first, the layers being separated by heavy paper. These units are joined by cables into mattresses on floating launching ways and are sunk with their long side perpendicular to the bank. The willow mattresses are constructed with the long edge parallel to the bank. Since its inception this type of revetment has been improved by increasing the size and, therefore, the life of the reinforcement and by increasing the thickness of the slabs from 3 to 3¾ in., but sufficient time has not elapsed to determine fully the relative durability of concrete and willow mattresses. The concrete mattresses, being smaller in size and with the long axis perpendicular to the bank, more readily adjust themselves to inequalities in the river bank than the longitudinal willow mattresses and, furthermore, they are nearly 20% cheaper.

For certain reaches of the river this type of concrete revetment is believed to be too light. For use in such places experiments are in progress (1927) with a mattress composed of overlapping and interconnecting concrete slabs 4 in. thick, 6 ft. wide, and 11 ft. long.

Mattresses, whether of willow or concrete, protect only the under-water slope, extending out from the water line to about 50 ft. beyond the foot of the slope. Above the water line the bank is graded to a slope of 1 on 3 and paved with rip-rap stone, or concrete.

To the end of the last fiscal year (1926) the Commission had expended in new revetments, and in repairs and renewals, $61 000 000, an average of $475 000 per mile of effective revetment. In addition to its expenditures in levees and revetments, the Commission is maintaining and operating a fleet of dredges at an average annual expenditure of $600 000, in order to maintain a navigable depth of 9 ft. over bars during low-water periods.

As revetment work progresses the volume of material annually caved into the river will decrease, and it is anticipated that this will greatly improve the low-water channel and lessen expenditures for dredging.

The levee work is primarily in the interest of flood protection and, as was mentioned previously, is paid for in part by local interests. The dredging work is in the interest of navigation and, like most other navigation projects, is paid for wholly by the Federal Government.

The revetment work on the main river is essential to both flood protection and to navigation, but under existing law it is regarded as part of the navigation project and paid for wholly by the United States, except in one or two places where local levee districts have voluntarily paid for such work in order to supplement what the Commission was able to do.

In appraising the work of the Mississippi River Commission it should be borne in mind that it has been working toward a limited objective at a rate fixed by Congress. It was never assumed by the Commission, nor by Congress, that its plan would do more than protect against a flood equal to that of 1912. In working toward this limited objective it has many times been importuned to provide special relief for New Orleans by the construction of one or more spillways above or below the city so that it might be spared the expense of raising its wharves to a height compatible with the 1914 grade line established for the entire river. Such work the Commission has heretofore declined to undertake on the ground that the limited funds at its disposal should be used in giving a uniform measure of relief throughout the valley and that to divert $5 000 000 or $10 000 000 to the construction of spillways at or near New Orleans would be unfair to those levee districts the levees of which were still not up to the grade line of 1914.

Flood of 1927

The rainfall throughout the valley of the Mississippi River which caused the flood of 1927 was extraordinary in volume and in duration and it occurred at a time when the natural storage in the Mississippi itself and the storage basins contiguous to it in the delta were already well filled. The rainfall in Eastern Oklahoma, Western Arkansas, and Southern Missouri was unprecedently heavy and caused discharge from the Arkansas River almost as great as that of ordinary high water in the Mississippi itself.

It is difficult to compare the magnitude of different Mississippi river floods at a given point on the basis of maximum measured discharges alone, for at the same gauge height the discharge will vary widely due to differences in slope, and the slope, in turn, will depend upon the extent to which the river basin is filled and upon the rate of rise.

Columbus, Ky., 22 miles below the mouth of the Ohio River, at Cairo, is a gauging station, and discharge measurements made there or in that vicinity are available for each flood-year since 1892. As a check on the observed discharges it is customary to assemble the volume contributed by the Mississippi and the volumes contributed by the Ohio at Evansville, Ind., and its principal tributaries below that point. Table 13 shows the volume of discharge

(as scaled from rating curves) contributed by tributaries of the Ohio and by the Ohio River as a whole. The greatest discharge that occurred within a period of 3 to 6 days before the flood crested at Cairo was used for all stations. The discharge at the maximum recorded stage for each station is also given.

TABLE 13.—VOLUME OF WATER CONTRIBUTED BY OHIO RIVER AND ITS TRIBUTARIES, IN CUBIC FEET PER SECOND.

* This column obtained by summation of quantities shown in the preceding columns, and not by measurement.

In Table 14, the Ohio River contributions are added to those of the Mississippi at St. Louis and the total compared with the maximum observed discharge at Columbus, as well as with the discharge at Columbus as scaled from rating curves. For the Mississippi River contribution there was used the highest gauge reading which occurred at St. Louis within a period of 2 to 3 days before the flood crested at Columbus.

The sum of the discharges at St. Louis and from the Ohio River does not represent the total discharge at Columbus, because it does not include the run-off from the drainage basins of Meramec, Kaskaskia, and Big Muddy Rivers and a number of smaller streams.

Table 14 shows that the maximum observed discharge at Columbus in 1912 and 1913 was nearly 300 000 sec-ft. more than was measured in 1927, yet the maximum gauge reading in 1927 was 1.6 ft. higher than in 1913. These differences are believed to be due in part to differences in the shape of the flood crests and more particularly to an incomplete levee line in 1912 that induced a slope and velocity that were abnormal at the time the discharge was measured. The discharge at Columbus obtained by summation of the flow of contributing streams was 1 702 000 sec-ft. in 1912 and 1 614 000 sec-ft. in 1927. On the other hand, if dependence be placed in the rating curve, the 1927 flood exceeded the 1912 flood at Cairo by 67 000 sec-ft. In formulating plans for protection

against floods of the future, it will be conservative and on the side of safety to assume a discharge corresponding to a foot on the gauge at or near maximum stages, no greater than that shown by past floods. In the 1927 flood a foot on the gauge at and near the maximum stage corresponds on the average to a flow of 60 000 sec-ft., and, as no flood of the past shows a smaller average discharge, that ratio has been used by the Commission in its present plans and estimates.

1904	383 000	994 000	1 377 000	1 389 000	1 502 000†
1907	429 000	918 000	1 347 000	1 433 000	1 543 000
1912	592 000	1 110 000	1 702 000	1 733 000	2 015 000‡
1913	323 000	1 395 000	1 718 000	1 750 000	2 015 000§
1916	617 000	869 000	1 486 000	1 497 000	1 775 000
1917	285 000	994 000	1 279 000	1 362 000	1 420 000
1920	446 000	869 000	1 315 000	1 422 000	1 527 000
1922	311 000	1 137 000	1 448 000	1 520 000	1 501 000
1927	800 000	814 000	1 614 000	1 300 000	1 728 000‖

* Another measurement at same stage gave 1 434 000 sec-ft.

† Another measurement at about same stage gave 1 447 000 sec-ft.

‡ Measured at 48.5-ft. stage. At the maximum stage the discharge measured 1 854 000 sec-ft.

§ Mean of seven consecutive measurements was 1 959 000 sec-ft.

‖ Cairo gauge was 53.7 ft. at time of observation.

The maximum discharge past the latitude of Arkansas City in April, 1927, has been estimated at 2 662 000 sec-ft. This is 250 000 sec-ft. more than in 1912 and about 200 000 sec-ft. more than in 1916.

The estimated maximum outflow from the latitude of Old River was 2 350 000 sec-ft., about 300 000 sec-ft. less than at Arkansas City. If to this difference the flow of the Yazoo and the Red Rivers is added, a measure of the regulating influence of storage in the lower ends of the Yazoo and Tensas Basins, and in the river itself, is obtained.

Subsequent to the flood of 1927 the Commission was directed by the Secretary of War and Chief of Engineers, U. S. Army, to revise its plans to conform to the new conditions, and the Commission has submitted a report on that work to the Chief of Engineers. The writer will outline herein in a general way the nature of the problem and refer briefly to some of the methods considered.

As a basis for a new project, it was determined to set up a probable future maximum flow at Cairo. The discharge at Cairo in 1927 was approximately 1 800 000 sec-ft. In determining how much larger a flood should be provided for, consideration was given to the fact that if to the maximum discharge of the Mississippi at St. Louis there was added the maximum discharges of the

Wabash at Mt. Carmel, the Ohio at Evansville, the Cumberland at Nashville, and the Tennessee at Florence, the total would aggregate more than 3 000 000 sec-ft. If the maximum discharge of the Ohio and the maximum discharge of the Mississippi at Cairo were added, the total would be about 2 700 000 sec-ft. If to the estimated discharge of the 1927 flood (1 800 000 sec-ft.), there be added the difference in flow, at flood stages, of the Ohio in 1913 (maximum) and in 1927, the total will be 2 400 000 sec-ft.

TABLE 15.

Miles below Cairo, Ill.	Station.	New levee grade.	Existing levee grade.	Increase in levee heights, in feet.
0	Cairo, Ill.	70.4	58.0	12.4
22	Columbus, Ky.	64.7	52.7	12.0

273	Mhoon Landing, Miss.	60.1	50.0	10.1
307	Helena, Ark.	71.0	58.5	12.5
354	Sunflower Landing, Miss.	72.6	56.0	16.6
392	Mouth of White River.	78.4	61.9	16.5
437	Arkansas City, Ark.	79.5	60.5	19.0
480	Greenville, Miss.	72.8	55.8	17.0
543	Lake Providence, La.	69.1	53.7	15.4
602	Vicksburg, Miss.	72.0	58.0	14.0
662	St. Joseph, Mo.	68.7	54.0	14.7
706	Natchez, Miss.	72.7	57.5	15.2
773	Red River Landing, La.	69.5	57.5	12.0
807	Bayou Sara, La.	61.8	51.5	10.3
841	Baton Rouge, La.	57.9	48.1	9.8
862	Plaquemine, La.	52.1	43.7	8.4
894	Donaldsonville, La.	46.4	39.0	7.4
911	College Point, La.	40.6	34.4	6.2
965	Carrollton, La.	30.8	25.2	5.6
1 047	Fort Jackson, La.	14.4	11.0	3.4

All these combinations may be classed as "possibilities", but it does not seem probable that rainfall sufficient to produce such coincident floods will ever occur. In its determination of this question the Commission gave full consideration to the views of the local Weather Bureau meteorologist at Cairo and to the views of the Chief of the U. S. Weather Bureau. For the purposes of this paper it is proposed to assume 2 250 000 sec-ft. as the probable maximum flood of the future at Cairo. If the relation between gauge and discharge established in the 1927 flood were maintained, such a flood, confined by levees, would reach a stage of 65 ft. on the Cairo gauge. This assumed discharge is 25% greater than that of 1927, a factor of increase relatively much larger than that assumed in the Miami Conservancy project, when the relative magnitude of the two drainage areas is considered. If protection against such a flood were provided by levees alone, it would require an increase in levee heights as shown in Table 15.

This increase in levee height is based upon a 5-ft. free-board instead of the 3-ft. free-board heretofore used, a modification that was generally recommended by the engineers of local levee districts as a result of their experience with the 1927 flood. These levee engineers were also practically unanimous in recommending that the levee section be strengthened by flattening the

river-side slope from 1 on 3 to 1 on 4, by increasing the crown width from 8 to 12 ft., and by flattening the land-side slope so as to contain completely a saturation line of 1 on 7 springing from a point on the river-side slope 2 ft. vertically below the crown. The flattening of the river-side slope was advocated largely as a means of protection against wave wash. The increased free-board and increased width of crown were advocated as increased factors of safety and the flattening of the land-side slope was for the purpose of reducing seepage during long-continued high stages. To increase the levees to such heights and to increase the section as outlined would require an expenditure for main river levees alone of more than $500 000 000.

The Commission in revising its project, considered all the many methods that have been suggested as substitutes for or as adjuncts to a levee system. Many of them have been covered by other papers and to include herein a discussion of them would result in duplication. However, even at the risk of duplication it seems desirable to refer briefly to reservoirs and to spillways and outlets.

Reservoirs

High floods in the Mississippi, as far as records are available, have crested at Cairo between February 22 and May 9, except the flood of 1916. The flood wave at Vicksburg is much longer and flatter than at Cairo and at this point the river is within 4 ft. of its crest for a period varying from 20 to 80 days. The length of the Mississippi River flood crest, the great distance of the head-water reservoirs from the region of the flood, and the difficulty of forecasting these floods, indicate that head-water reservoirs above Cairo to be effective must store water for a period of about 90 days. Data concerning 245 proposed reservoirs were examined and from the storage graphs there was determined the percentage of reservoir capacity which would have been utilized each flood-year.

A first study concerned head-water reservoirs above Cairo and assumed them to be operated solely in the interest of Mississippi River flood reduction. Reservoirs having an aggregate capacity of 71 000 000 acre-ft. were considered, the cost per acre-foot ranging from 50 cents to $112. A storage-cost curve was prepared based on storage at a uniform rate during the storage period, on an efficiency as measured by the quantity of water stored equal to 75% of reservoir capacity, and on a relation between gauge and discharge at Cairo of 1 ft. equals 60 000 sec-ft. From this cost curve it appeared that the cost of reducing flood heights at Cairo would range from $62 000 000 for the first foot to $230 000 000 for the fourth foot, and that a reduction of 4 ft. by means of such reservoirs, equivalent to 240 000 sec-ft., would cost $560 000 000.

A more detailed analysis was then made using actual rates of storage instead of assumed uniform rates and actual efficiency of reservoirs instead of an assumed average of 75 per cent. Allowance was also made for the effect of storage in the river valleys between the reservoirs and Cairo. This more detailed study was limited to the Ohio Basin and comparison made between the floods of 1913 and 1922. The effect of valley storage was determined approximately by showing graphically the relation between the inflow

into the Ohio River from its tributaries and the outflow as measured near its mouth (Figs. 2 and 3). The inflow from the discharge diagrams of tributaries having a total drainage area of 170 100 sq. miles, has been increased by direct ratio to allow for an additional drainage area of 33 800 sq. miles. The composite inflow graph of all the tributaries was synchronized with respect to the outflow graph by taking into consideration the time of travel of water from the mouth of each tributary to the mouth of the Ohio. The difference between the inflow and the outflow curve appears to be a direct measure of the effect of valley storage and the true effect at Cairo of reservoir storage in the Ohio Basin can only be determined by taking into consideration the modifying influence of valley storage. The 1913 flood in the Ohio Valley was characterized by a sharp peak, whereas that of 1922 was a long low flood. In the latter, valley storage was a much less important factor than in the former.

The cost and effect of reservoirs was analyzed also on the assumption of joint use, that is, a combination of Mississippi River flood control with local flood control, the development of power, and improvement for navigation, or by a combination of three or more uses. A great many such combinations are possible and although the several uses are more or less conflicting, it may be said generally that such joint use will result in some reduction of cost per acre-foot chargeable to Mississippi River flood control.

A group of the most desirable reservoirs above Cairo, as determined by the ratio of benefits to costs, was then selected for further study. This group had a capacity of about 38 000 000 acre-ft., the average gross cost being between $10 and $11 per acre-ft., and the net cost chargeable to Mississippi River flood control between $7 and $8 per acre-ft. To reduce flood heights at Cairo by this selected group would require a gross expenditure for the first foot of reduction of $104 000 000, or a net expenditure chargeable to the Mississippi River of $40 000 000, assuming that the other interests benefited could be induced to pay the difference. The second foot of reduction would cost $160 000 000, of which it is estimated that $17 000 000 could equitably be charged to other interests. The average effect of this group in reducing gauge heights at Cairo during past floods would have been 2.65 ft., and had the entire group been built the average net cost under the assumptions made would be $115 000 000 per ft. of reduction on the Cairo gauge, or nearly $10 000 000 per in. of reduction. Expressing the reduction in terms of discharge, the cost would average $190 000 000 per 100 000 sec-ft. for a maximum reduction of 159 000 sec-ft.

Suggested reservoir sites on the St. Francis, White, and Arkansas Basins were also considered. These reservoirs are generally located in areas of heavy rainfall, which are important contributors to floods in the Lower Mississippi, and the proposed reservoirs are of such size that their capacity could be utilized effectively during most Mississippi River floods. These reservoirs have a gross capacity of 25 000 000 acre-ft. and are estimated to cost $215 000 000, or $8.50 per acre-ft. This cost may be reduced under a joint-use plan; furthermore, by reason of their proximity to the delta they should be more valuable than an equal amount of storage 1 000 miles above Cairo.

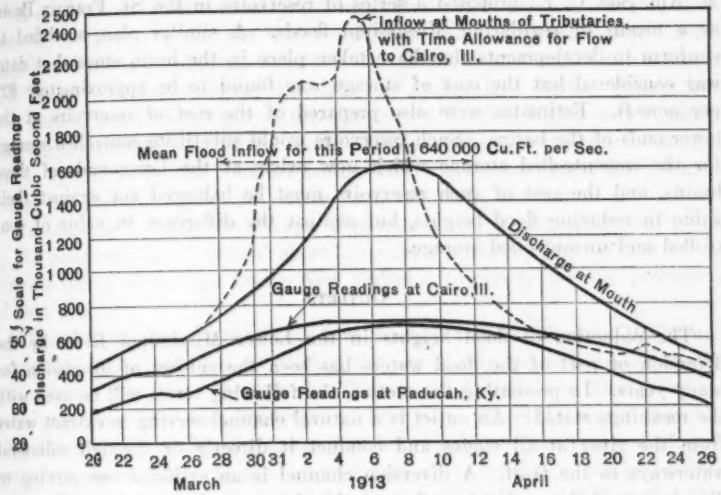

FIG. 2.—INFLOW AND OUTFLOW OF OHIO RIVER DURING 1913 FLOOD.

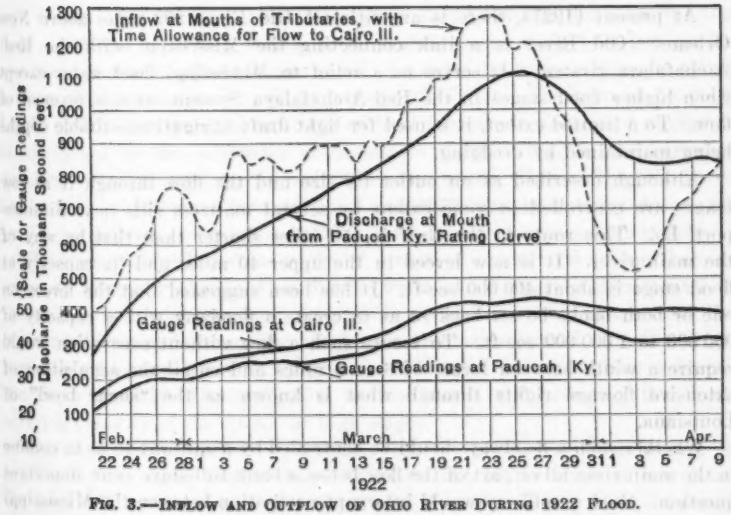

FIG. 3.—INFLOW AND OUTFLOW OF OHIO RIVER DURING 1922 FLOOD.

Studies were also made of suggested reservoirs in the St. Francis, Yazoo, and Tensas Basins. About thirty years ago the late James A. Seddon, M. Am. Soc. C. E., proposed a series of reservoirs in the St. Francis Basin as a means of regulating Mississippi floods. A similar plan, modified to conform to developments that have taken place in the basin since that date, was considered but the cost of storage was found to be approximately $27 per acre-ft. Estimates were also prepared of the cost of reservoirs at the lower ends of the basins. Such reservoirs would substitute controlled storage for the uncontrolled storage which now exists at the lower ends of these basins, and the cost of such reservoirs must be balanced not against their value in reducing flood heights, but against the difference in value of controlled and uncontrolled storage.

Outlets

The reduction of flood heights in the Lower Mississippi River by the diversion of part of the flood waters has been the subject of discussion for many years. In presenting the matter, the following terms will be used with the meanings stated: An outlet is a natural channel serving to extract water from the river at all stages and conduct it directly or through collateral waterways to the Gulf. A diversion channel is an artificial one serving to divert part of the main river flow to the river at a lower point or by independent collateral channels to the Gulf, the flow into it being wholly or partly under control. A spillway is a structure designed to afford regulated entrance of flood waters into a diversion channel.

At present (1927), there is an outlet at Old River 202 miles above New Orleans. Old River is a link connecting the Mississippi with the Red-Atchafalaya System. It serves as a relief to Mississippi flood water except when higher flood stages in the Red-Atchafalaya System cause a reversal of flow. To a limited extent, it is used for light-draft navigation, suitable depths being maintained by dredging.

Although described as an outlet its size and the flow through it at low stages are controlled to some extent by several mattress sills near Simmesport, La. This route to the Gulf is 150 miles shorter than that by way of the main river. It is now leveed in the upper 40 miles and its capacity at flood stage is about 400 000 sec-ft. It has been suggested that the levees on one or both banks be set back so as to create a floodway with a capacity of 900 000 to 1 000 000 sec-ft. To secure such a flow without excavation would require a width between levees of 6 to 8 miles and entail the acquisition of extensive flowage rights through what is known as the "sugar bowl" of Louisiana.

Whether such a floodway should be controlled by a spillway so as to confine in the main river all or part of the flow below a bank-full stage is an important question. Such a spillway would interrupt navigation between the Mississippi and the diversion channel unless a lock were also provided. On the other hand unless controlled, so large a diversion may cause silting in the main

channel to such an extent as to interfere with navigation at low stages and to diminish its flood-carrying capacity at high stages.

A diversion channel through the Tensas Basin with capacity ranging from 600 000 to 750 000 sec-ft. was also considered. Such a channel would leave the main river at or near the mouth of the Arkansas and extend to the upper end of the proposed floodway through the Atchafalaya Basin. Study was also made of a diversion channel through the St. Francis Basin, with capacity ranging from 300 000 to 500 000 sec-ft. Unless such a channel were extended to the White River and thus connected with the Tensas Basin diversion, it would not permanently divert water from the main channel.

In addition to these three major diversion plans, consideration was given to the construction of several short diversions with capacity of 250 000 to 300 000 sec-ft. above and below New Orleans, primarily for the protection of that city.

Diversion of part of the flood flow through the St. Francis Basin will apparently cost more than to confine the entire flow between levees on the main river. Diversions through the Tensas and Atchafalaya Basins are far more promising from the standpoint of first cost. Even if cheaper than the plan which would confine the entire flow between levees, the creation of such secondary channels for the discharge of part of the flood flow can be justified only if the opponents of diversion channels are mistaken in their belief that they will not permanently lower flood heights.

Opponents of outlets use as an illustration the changes in the relation of stage to discharge at Red River Landing, a short distance below the Atchafalaya Outlet. The records of the Mississippi River Commission show for the flood of 1882 a measured discharge of slightly more than 1 500 000 sec-ft. at a stage of 48.5 ft. In 1912, practically the same discharge was measured at a stage of 53.2 ft. and, in 1927, at a stage of 57.5 ft. The increase in flood height of 9 ft. between 1882 and 1927 without increase in volume of discharge is attributed by the opponents of outlets to deterioration in the carrying capacity of the channel of the main river due to the effect of the Old River Outlet. (The difference between 1882 and 1912 may be entirely accounted for by the difference in slope in the two cases caused by crevasse effect below.)

Evidence obtained from a study of crevasses supports the view that an outlet or secondary channel that diverts water at all stages is detrimental to the main stream, and that the larger it is in proportion to the main stream, the greater will be the deteriorating effect upon the main channel. Such a diversion tends to cause a raising of the bed below the outlet, thereby reducing the depth available for navigation at low stages and reducing the flood-carrying capacity of the stream at high stages.

Opponents of controlled diversions, even if the diversion be limited to over-bank flow, argue that if water be taken out of the river at any point the level will be lowered at that point and the slope of the river increased above the point of diversion and reduced below that point; that the increased velocity above will increase the silt-carrying capacity of the river, and that

it will approach the spillway with a greater load of silt than it would have had under natural conditions; that the reduced slope and reduced velocity below the spillway will result in sedimentation and reduction in the cross-section of the river; that this will continue until the river is again able to carry off its portion of the sedimentary matter; that the necessary increase in velocity can only be obtained by increased head; and that increased head means an increased flood level.

This belief, that the Mississippi River is so charged with sedement that the reduction in slope and velocity below a controlled diversion channel will cause deposits, is not borne out by the findings of Humpreys and Abbot. Furthermore, if the diversion is so built that it will not come into action until after the river reaches a bank-full stage (approximately 1 000 000 sec-ft.) and so controlled that the flow through it can be reduced as soon as the crest passes, the changes in slope and velocity can be kept within such narrow limits that deposits should not occur. Even if some sedimentation does take place, it should be completely removed later by the river itself, if the spillway is closed as soon as the discharge of the river falls within the capacity of the main channel.

Conclusion

Protection against an assumed probable maximum flood at Cairo of 2 250 000 sec-ft. can be provided by enlarging and strengthening the existing levees, but, no matter how well the levees are built, nor how well they are protected by revetment of the banks, an 1 800-mile levee line of the height necessary to contain such a flood would carry with it a menace to the people living behind it that should be avoided if practicable.

Head-water reservoirs above Cairo as a means of reducing levee heights will apparently cost very much more than a series of diversion channels or floodways through the delta basins.

Some of the proposed diversions will apparently justify themselves from an economic standpoint in that they will cost less than corresponding increase in levee heights; others will cost more, but may be justified by reason of the greater safety that they will afford the inhabitants.

Such secondary channels are not substitutes for levees on the main river. Even with all the proposed diversion channels built, the existing levees will have to be maintained and even increased in height in order to provide protection against the assumed flood of 2 250 000 sec-ft., at Cairo.

Whatever may be assumed as the probable maximum flood of the future, an even greater flood may some day occur, sufficient to overtop the levee line. To provide for such a contingency, it has been proposed to construct along the crown of the levee a series of over-bank spillways that would be brought into play only when overtopping was imminent. Such structures would provide the means of substituting a minor disaster for a major one and permit prompt recovery from the effects of such a super-flood.

In the writer's opinion, the most dependable, as well as the cheapest, method of protecting the delta basin of the Mississippi River against a

probable future flood lies in a system of main river levees, supplemented by a series of controlled diversion channels through which excess flood waters can be carried to the Gulf.

As an integral part of such a flood-control plan, the main river should be stabilized by revetting the caving banks. While such stabilization is regarded as an essential part of the flood-control project, it will also greatly benefit navigation at low stages.

FOREST COVER AS A FACTOR IN FLOOD CONTROL

By E. F. McCarthy,* Esq.

In an address before the Mississippi Flood Control Conference at Chicago, Ill., early in June, 1927, United States Forester W. B. Greeley took the position that, while the main reliance for handling large flood discharges must be placed upon engineering structures, forests have a definite part in flood control, together with other forms of land use which check erosion and favorably influence natural storage conditions. This attitude is the rational one, and engineers facing the problem of flood control in the Mississippi will doubtless feel that any agency which will assist in lowering the flood crests and in retaining the flood water within predetermined bounds should be used if economically feasible.

The relation of forest to stream flow is a subject which has received extensive discussion. Several good bibliographies have been collected. One is incorporated in the Final Report of the National Waterways Commission,† and a later one is contained in a report by the California State Board of Forestry.‡ No attempt has been made to repeat references in either of these publications. The Forestry Committee on the Relation of Forests and Waters submitted the following statement to the Fifth National Conservation Congress:§

"In the mountains, the forests break the violence of rain, retard the melting of snow, increase the absorptive capacity of the soil cover, prevent erosion, and check surface run-off in general, thus increasing the underground seepage and so tend to maintain a steady flow of water in streams."

Zon† has summarized the effect of forests on stream flow, as follows:

"Among the factors, such as climate and character of the soil, which affect the storage capacity of a water-shed, and therefore the regularity of stream flow, the forest plays an important part, especially on impermeable soils. The mean low stages as well as the moderately high stages in the rivers depend upon the extent of forest cover on the water-sheds. The forest tends to equalize the flow throughout the year by making the low stages higher and the high stages lower.

"Floods which are produced by exceptional meteorological conditions cannot be prevented by forests, but without their mitigating influence the floods are more severe and destructive."

A study was conducted by the U. S. Forest Service during the summer of 1927 to determine the relation of the forests to floods in the Mississippi.

‡ "Erosion and Flood Problems in California," by E. N. Munns (Rept. by California State Board of Forestry to the Legislature (1921) on Senate Concurrent Resolution No. 27).

§ "The Relation of Forests and Water," by Raphael Zon and others, Sub-Committee on Forest Investigations.

The collection of information relative to the Ohio drainage came under the supervision of the Central States Forest Experiment Station, so that direct reference will be made to this tributary.

The Ohio Basin, which contains approximately 203 230 sq. miles, once practically all forested, now has an estimated forest cover of 68 220 sq. miles. About 33 120 sq. miles of this land is woodland incorporated in the farms, of which about one-third is pastured. These statements have been qualified carefully because exact information in regard to the actual forest cover and its condition has never been collected for this region. In only a few instances, notably in Illinois, has an effort been made actually to map the existing woodland. The best general statistics are those included in the Census of Agriculture for 1925, and even this report does not adequately classify land lying outside the farms so that an accurate judgment can be made as to the amounts of forested and non-forested wild land. The foregoing statement of woodland acreage is based on the Census report, modified by the writer's judgment of the forested acreage of wild land. Of course, all available information which could be procured from State and individual sources has been used. From this summary the Ohio Valley may be considered as one-third forested.

The present trend, especially in the mountainous and hilly sections, is to abandon farm land rather than to extend its present acreage by further clearing. This tendency is so obvious as to attract even casual observation. The causes are chiefly three: (1) The inability of production on rough land to compete with that on farms more favorably situated as to soil, topography, and market; (2) the severe erosion and destruction of the steeper fields; and (3) industrial development and improvement of road communications which is draining the forested area of its labor element.

Many of the broad-leafed species may be found in the forest of the Ohio Valley. The exceptions to this are a comparatively limited acreage of spruce and fir forest in the higher plateau of West Virginia and the Southern Appalachian Mountains, and the mixture of scattered pine and hemlock found in some places with the broad-leafed species. The more exposed ridges also may support small patches of pure yellow pine. From this statement it is obvious that this entire forested area each year receives a carpet of leaf litter, chiefly from hardwoods, which are left largely defoliated during the winter season.

The forest of the Ohio Valley is now very unsatisfactorily stocked. Even in its virgin condition there were large spaces in the forest crown cover. Cutting, fire, and grazing have made further serious inroads on the virgin stand. The older timber now left is only a remnant of the original stand. These influences, in turn, have increased the general undergrowth of rhododendron, laurel, and other shrubs. Significant, in so far as flood prevention is concerned, is the thinness of the stand which now occupies the forested land of this valley. Only in the few places which have received adequate protection from fire for a considerable number of years is there a dense stand of timber with a well-covered forest floor. In the past the rougher mountain and plateau lands have been frequently burned over. In 1927, 211 424 acres

of land were reported burned in Ohio, Indiana, Kentucky, Tennessee, and West Virginia. This represents about 0.7% of the total wooded acreage of these States. The foresters of the Ohio Valley States recognize the necessity for better protection from fire and improved management of timber lands, both for increasing the protective value to their water-sheds and for the yield of timber.

The relation of the forest to run-off is most closely established through its influence on erosion, since it is through the washing away of the finer soil particles that channels are established for the flow of water. The first place to seek control of a flood is at its source where every small impediment is most effective in delaying the union of raindrops into rivulets and these, in turn, into streams strong enough to sweep clear a direct channel. The best that can be done at the source is to secure the most effective percolation of water from the surface to the water-table.

The fact is well established that the forest, through its littered floor and porous soil, does cause impediment to the flow of water on the ground surface and does increase the water storage, thereby maintaining the flow of springs in dry seasons. A large volume of evidence has been accumulated in support of this contention. Several striking examples are cited.

In 1922, Charles G. Adsit, M. Am. Soc. C. E., Vice-President and Executive Engineer of the Georgia Railway and Power Company, stated:

"At our Morgan Falls Plant on the Chattahoochee River, which is below large cultivated areas, the reservior in 1904 covered 750 acres. After ten years' service, there was no reservoir capacity worth mentioning left, it having all silted shut, leaving only a channel through the center of the reservoir for the river flow. On the other hand, our Mathis Reservoir, above which is only forested area, after ten years' service, shows little or no sign of silt whatsoever."

The following statement is made in a recent letter by Edgar P. Kable, General Manager, The York Water Company, York, Pa.:

"Our observations of the effect of forest planting on our water supply in dry times has been that it has increased the dry weather run-off very materially.

"We have a 700-acre tract planted with 680 000 evergreen trees and although we have no gauge at present, nor did we have prior to the building of the dam, yet this fact is noticeable.

"The quality of the water in the stream has also materially improved as there is very little erosion from the banks, and, as an example, when there was a great downpour of rain * * *, the water in this dam remained clear, whereas some of the neighboring streams became very turbid."

The litter-covered forest floor is generally recognized as the best protection against erosion of soil. Through the action of the litter in preventing the packing of soil by rains, the forest soil remains in a loosened condition throughout the season. The soil is loosened by the action of frost, as well as rodents, and other animal life, and is especially porous in the early spring months at the time when the precipitation or accumulation of snow water is greatest. A mere comparison of the forest soil made porous by these agents and by the penetration of tree roots, with the packed soil of adjacent fields,

will convince any one of the value of this cover in retarding run-off. The action of the litter in delaying run-off is most pronounced in the first few rods of movement of the water while it is accumulating in the natural drainage channels.

The terrific loss of soil through erosion is not generally understood, and an excerpt from *Research Bulletin 63* of the Missouri Agricultural Experiment Station* is inserted to bring out this point. Experiments were conducted for a period of six years on carefully controlled plots with an average gradient of 3.68 per cent. In summarizing the results, the authors state:

"If farm land should erode as rapidly as the land in these experiments the surface 7-in. layer would be removed at the following rates: uncultivated land in 29 years; plowed 4 in. deep in 24 years; plowed 8 in. deep in 28 years; planted to corn annually, in 56 years; wheat, annually, in 150 years; rotation, corn, wheat, and clover in 437 years; bluegrass sod in 3 547 years.

"The chemical analyses showed that the amounts of nitrogen, phosphorus, calcium, and sulphur in the eroded material from corn or wheat land may equal or exceed the amounts taken off in the crops. There were only small amounts of nitrogen, as nitrates, lost in the run-off water."

This Missouri experiment brings out the great difference in loss of soil from bare or cultivated land and that protected by bluegrass sod. While it does not afford evidence of the protective value of the forest, it does indicate the loss which might be expected, even on comparatively level land, if a sod cover should fail and leave the land bare.

The most striking example of complete removal of soil in a forest region is afforded by the area damaged by smelter fumes near Ducktown, Tenn. Here, each few feet of surface has developed its water channels and tremendous quantities of the surface soil have been washed into the tributaries of the Hiwassee River. The significant thing in connection with the Ducktown area is that the soil accumulated during ages, under the protection of a forest cover, was eroded in a few years when exposed by the damage from smelter fumes.

The dry weight of hardwood litter annually deposited on the forest floor has been estimated at about 2 tons per acre. This will vary somewhat according to the species and the density of the stand. The rapidity of disintegration also varies, as influenced by wind and weathering. For use in this paper, determinations were made on plantations with an average age of 17 years, located at the Ohio Agricultural Experiment Station, at Wooster, Ohio. The work was done in the week ending October 8, 1927, before the leaf crop had fallen. The litter on sample areas was weighed and its moisture content determined. The dry weight of litter per acre on these plantations varied from 1 827 lb. to 17 545 lb. and is able to absorb 1½ to 2½ times its dry weight in water. It is notable that the litter underneath the soft woods, pines, spruce, and Douglas fir, exceeds that of the hardwoods at this time of year.

The relative influence of forested and non-forested areas on run-off and erosion has been specifically studied at several places in recent years. The most notable of these, perhaps, is the work being done by the U. S. Forest

* "Erosion and Surface Run-Off Under Different Soil Conditions," by L. F. Duley and M. F. Miller.

Service in co-operation with the U. S. Weather Bureau at the Wagon Wheel Gap Station, in Colorado. Here, two water-sheds as nearly similar as could be found were subjected to measurements for a period of years. One of them was deforested and the measurements were then continued for a further period of years. A preliminary report of this work has been made,* and the final report is now (1927) in preparation. Experience gained in the Wagon Wheel Gap experiment shows the extreme difficulty of securing adequate values through the study of paired water-sheds.

A less extensive study of run-off has been made† by C. E. Ramser, M. Am. Soc. C. E. While attempting to determine the drainage requirements for road purposes, he found the forest an important factor in controlling the rate of run-off. He says of his results, "these values show quite conclusively that timber has a decided influence in reducing the rate of run-off from a water-shed". He further qualified this statement, however, by a discussion of the influence of duration of rainfall on the rate of run-off. His work is further quoted in the Appendix.

A recent paper by Mr. H. Burger,‡ reports a study in Switzerland, where a comparison was made of forested and non-forested water-sheds. He found that the crest of the flood was not only delayed by the forest cover, but that the total run-off per square kilometer was also reduced. In both these instances neither water-shed was completely covered by forest, but a sufficient difference existed to bring out these facts.

The most conclusive study made thus far is that on two water-sheds in the White Mountains.§ In comparing two water-sheds, one largely forested and one deforested and open, the following conclusions have been drawn: At the end of each period of observation there was more snow on the forested than on the deforested basin; the loss of water from snow storage was heavier on the deforested basin; the rate of run-off from the forested basin was less than two-thirds that from the deforested basin; the maximum flood flow from the forested basin never exceeded 71% of that on the deforested basin; and, lastly, considering the precipitation over the entire period, the forested basin added largely to the ground-water storage, whereas the deforested basin drew in large amounts from that storage.

Mr. I. T. Bode,‖ in describing the results of his work in Iowa, claims an increase of water storage in forested lands as compared with the open prairie land adjoining.

In considering the effect of forest cover on the catchment of precipitation, the influence of the trees themselves in intercepting both rainfall and snowfall must be considered. This influence is particularly important in light rains when a large proportion of the precipitation may be intercepted by the

tree crowns and re-evaporated into the air without having reached the forest soil.

Robert E. Horton, M. Am. Soc. C. E., has discussed this subject,* and has also investigated the loss of water by transpiration from trees.† He indicates that from 0.02 to 0.07 in. of rainfall per shower may be intercepted, and that the total loss for the summer season may be as high as 40% of the total precipitation.

Mr. H. S. Graves‡ has reported loss through interception in forests as varying from 20 to 60% of precipitation. While no very exact information exists, and the interception is admittedly less in regions of heavy rains, the loss through interception of the crowns of trees must be considered, together with transpiration and ground storage, as a factor in flood control.

It is evident that there is still a large field for research in determining the exact relation of the forest to the retention of flood waters. In spite of this fact, the evidence collected thus far is of a positive nature and indicates a material and beneficial influence.

The rapidly increasing number of storage reservoirs for power purposes and the increasing value of forest-covered water-sheds as sources of potable water for neighboring cities, are additional reasons for the maintenance of good forest conditions on the upper reaches of mountain streams. Not only should the abandoned fields of the Appalachian Mountains and Cumberland Plateau tributary to the Ohio drainage be forested, but many areas of cleared land in the hill sections of Illinois, Indiana, and Ohio, can be restored to forest cover both with benefit to the flood situation and profit to the owners.

In summarizing the influence of the forest on flood control, the outstanding service which it accomplishes is the protection of the rougher land from erosion. This, in turn, has a direct influence through the control of silting on practically all the engineering work undertaken.

The forest is a natural storage for water, because it delays run-off, intercepts rainfall, and retains the fine soil and humus in place on the steeper slopes.

APPENDIX

China has long been held up as a terrible example of forest destruction. Mr. W. C. Lowdermilk§ has recently prepared a preliminary report on the problem of forest conservation in Shansi, China. The following abstract is taken from this report:

"The Taiyuan plain was suffering from a long drought when we reached Taiyuanfu. The crops were dying for want of rain, even the wild grass had not started (July 3) and a famine was feared.

"The rain clouds broke shortly after our arrival. The moisture which had been accumulating in the atmosphere, superheated by the roasting hills, came down in torrential volumes. The streams were suddenly overcharged with raging waters, heavily laden with mud and silt. The water supply so sorely

‡ *Monthly Weather Review*, Vol. 42, December, 1914, p. 671.

§ "The Problem of Forest Conservation in Shansi, China." (In mss.)

needed for agricultural crops quickly ran off the steep barren slopes and brought floods and destruction in the place of the desired benefits of rain after drought. Despite the efforts made to catch the flood waters for irrigation, most of them soon passed by and were gone. Dry weather in the fall months again made the conditions of the people serious and threatened them with famine. Being deprived of their soil and forest cover, the mountains no longer serve as a storehouse of water to be made available, when most sorely needed, to the fields in the plains.

"Our party was able to study these forces at work and to follow the processes of the denudation of mountain slopes. Far back at the foot of the famous Lu Yah Shan near the Great Wall was found a small remnant of what was once a great forest cover. Now only a few score of square li of the original forest are left. Yet here may be found the beneficent influences of a forest cover. From out this natural forest area, consisting of trees and a deep porous soil of decaying vegetable matter, flows now a beautiful perennial stream. It was scarcely affected by the heavy rains of the summer [1924], whereas the stream beds draining the barren slopes became raging torrents after an hour of rainfall. But now this last remnant of true and natural forest is being attacked, for not less than 500 wood cutters began in the summer of 1924 to clear the tract.

"The cutting of trees is not the cause of forest destruction in the mountains of Shansi; it is, on the contrary, the digging up of the soil on the mountain slopes for agricultural crops that begins the process of destroying the soil cover."

The following is an abstract from the paper by Mr. H. Burger* previously mentioned:

In two small water-sheds in the Canton of Berne, Switzerland, measurements have been taken which indicate very definitely the effect of the forest cover on run-off. These two water-sheds are similar in altitude, exposure, slope, and character of soil. They are 3 km. distant from each other. One (the Sperbelgraben) is entirely wooded, the other (the Rappengraben) is only 35% wooded. The entirely wooded basin has an area of 56 hectares, the other, 70 hectares.

On June 22, 1926, at 5:00 P. M., a violent storm took place, during the course of which 28 mm. of rain fell on the wooded basin and 29 mm. on the other. The maximum flow from the partly forested basin was 1 079 liters per sec. for each 100 hectares and the crest occurred ½ hour after the beginning of the rain. The maximum flow from the completely forested basin was only 240 liters per sec. and the crest occurred about 5 hours after the storm began.

The total run-off per square kilometer during the period from the beginning of the storm until June 23 at 6:00 A. M., was 7 696 cu. m. on the partly forested basin and only 4 720 cu. m. on the completely forested basin. By subtracting the amount of normal flow, observed just before the storm in each case, the run-off due entirely to the storm is obtained. This is 6 184 cu. m. for the partly forested basin and 2 970 cu. m. for the completely forested basin. On the partly forested basin, 21% of the storm-water ran off; on the completely forested area only 10 per cent.

The purpose of the experiments made by C. E. Ramser, M. Am. Soc. C. E., was to determine the rates of run-off from small agricultural areas. They consisted in making rainfall and run-off measurements on six water-sheds ranging in area from 1¼ acres to 112 acres. The following quotation from Mr. Ramser's report† indicates the effect of timber upon rate of run-off:

* *Swiss Forestry Journal*, March, 1927.

† "Run-Off from Small Agricultural Areas." *Journal of Agricultural Research*, Vol. 34, No. 9, pp. 797–823.

"The effect of timber upon the rate of run-off is shown by a comparison of the results obtained for Water-Sheds Nos. 1 and 4, where the timbered areas were 14 and 38.9% of the respective water-sheds. In Table 8 it is seen that the run-off coefficients for Water-Shed No. 1, for all rains except that of July 18, range from 0.33 to 0.49, and for Water-Shed No. 4, from 0.22 to 0.35. These values show quite conclusively that timber has a decided influence in reducing the rate of run-off from a water-shed. However, the results obtained for the rain of July 18—for which run-off coefficients of 0.51 and 0.46 for Water-Sheds Nos. 1 and 4, respectively, were obtained—tend to show that the effect of timber in reducing run-off is slight when the maximum rate of run-

TABLE 8.—EFFECT OF TIMBER ON RUN-OFF COEFFICIENTS FOR WATER-SHEDS NOS. 1 AND 4; WATER-SHED NO. 1, 14.0 PER CENT. IN TIMBER; WATER-SHED NO. 4, 38.9 PER CENT. IN TIMBER.

Date of rain, 1918.	AVERAGE RATE OF RAINFALL DURING TIME OF CONCENTRATION, IN INCHES PER HOUR.		COEFFICIENT OF RUN-OFF (RATIO OF MAXIMUM RATE OF RUN-OFF OF AVERAGE RATE OF RAINFALL).		RAINFALL PRIOR TO PERIOD TAKEN AS TIME OF CONCENTRATION, IN INCHES.	
	Water-shed No. 1.	Water-shed No. 4.	Water-shed No. 1.	Water-shed No. 4.	Water-shed No. 1.	Water-shed No. 4.
February 19	3.40	1.89	0.40	0.22	0.39	0.37
April 16	3.84	2.92	0.33	0.29	1.21	1.19
April 28	4.44	3.77	0.41	0.25	0.09	0.09
May 7	3.60	3.51	0.38	0.28	0.18	0.18
May 12	1.92	1.89	0.41	0.30	0.10	0.10
May 23	3.12	2.83	0.49	0.35	0.38	0.38
June 1	3.24	3.00	0.36	0.28	0.46	0.38
June 6, 11:00 P. M.	3.28	2.14	0.42	0.28	0.72	0.69
July 18	4.20	3.51	0.51	0.46	0.76	0.71

off occurs after considerable rain already has fallen. This is to be explained by the fact that interception and percolation on timbered areas are much greater at the beginning of a rain than later, so that an increasingly greater proportion of the rainfall runs off as the rain continues. The falling rain is intercepted by the trees, and the cover of leaves on the ground, until saturated, absorbs a large portion of the rainfall. On April 28 the average rates of rainfall were greater than on July 18, yet the rates and coefficients of run-off were smaller, being 0.41 and 0.25 as compared with 0.51 and 0.46 for the rains of April 28 and July 18, respectively. However, the rain that fell prior to the time of concentration on April 28 was 0.09 in. for both water-sheds, while on July 18, it was 0.76 in. for Water-Shed No. 1 and 0.71 in. for Water-Shed No. 4."

RESERVOIRS FOR MISSISSIPPI VALLEY FLOOD PROTECTION

By William Kelly,* M. Am. Soc. C. E.

For many years there has been an insistent demand for reservoirs to regulate stream flow throughout the United States in the interest of flood protection, navigation, irrigation, drainage, power development, and various other works connected with water resources. In fact, the idea that reservoirs will cure most of the evils from which the country is suffering has been widely accepted as more or less axiomatic in spite of the fact that such projects as have been studied in detail have presented so many difficulties that few of them have been found economically feasible. For five years, as Chief Engineer of the Federal Water Power Commission, the writer spent most of his time studying reservoir possibilities throughout the country to determine whether proposed power developments would conform to a general plan insuring maximum economic use of the water resources for all purposes, including irrigation, flood protection, navigation, etc. As a result of this experience the writer, while not accepting reservoirs as cure-alls, believed that they might form a valuable part of a complete Mississippi flood project.

So far as the Mississippi Valley is concerned, the Mississippi River Commission has often considered the subject of reservoirs, but has never found a possibility of obtaining results that would justify a recommendation for diverting any of its limited funds for this purpose. Many think that the reservoir plan for Mississippi flood relief has not received the consideration it merits. Be that as it may, General Jadwin, the Chief of Engineers, has determined to have the subject studied as thoroughly as all other phases of the flood problem and if there are any reservoirs that can profitably be developed for Mississippi flood protection, they will undoubtedly be included in the project recommended.

It should be noted that the policy of giving Federal aid for flood protection is a quite recent development. Federal jurisdiction over streams is conferred by the Commerce Clause of the Constitution. Twenty-five years ago such jurisdiction and responsibility was limited strictly to improvements for navigation. There has been no change in the Constitution in this respect, but gradually popular demand has caused Congress to extend Federal assistance for flood protection on the principal navigable streams to a point where its relation to navigation improvements is almost lost to sight. Perhaps if Congress had not so acted the public demand would have been strong enough to amend the Constitution.

The great Mississippi flood of 1927 has renewed the demand for further Federal activity, and in recognition of this demand and of the policies developed by Congress, the Administration has directed studies to be made of

* Col., Corps of Engrs., U. S. A.; Vice-Pres., Buffalo, Niagara, & Eastern Power Corporation, Buffalo, N. Y.

the Mississippi flood problem on a much more comprehensive basis than ever before. Early in June, 1927, a board of seven Engineer Officers was appointed to study the reservoir problem. The Board was given broad instructions to consider the question from every angle. It was authorized to call upon District Engineer Officers of the Army for any assistance needed, and to get data from every source where they could be found. The only limitation placed on the Board was that its report should be completed in time to be considered with the reports of boards studying other phases of the flood problem, so that any reservoirs found to be feasible, could be included in a complete report on Mississippi Valley flood protection to be submitted to Congress in December, 1927.

The Reservoir Board immediately laid out a program of studies along the following lines:

1.—To determine the effect on Mississippi floods of the larger reservoir systems already built in the Mississippi Drainage Basin as a practicable indication of what can be done.

2.—To determine reservoir capacities, costs, and effect on Mississippi floods of all practicable reservoirs on the tributaries of the Mississippi, both when operated primarily in the interest of Mississippi floods and when operated to get the maximum economic results, considering all uses of the reservoirs.

3.—To determine reservoir possibilities in the valley of the Mississippi and its main tributaries.

The task set the Board is a tremendous one to complete in the time available; but thanks to the excellent organization placed at its disposition and to the data available from previous studies, it is believed that the results obtained will be sufficiently complete and reliable to determine what can be done with reservoirs to ameliorate floods in the Mississippi, and what such amelioration will cost. Unfortunately, the final results of the Board's studies are not as yet available (October, 1927), so that this paper is no more than the writer's digest of the data now at hand. Some of the figures will doubtless be modified when the final report is made.

In order to determine the effect of reservoirs on Mississippi flood flows, it is necessary to establish some rule for reservoir operation. Practically all large Mississippi floods have occurred during the 90 days from February 15 to May 15. While there have been a few fair-sized floods both before and afterward, it is believed that this period fairly covers the time within which disastrous floods will occur.

The time consumed by water released from reservoirs on tributaries in traveling to the Mississippi varies from 3 days to 5 weeks, with an average of more than 2 weeks. Large Mississippi floods are produced by widespread heavy rainfall occurring throughout the valley when the river is already running full. The Board has been unable to find any means of predicting a large flood in the Mississippi as much as two weeks in advance of its occurrence. Hence, on the average the best dependable results from reservoirs will be obtained by filling them as uniformly as the stream flow will permit so as to hold water back from the Mississippi during the 90 days of probable flood,

February 15 to May 15. In its studies the Board has adopted such a procedure as the rule for reservoir operation. It is possible that for some of the reservoirs a more efficient rule of regulating might be found as a result of experience in their operation, but it is not likely that the increased efficiency would more than offset the probable error due to determining the dependable effect from only five floods, as the Board has been forced to do. A brief résumé of the studies on existing reservoir systems will be given.

Miami Conservancy District

These reservoirs are designed to protect the cities on the Miami River from disastrous local floods. Their action, which is automatic, is effective only during floods of considerable magnitude. It consists of storing all the flood flow in excess of the capacity of the valley below the reservoirs. As soon as the natural flow has fallen below the danger point, this stored water is discharged at a rapid rate. The effect on moderate local floods is a minor one and small floods are entirely unaffected. The costs and capacities of the reservoirs are as given in Table 16.

TABLE 16.—Costs and Capacities of Miami Conservancy District Reservoirs.

Reservoir.	Capacity, in acre-feet.	Cost.	Cost, per acre-foot.
Taylorsville	186 000	$4 170 000	$22.40
Lockington	70 000	2 020 000	28.90
Huffman	167 000	3 680 000	21.70
Englewood	312 000	4 050 000	13.00
Germantown	106 000	1 620 000	15.30
Total	841 000	$15 490 000	$18.40

These works appear to have been very successful in affording the designed protection to the Miami Valley. Their effect on the Ohio and Mississippi floods is to decrease the flood flow for 1 day, or 2 days, and then increase it by a somewhat smaller amount for several days. Whether the net result is to increase or decrease the maximum flow of the larger river is mainly a matter of chance.

This effect was computed for the years of the last five great Mississippi floods. Table 17 shows the results on the Ohio River.

TABLE 17.—Effect of Miami Reservoirs on Ohio River Floods.

Year.	Maximum Natural Discharge.		Maximum Discharge, with Reservoir Operating.		Effect of Miami reservoirs, in second-feet.
	Quantity, in second-feet.	Date.	Quantity, in second-feet.	Date.	
1912	558 000	March 30	553 000	March 30	5 000, decrease
1913	868 000	March 31	890 000	March 30	22 000, increase
1916	520 000	April 2	520 000	April 2	No effect
1922	540 000	March 19	540 000	March 19	No effect
1927	396 000	March 26	398 000	March 22	2 000, increase

It appears from Table 17, therefore, that these reservoirs have no dependable effect in reducing the magnitude of maximum floods of the Ohio River and that, in some instances, the effect may be adverse.

The effect on the floods of the Mississippi is dependent on the time required for the effects at the mouth of the Miami to be felt at Cairo, Ill. This has been taken to be nine days. If the effect of "valley storage" in the Ohio between the Miami and Cairo be neglected, the results are as given in Table 18.

TABLE 18.—Effect of Miami Reservoirs on Mississippi River Floods.

Year.	Maximum Natural Discharge.		Maximum Natural Discharge, with Miami Reservoirs Operating.		Difference, in second-feet.
	Quantity, in second-feet.	Date.	Quantity, in second-feet.	Date.	
1912	1 946 000	April 5	1 945 000	April 5	1 000, decrease
1913	1 677 000	April 4	1 725 000	April 7	48 000, increase
1916	1 903 000	February 5	1 903 000	February 5	No effect
1922*	1 582 000	April 25	1 584 000	April 25	2 000, increase
1922*	1 595 000	March 25	1 596 000	March 25	1 000, increase
1927	1 800 000	April 19	1 800 000	April 19	No effect

* There were two flood peaks of nearly equal magnitude at Cairo in 1922.

Table 18 shows that the effect on the Mississippi may be either beneficial or the reverse. The effect of the "valley storage" on variations of flow at the mouth of the Miami of only a few days' duration is such that the actual results at Cairo would be similar to those in Table 18, but of less magnitude.

If these Miami reservoirs, instead of being used as detention basins for the protection of that valley, had been used as reservoirs for the protection of the Mississippi under the operating schedule adopted by the Reservoir Board, their effect would have been to reduce the crest at Cairo by quantities varying between 1 000 and 7 000 sec-ft. for different flood-years. The dependable effect would not exceed 0.2 in. on the Cairo gauge. If the reservoirs were used in this manner a new method of protection for the Miami Valley would have to be provided, and the total cost probably would be in excess of $30 000 000.

Keokuk Reservoir

As now operated, the Keokuk Reservoir has no measurable effect on Mississippi floods. If operation were modified in the interests of flood protection the pond might be drawn down 6 ft. below the normal stage by February 5, and the resulting 142 800 acre-ft. filled uniformly over the probable 90-day flood period. This would give a reduction of 790 sec-ft. on Mississippi floods, and would lower the flood height at Cairo by less than $\frac{1}{7}$ in. It would entail a power loss of 16 000 000 kw-hr., the value of which, if replaced by steam power, is greater than the cost of obtaining similar flood benefit by other means.

The level of the pool cannot be raised more than 3 ft. without excessive flowage damages. It might be raised 3 ft., giving 100 000 acre-ft. additional storage, at an estimated cost of about $5 200 000, or $52 per acre-ft. Such a

storage would reduce the flood flow about 560 sec-ft. and the crest height at Cairo about 0.1 in. The cost would be more than ten times as much as the cost of levees to take care of the same flow at the top of the flood.

Reclamation Service Reservoirs

The U. S. Reclamation Service has built a number of large irrigation reservoirs in the Mississippi Drainage Basin. To determine what effect they have had on Mississippi floods, data are available for eight of these reservoirs for 1922 and 1927, as shown in Table 19.

TABLE 19.—Irrigation Reservoirs in Mississippi Drainage Basin.

Name.	Capacity, in acre-feet.	Approximate cost.	Cost, per acre-foot.
Pathfinder	1 020 000	$2 000 000	$ 2
Lake Mintare	60 800	500 000	8
Lake Alice	12 000	100 000	8
Winter Creek	3 700	100 000	27
Belle Fourche	208 000	1 200 000	6
Willow Creek	17 000	200 000	12
Shoshone	457 000	1 400 000	3
Nelson	40 000	200 000	5
Total	1 813 500	$5 700 000	$3.15 (average)

At the time when the water that was to contribute to the crest of the 1927 flood was passing these sites the Shoshone Reservoir was discharging 550 sec-ft. more than normally. The Pathfinder and Belle Fourche Dams were storing at moderate rates, about 600 and 250 sec-ft., respectively. At the other sites, stream flow and storage were both very low. It should be noted that the time in question comes in March, before the first spring thaws occur in this mountainous northern country. The aggregate storage rate for the eight reservoirs is estimated at 325 sec-ft.

In 1922 the flood had two practically equal crests at Cairo; one late in March and one late in April. From the earlier one the irrigation reservoirs held back about 900 sec-ft., while from the later they withheld more than 3 200 sec-ft.

The quantity held back in the 1927 flood was equivalent to about $\frac{1}{3}$ in. on the gauge at Cairo. This is based on the actual operation of the irrigation reservoirs. With the exception of Shoshone, it appears that they were storing practically all the water there was and that the volume could not have been increased materially. The Shoshone Reservoir was being used for the joint purpose of irrigation and power development. Had it been operated primarily for Mississippi flood control, it could probably have stored about 500 sec-ft.

Reservoirs at Head-Waters of the Mississippi

In the State of Minnesota, on the head-waters of the Mississippi River, six reservoirs are maintained by the United States. They are operated pri-

marily for the purpose of increasing the navigable depths in the Upper Mississippi above Lake Pepin during periods of low water. They also serve to increase the amount of water power developed during these periods and to diminish the damage caused by local floods. These purposes are accomplished in a fairly satisfactory manner; but ever since the reservoirs were finished the War Department has been receiving frequent demands to operate them in some other way to benefit other interests.

The cost of these reservoirs was very small as they were formed by the construction of low dams at the outlets of natural lakes at a time when price levels were down and land and flowage rights were cheap, as the country was largely undeveloped. The District Engineer at St. Paul reports the capacities and costs as in Table 20.

TABLE 20.—HEAD-WATER RESERVOIRS, MISSISSIPPI RIVER.

Name.	Capacity, in acre-feet.	Cost.	Cost per acre-foot.
Lake Winnibigoshish	967 170	$368 200	$0.38
Leech Lake	743 840	246 800	0.33
Lake Pokegama	120 760	197 000	1.63
Sandy Lake	72 500	218 000	3.00
Pine River Reservoir	177 520	215 500	1.21
Gull Lake	70 970	77 200	1.08
Total	2 152 226	$1 322 700	$0.61

The effect of the operation of these reservoirs in reducing the floods of the Lower Mississippi was studied for each of the great floods of recent years with the following results.

Flood of 1912.—In this year the flood crest reached Cairo in the early part of April and the operation of the Minnesota Reservoir System caused a reduction of about 1 100 sec-ft., or less than 0.2 in. on the gauge at Cairo.

Flood of 1913.—The flood crest reached Cairo early in April. The Upper Mississippi was at a low stage at the time corresponding to this flood wave, and the reservoirs were discharging water in order to maintain navigable depths. This resulted in increasing (rather than decreasing) the flood discharge by about 230 sec-ft.

Flood of 1916.—The flood crest reached Cairo early in February. Conditions in the Upper Mississippi were similar to those in 1913 and the operation of the reservoirs increased the flood discharge about 250 sec-ft.

Flood of 1922.—This flood had two approximately equal crests at Cairo, the first late in March and the second late in April. The operation of the reservoirs reduced the earlier crest by 500 sec-ft., and the later crest by 1 700 sec-ft., or about $\frac{1}{3}$ in. on the gauge at Cairo.

Flood of 1927.—The flood crest reached Cairo just after the middle of April. Operation of the reservoirs caused a reduction of about 1 200 sec-ft., or slightly more than 0.2 in. on the gauge at Cairo.

In 1912, 1922, and 1927, the reservoirs were storing the entire flow of their streams except the minimum that had to be passed to prevent damage to

navigation and power development. If they had been operated solely for the benefit of the Mississippi floods they could have done no more without damage to these interests. In 1913 and 1916, they were contributing a small increase to the Mississippi floods to the benefit of navigation and power.

Summary.—Leaving out the Miami regulation which is more apt to be detrimental than beneficial, the three projects just discussed have a combined storage capacity of about 4 150 000 acre-ft. As now operated their combined dependable reduction of Mississippi flood peaks is about 75 sec-ft.; that is, to reduce past floods 1 sec.-ft. has required more than 55 300 acre-ft. of storage. If these reservoirs had been operated primarily for Mississippi flood protection they might have reduced Mississippi floods by 2 200 sec-ft., or nearly thirty times as much. These ratios are interesting, but should not be used indiscriminately.

Possible Reservoirs on the Tributaries of the Mississippi River

For this next study the water-shed of the Mississippi was divided into five principal divisions, as follows: (1) The Ohio River and its tributaries; (2) the Upper Mississippi River; (3) the Missouri River; (4) the Arkansas River group of tributaries; and (5) the Red River group of tributaries.

The Upper Mississippi has been taken to include that part of the river between St. Louis, Mo., and Cairo. The Arkansas group includes the White, Black, and St. Francis Rivers and minor tributaries between Cairo and Arkansas City, Ark. The Red River group includes the Ouachita and Yazoo Rivers and neighboring small streams. Each of these divisions differs from the others in its run-off characteristics and also in its effect on Mississippi floods. Table 21 shows the drainage area of each division and the percentage of flood flow contributed by each in recent floods.

TABLE 21.—Principal Tributaries of Mississippi River with Drainage Areas and Percentage of Flows Contributed.

Division.	Area, in square miles.	Percentage of Flow at Cairo, Ill.					
		1912.	1913.	1916.	1922*.	1927.	Average.
Ohio	203 000	61	72	57	70 57	46	60
Upper Mississippi	186 000	23	25	32	19 28	26	28
Missouri	530 000	16	3	11	11 15	18	12
		Percentage of Flow at the Mouth of the Arkansas River.					
Arkansas	202 000	12	9	17	19	40	19
		Percentage of Flow at the Mouth of the Red River.					
Red	104 000	13	8	13	15	14	13

* In 1922 there were two nearly equal flood crests at Cairo.

The percentages of flow at Cairo are fairly accurate, but those at the Arkansas and Red Rivers are rather uncertain, due to difficulties in determining the actual flow in the Mississippi at these points.

The District Officers reported on all reservoirs that could be found with a capacity of 100 000 acre-ft. or more. In all, 321 reservoirs were included in the reports. Of these, 124 were thrown out as impracticable, or unnecessary, chiefly because there was not sufficient water to fill them at the time they are needed.

Table 22 gives a summary of the 197 reservoirs which have been studied in detail.

TABLE 22.—Summary of Possible Flood Control Reservoirs.

Division.	Number of reservoirs.	Total capacity, in acre-feet.	Total cost.	Average cost per acre-foot.	Percentage of drainage area above lowest reservoir.	Percentage of total rainfall of Mississippi River above lowest reservoir.
Ohio	90	29 200 000	$543 000 000	$18.60	30	Not available.
Upper Mississippi	54	17 400 000	305 000 000	17.50	86	
Missouri	7	32 700 000	232 000 000	7.10	84	
Arkansas	32	23 500 000	201 000 000	8.60	58	
Red	14	8 700 000	32 000 000	3.70	45	
Total	197	111 500 000	$1 313 000 000	$11.80	65	45 in 1927

From the hydrographs and storage curves of the reservoirs, graphs were prepared showing the aggregate storage rate in the reservoirs of each of the five divisions for each day of the 90-day storage period. The actual reduction of flow in the Mississippi Valley is quite different from the sum of the rates of storage at the various reservoirs, because of the retarding and equalizing effect of the storage in the valleys of the tributaries between the reservoirs and the Mississippi. For example, between high and low water the Ohio has a storage capacity in the main valley of about 12 000 000 acre-ft., more than 40% of the capacity of all the reservoirs available on its water-shed.

Computations to determine the effect of this valley storage are not yet completed (October, 1927). A rough approximation, therefore, has been used to obtain the figures in the computations to follow. The reduction in maximum flood discharge that would have been brought about by the reservoirs of each division is shown approximately in Table 23. In this table, as in the previous tables, the results at Cairo are fair, but those at points below are not so good, owing to doubt as to the flow in the Mississippi River at these lower points.

The effect on gauge heights of this reduction depends on the increment of discharge corresponding to a change of stage of 1 ft. near the crest of high confined floods. The increment of discharge varies considerably in

different floods due principally to changes in the slope of the river caused by variations in relative contributions by the tributaries. Studies on this subject are still in progress, but it is believed that the following discharges can be taken as fairly safe: (*a*) 65 000 sec-ft. at Cairo; (*b*) 80 000 sec-ft. at the mouth of the Arkansas River; and (*c*) 75 000 sec-ft. at the mouth of the Red River. The last quantity is a joint increment for the Lower Mississippi and Atchafalaya Rivers.

TABLE 23.—NET MAXIMUM FLOOD DISCHARGE AS REDUCED BY RESERVOIRS, IN SECOND-FEET.

Division.	1912.	1913.	1922.	1927.	Minimum.
Ohio	195 000	210 000	200 000	140 000	140 000
Upper Mississippi	80 000	85 000	80 000	95 000	80 000
Missouri	140 000	90 000	90 000	110 000	90 000
Total at Cairo	415 000	385 000	370 000	345 000	345 000
Arkansas Group	120 000	45 000	130 000	250 000	45 000
Total at mouth of Arkansas	600 000	340 000	500 000	600 000	340 000
Red River Group	20 000	8 000	35 000	50 000	8 000
Total at mouth of Red River	430 000	250 000	420 000	450 000	250 000

Table 24 shows the approximate dependable effect reservoirs would have had in reducing maximum flood heights that have heretofore occurred.

TABLE 24.—EFFECT OF RESERVOIRS IN REDUCING MAXIMUM FLOOD HEIGHTS.*

Division.	At Cairo, in feet.	At mouth of Arkansas River, in feet.	At mouth of Red River, in feet.
Ohio	2.15	1.75	1.88
Upper Mississippi	1.23	1.00	1.08
Missouri	1.88	1.12	1.21
Total at Cairo	5.30	....	....
Arkansas Group	....	0.56	0.61
Total at mouth of Arkansas River	....	4.25	....
Red River Group	....	....	0.11
Total at mouth of Red River	....	....	3.36

* The total effect of several divisions on the same gauge is not the same as the sum of their effects on that gauge.

The estimated cost of reservoirs to produce this lowering of gauge heights is $1 313 000 000.

In Table 25 is shown the cost of reducing the Mississippi River discharge 1 sec-ft. by reservoirs in each of the five divisions.

The studies of other boards working on the Mississippi flood protection problem indicate that it is feasible to protect the valley against the maximum probable flood by levees, spillways, and by-passes, which means that reservoirs are not essential to a Mississippi flood project and, consequently, their adoption or rejection should rest on their economic value. The studies have not reached a point where final results can be given; but an estimate has been made of the difference in cost of protecting the valley by levees against the

maximum probable flood and against a flood of 300 000 sec-ft. less. The results are probably higher than the cost of any alternate method that might be adopted, such as the provision of a by-pass through Tensas Basin, or of a large amount of storage in St. Francis Basin. The results are given in Table 26.

TABLE 25.—COST OF REDUCING MISSISSIPPI RIVER DISCHARGE 1 SECOND-FOOT BY RESERVOIRS.*

Division.	Reservoir capacity, in acre-feet.	Cost of reservoirs.	Dependable reduction, in second-feet.	Cost per second-foot of reduction.
Ohio	29 200 000	$543 000 000	140 000	$3 870
Upper Mississippi	17 400 000	305 000 000	80 000	3 800
Missouri	32 700 000	232 000 000	90 000	2 590
Arkansas Group	23 500 000	201 000 000	45 000	4 490
Red River Group	8 700 000	32 000 000	8 000	4 020

* Reservoirs in the Arkansas and Red River groups reduce the flow only in that part of the Mississippi River lying below them, respectively.

From Table 26 it appears that a reduction of flow at Cairo by 1 sec-ft., is worth $860. The cost of obtaining it by reservoirs on the Ohio would be $3 870, or 4.5 times as much; on the Upper Mississippi, $3 800, or 4.4 times as much; and on the Missouri, $2 590, or 3 times as much.

TABLE 26.—SAVING IN COST OF FLOOD PROTECTION BY LEVEES DUE TO A REDUCTION OF 300 000 SECOND-FEET IN MAXIMUM FLOOD FLOW.

Part of river.	Estimated cost.	Cost per second-foot of reduction.
Cairo to mouth of Arkansas	$ 27 000 000	$ 90.00
Mouth of Arkansas River to mouth of Red River	192 000 000	640.00
Mouth of Red River to Gulf	39 000 000	130.00
Total	$258 000 000	$860.00

A reduction in the discharge of the Arkansas group of 1 sec-ft., is worth $640 plus $130, or $770. The cost of obtaining this by reservoirs is $4 490, or 5.8 times as much. A similar reduction on the Red River group is worth only $130 and the cost of obtaining it by reservoirs is $4 020, or 31 times as much.

This relation can also be set up by comparing the cost of an acre-foot of storage with the cost of an equivalent amount of protection by levees. Table 27 shows such a comparison.

Columns (5) and (6), Table 27, show the costs, which should be compared with the values in Column (4). It appears that only in the Upper Mississippi Division are any reservoirs found the cost of which is less than their computed values for flood protection. Four such reservoirs are found in that Division. Their combined capacities total about 846 000 acre-ft.; and they would lower

the gauge height at Cairo about ¾ in. A further analysis of them is being made to see what would be the effect on other interests of taking these reservoirs for Mississippi flood protection.

TABLE 27.—COMPARISON OF COST OF AN ACRE-FOOT OF STORAGE TO COST OF EQUIVALENT LEVEE PROTECTION.

Division. (1)	Value of 1 sec-ft. (2)	Acre-feet required for 1 sec-ft. (3)	Value of 1 acre-ft. (4)	Average cost of 1 acre-ft. (5)	Cost of 1 acre-ft. in cheapest reservoir. (6)
Ohio	$860	208	$4.13	$18.60	$6.00
Upper Mississippi	860	217	3.96	17.50	2.50
Missouri	860	364	2.36	7.10	4.22
Arkansas Group	770	522	1.48	8.60	3.94
Red Group	130	1 087	0.12	3.70	1.97

The studies of the Board have shown that many reservoir sites have an economic value for local use that is greater than their value for Mississippi flood protection, so that before any reservoirs are appropriated exclusively for such protection, a careful analysis should be made to ascertain what the effect of this action would be on local interests. On the assumption that the best interests of the country will be served only when reservoirs are used to produce their maximum economic value, it may be concluded that if reservoirs have a large potential local value they should not be lightly appropriated for exclusive Mississippi flood use. It has been found that operation of reservoirs for local purposes will generally greatly reduce their value for Mississippi flood protection, and, in fact, may even make that value a negative quantity, as already shown in the case of the Miami Conservancy Reservoirs and the reservoirs at the head of the Mississippi.

The costs of reservoirs noted in this paper are the total costs as estimated by the District Engineers. In some cases benefits would result to other interests, which might somewhat reduce the costs to be charged to Mississippi flood protection. The estimates of such benefits are not yet complete, but the indications are that, while they may justify further analysis of a few reservoirs, they will not materially change the general results.

RESERVOIRS FOR COMBINED USE

In addition to the studies of reservoirs to be built and operated primarily for Mississippi flood protection, the Board has made extensive studies of the results to be obtained should reservoirs be built and operated for their greatest economic value, considering all uses. Obviously, the time and funds available were not sufficient for completing such studies for all the streams in the Mississippi Drainage Basin. There are almost an infinite number of ways in which any stream can be developed and operated. The Board, therefore, concentrated its efforts on the streams on which other interests had proposed

and studied developments. The results of its studies are not yet (October, 1927), in such shape that a complete digest of them can be presented; but some of the results can be indicated.

In general, it appears that the value of reservoirs for local flood protection, irrigation, power, or navigation, or for a combination of such uses, is much greater than their value for Mississippi flood protection. In other words, Mississippi flood protection, if proper weight be given to economics, will generally be a minority interest in reservoir development, and the practical question arises as to how far a minority interest can go toward securing participation of the majority interests. Such an undertaking can be accomplished in only two ways: Either the minority interest must wait till the majority interest is ready to proceed, or it must undertake the financing for both interests and assume the risk of being able to dispose profitably of the majority interest after development is made.

There may be some streams on which the majority interests will be ready to proceed before the Mississippi flood project is carried out, and on such streams it may be practicable to secure a certain amount of Mississippi flood protection by contribution commensurate with its value. On the other hand, the need for such protection is immediate, and its cost, at best, promises to burden the Treasury with all or more than it should properly bear. There will doubtless be advocates ready, as in the past, to use the urge for Mississippi flood protection as a means to induce the Federal Government to undertake comprehensive projects for complete development of some or all of the streams, regardless of what proportion of the benefits may accrue to flood protection. Such projects should be studied and treated on their own merits, with due consideration to all interests; and it is to be hoped they will not be permitted to delay action on a Mississippi flood project should it not include them.

Thus far, the Board has found no reservoir projects that it feels justified in recommending for combined development, but, as stated previously, it recognizes that such projects may develop before the Mississippi flood project is too far completed to make use of them. At such time, it will not be difficult to reach a conclusion as to what use can be made of them.

Otherwise than those mentioned, it is believed that dependable benefits to Mississippi floods that may result from the development of reservoirs for combined uses, will not be large and that they should be counted on solely as contributing to the factor of safety on whatever Mississippi flood project is adopted. The Board is endeavoring to arrive at a measure of the probable benefits to Mississippi flood protection should the maximum economic development of all streams in the drainage basin be accomplished. At best, such an estimate cannot be accurate and perhaps the nearest approach to an answer will come from determining the effect on Mississippi floods of equating the flow of the tributaries as nearly as the available reservoir capacities will permit. From the studies to date (1927), it appears that it may not exceed 10% of the effect of the same reservoirs used primarily for Mississippi flood protection.

Valley Reservoirs

In addition to reservoirs on tributaries, the Board was charged with the duty of determining whether any feasible reservoirs could be found in the Valleys of the Mississippi and Ohio themselves.

The results of the studies on this subject are not yet completely available, but it appears that reservoirs could be built on the main river at Commerce, Mo., in the St. Francis Basin, at the mouth of the Yazoo, and in a few other places. No practicable reservoir sites were found in the main Valley of the Ohio.

The cost of the reservoir at Commerce, Mo., appears to be too great to make it feasible at this time, even when credited with all possible benefits from power navigation. The reservoirs at the mouths of the lower tributaries, such as the Yazoo, do not offer much promise. The St. Francis Basin offers the best reservoir possibilities in the valley. To create a reservoir there, however, will drown out several towns and necessitate the relocation of many miles of railroad and highway. The estimates of the flowage damages are not yet complete, and until available, no opinion as to the feasibility of the project is justified.

To conclude, the prospects for reservoirs as a part of a Mississippi flood project, are not very good. One after another of the possibilities have "washed out" till practically nothing is left, except certain relatively small reservoirs on the Upper Mississippi and certain reservoirs in the Mississippi Valley proper or at the mouths of the principal tributaries and even they do not look very promising.

The Board, urged on by the Chief of Engineers, has used every effort to find feasible reservoirs. Its studies have been far-reaching and while the limited time available has made it necessary to adopt certain "short cuts" and approximations, it is the writer's belief that the results will be sufficiently accurate to permit a dependable determination of the extent to which reservoirs may enter into the Mississippi flood project to be adopted.

THE BASIS OF THE CASE AGAINST RESERVOIRS FOR MISSISSIPPI FLOOD CONTROL

By Arthur E. Morgan,* M. Am. Soc. C. E.

There has been a fifty-year controversy between the proponents of reservoir control and of levee control for Mississippi floods. The writer is not attempting to settle that issue. He does not know the aggregate possibilities for reservoir control, and any estimate made without very extensive and thoroughgoing investigation can be but a guess.

It is a fundamental axiom of sound engineering that when great issues are at stake, no conclusion of large importance should be left to chance. Actual and definite studies of actual cases are necessary. Until they have been carried to a point where, as nearly as is reasonably possible, all major possibilities have been conclusively determined, there is no adequate basis for far-reaching engineering policy.

If, as is contended by the members of the Mississippi River Commission, the case against reservoir control for the Mississippi has been properly established, it is because a definite study of the matter has been made, and because a conclusion has been reached in accordance with the evidence. The transmission of an authoritative dogma from one generation to another will not suffice. Somewhere along the way that authoritative doctrine must have been established by scientific methods, and those methods and results must be subject to re-examination.

The writer decided that the best contribution he could make to this discussion was to try to discover the exact nature of the evidence which has led the Mississippi River Commission to reject reservoirs. He has read a vast amount of literature on the subject, especially the writings of members of the Commission and of Army Engineers, and he has constantly watched for references to other and authoritative opinions and reports.

The whole controversy has been clouded by two factors. First, it has been made to appear as an issue of levees *versus* reservoirs, on the assumption that they are mutually exclusive.

Such is not the case. In a great problem like that of the control of the Mississippi it would be almost miraculous if 100% of the desired results could be achieved by only one method. The real problem is to discover and appraise all possibilities, and then, by careful analysis and synthesis, to design a total improvement in which each method is introduced to whatever degree is most effective and economical. If even 10% of the desirable results can be secured by each of two or three other methods, then control by levees may be reduced to far more manageable limits.

So far as the writer can discover, up to 1927 this attitude of endeavoring to work out a solution that will use all desirable methods never has been taken by the Mississippi River Commission, but rather the attitude of an armed camp in the battle of levees and revetment against all other methods of control.

* Pres., Antioch Coll.; Pres., Dayton Morgan Eng. Co., Dayton, Ohio.

Second, great confusion has been brought into the controversy by the absence of a basis for comparison. There frequently has been a general admission that reservoir control would be preferable to levee control if it were economically as feasible. To determine that levee control is less expensive it is necessary to know approximately what each would cost. Now, neither of these costs ever has been adequately determined. The Mississippi River Commission estimates of the discharges to be provided for by a levee system, and of the works ultimately necessary, always have been made by arbitrary "practical" methods, which by all the laws of probability were bound to fail. The writer agrees with the statement of N. C. Grover, M. Am. Soc. C. E., that students of hydrology have long known that a flood of the magnitude of that of 1927 was inevitable.* The failure to recognize flood possibilities is one of the causes of inadequate estimates.

That the official estimates have been presented to the public as the full cost of levees in a program of complete protection, there can be no doubt. The report of the Special Engineering Board of 1874-75, which led to the establishment of the Mississippi River Commission, largely established the policies by which it has been controlled. This report indicated a cost of less than $46 000 000 for complete control by levees.

The late H. M. Chittenden, M. Am. Soc. C. E., at one time Chief of Engineers U. S. Army, formerly was a recognized authority of the Army Engineers against reservoirs. In deciding against reservoir control on the basis of cost, he referred to the report of the Mississippi River Commission for 1896, as authority for the statement: "Take $40 000 000 and reinforce the entire levee system of the Mississippi. That will make it impregnable. * * *"†

In 1896 the levee system was only well begun. If $40 000 000 would make it impregnable, then it was almost certain that reservoir control would be more expensive.

In the 1896 report of the Chief of Engineers, U. S. Army, the estimated cost of complete protection by levees is $18 000 000. In 1912, the President of the Commission stated that $73 000 000 was ample to do all remaining necessary work.‡ In 1922, a member of the Commission stated:§

"There is no uncertainty as to the outlay that will be necessary to * * * complete flood control * * * neither is there material uncertainty as to the grade line to which the levees must be constructed * * * no increase in height is now contemplated, except to meet local conditions such as are due to shifting of the channel through chutes or cut-offs."

In 1924 the Chief of Engineers stated‖ that 90 000 000 cu. yd. would complete the work. In 1925, in an article entitled, "Why the Mississippi River Commission Sticks to the Policy of Levees Only",¶ the President of the Commission stated:

---

* See p. 694.

† *Transactions*, Am. Soc. C. E., Vol. LXII (1909), p. 304.

‡ *Engineering Record*, October 26, 1912, Vol. 66, p. 471.

§ *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1479.

‖ *Loc. cit.*, Vol. LXXXVII (1924), p. 976.

¶ *Engineering News-Record*, Vol. 94, p. 513.

"There are now completed or nearing completion 1 824 miles of levee line on the Mississippi River, containing 429 000 000 yards of earth, and requiring about 76 000 000 yards to finish it. That would have been the end of the Commission's levee building but for the fact that Congress has recently extended the Commission's jurisdiction to the tributaries and outlets. * * *"

Year by year the Commission has reported the approach of the levee system to final completion. Under the heading "Effect of Improvement", the Commission formerly reported:*

"It may be stated that in a general way the improvement [of the Mississippi] is providing a safe and adequate channel for navigation and is now in condition to prevent the destructive effects of floods in all except the most extreme high waters. * * *"

For the past three years, beginning with the report of 1924, this qualifying clause has been omitted, and the statement reads: "* * * is now in condition to prevent the destructive effects of floods".†

The writer believes he has quoted enough to indicate that the estimates of the Mississippi River Commission have been inadequate. These estimates of the cost necessary to complete the levee system seldom have been more than 20% of the true cost, and sometimes less than 10 per cent. The writer believes that this extreme inadequacy of its estimates has rendered difficult, if not impossible, any dependable comparison between the cost of levee protection and reservoir protection.

On the other hand, until recently there has not been even a remote effort on the part of the Commission to discover and to estimate the cost of the most favorable opportunities for reservoir control. Thus, there is the remarkable situation of fifty years of insistence of the superiority of levees over reservoirs, without a thorough-going engineering analysis of the cost of either.

Perhaps, however, the members of the Mississippi River Commission are so thoroughly informed concerning the principles and facts of reservoir control that their informal judgment is sufficient. The writer has searched their writings of nearly half a century to find evidence of that clear understanding, but he finds it to be almost completely lacking. They have many times given their reasons for rejecting reservoirs, the more important of which will be mentioned.

In 1912, the President of the Mississippi River Commission stated:‡ "To control the flow of every stream in the Mississippi Valley by reservoirs is a pretty large job, even for the United States Government, but that is what the control of the Mississippi during floods by reservoirs signifies." This statement, of course, is incorrect. A similar impression is repeatedly given by referring to the vast drainage area of 1 250 000 sq. miles to be controlled. In fact, although the Ohio drains but one-third of the drainage area of the Mississippi above Cairo, Ill., and but 16% of the drainage area of the whole river, it delivers from 55 to 85% of the flood waters that pass Cairo. The control of that third of the water-shed above Cairo would go far toward furnishing all the control necessary at Cairo, and for a considerable distance

* Rept., Chf. of Engrs., U. S. Army, 1923, Vol. I, p. 1862.
† *Loc. cit.*, 1926, Vol. I, p. 1793.
‡ *Engineering Record*, Vol. 67, May 3, 1913, p. 506.

below. These men reiterate that the Ohio supplies only a third of the total annual run-off at Cairo, as if that statement were significant. The fact that it delivers 55 to 85% of the flow of great floods at Cairo is the important item.

In 1922, another member of the Mississippi River Commission stated* that "this shifting of the locus of great floods over such great areas prevents reservoir control." In illustration he mentions five floods as originating in the Ohio and the floods of 1844 and 1903 as originating in the Mississippi above Cairo. This statement is misleading, for both the floods he mentioned as coming from the Mississippi above Cairo, although they were the two record floods on the upper river before 1927, did not furnish enough water to be of importance below the mouth of the Ohio. The 1903 flood, which did such damage below Cairo, was not the summer flood from the Upper Mississippi, but a spring flood from the Ohio.

The public is repeatedly informed that the Commission and the Army Engineers know the value and limitations of reservoirs because they built and operate those on the Upper Mississippi in Minnesota.† These Minnesota reservoirs referred to by both friends and enemies of reservoirs as "the greatest system of reservoirs in the world", have practically no significance in the problem of flood control for the Mississippi, except to a minor degree within the State of Minnesota. They control an exceedingly small part of the total flow, and are too far removed from the lower river to have any appreciable effect on floods. What the Mississippi River Commission has learned about flood control by the operation of the Minnesota reservoirs is nothing of importance to the lower river.

This same President of the Commission makes a statement that is frequently repeated by the Army Engineers, and has been taken by them almost as an axiom. It is that, because of the lack of sites lower down, flood-control reservoirs must be limited to the head-waters of streams.‡ Flood-control reservoirs are best located low down on the streams, as nearly as possible just above the property they are to protect. Contrary to the frequently repeated statements of the members of the Mississippi River Commission, suitable sites low down on the main tributaries probably do exist.

Many engineers look back to the classic paper against reservoirs by Gros, Inspector-General of the Department of Bridges and Roads of France, in which the same assumption was made that dams must be limited to head-waters. This being almost the only European paper on the subject published in the American technical press until recent years, it is almost the only one referred to in their discussion.§

This paper, first published in 1881, was then reasonably sound in view of the existing limitations of dam design, although it is partisan. In those days French dams must be of cut-stone masonry, founded on solid rock. To-day,

* *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1462.

† *Engineering Record*, Vol. 66, p. 470; *Engineering News-Record*, Vol. 94, p. 557.

‡ *Transactions*, Am. Soc. C. E., Vol. LXII (1909), p. 351; *Engineering Record*, Vol. 66, p. 470.

§ *Engineering News*, Vol. 25, March 14, 1891, p. 258

some of Gros' most serious objections are of small importance. The dams of the Miami Conservancy District would have been totally beyond his horizon. Engineering design has been revolutionized, and the valleys of large rivers often furnish safer and better sites for great dams than the head-waters.

A far more important French discussion of about the same period is that by Lechalas in "River Hydraulics", published in Paris in 1884,* although it, too, is partly obsolete.

The assumption that sites for flood-control dams can be found only on head-waters permeates the thinking and writing of the Army Engineers and members of the Mississippi River Commission, and largely destroys any value their studies might otherwise have had.

A President of the Mississippi River Commission, who served as Chairman of the Special Committee on Floods and Flood Prevention of the Society, states that all the reservoirs of a certain suggested system on the Upper Ohio would hold the total flood flow of the Mississippi for only one day, and that, as a flood may last forty days, it is implied that forty times as much reservoir capacity would be necessary.† This kind of reasoning is found throughout the discussions of members of the Mississippi River Commission. It represents one of the defects in the current reasoning on the subject. Even in the great flood of 1927, a holding back of 20% of the total flood flow probably would have been more than adequate. While the excess flow at the crest of the flood may be one-half or more of the total flow, the crest flow lasts for only a small portion of the total flood period. It should be recognized, however, that reservoir storage never can be perfectly timed to hold back the crest only, and that therefore reservoirs seldom operate with the highest theoretical efficiency.

Members of the Commission and Army Engineers repeatedly state that reservoirs on the Ohio System would soon fill with silt and be useless,‡ yet a careful study by Stabler, with reference to a proposed system of reservoirs on the Ohio, indicated that if all the silt above them were held, they would lose less than 10% of their capacity in 700 years.§ In flood-control retarding basins like those of the Miami Conservancy District, not more than one-third of the annual silt load is held in the basins, so that the life of a retarding basin on the Ohio would run into thousands of years before 10% of its capacity would be lost.

Another member of the Mississippi River Commission states,‖ "Nature has greatly simplified the problem of flood control by making the drainage of the flooded lands, in the larger basins, comparatively simple." Yet it is a fact that there are few more difficult problems of drainage and flood control than are found in these same basins. In the great St. Francis and Yazoo Basins there are four or more streams emerging from the hills, each of which has a maximum flood flow of 100 000 to 150 000 cu. ft. per sec., with an initial

* "Théorie Général des Réservoirs d'Emmagasinement des Crues" from "Hydraulique Fluviale," by Lechalas, p. 434, Baudry et Cie., Paris, 1884. The Dayton-Morgan Engineering Co. has a translation of this article, prepared by K. C. Grant, M. Am. Soc. C. E.

† *Engineering Record*, Vol. 66, p. 471.

channel capacity in the basin of less than 3% that amount. Control of these streams by reservoirs is feasible and probably is the only feasible method within reasonable cost. Such reservoirs would help solve the general Mississippi problem, and without them much of the land protected by levees will still be subject to destructive local flooding after the great river is controlled. In the writings of the Army Engineers and of the Mississippi River Commission for forty years one finds scarcely a hint of this great problem. It nearly always has been ignored in their general plans.

Repeatedly, the objection is made that reservoirs must not be built because of the valuable farm land that would be flooded. In all the discussion of the subject by members of the Commission one sees no inclination to offset this loss by the gain of a greater area of fertile land along the Mississippi between the river channel and the levees. In referring to the valuable storage along the river, a President of the Mississippi River Commission states that the levees are "several miles apart", the river channel being somewhat less than a mile wide; but while he denounces the waste of land by reservoirs, he does not mention this greater loss of fertile land along the river. Much of the reservoir area would be river bed or rough wooded hillside, whereas most of the land along the Lower Mississippi between the river channel and the levees is very fertile, sandy loam. In this item, which is repeatedly referred to as a controlling objection, the gain by reservoirs would wholly or largely offset the loss in the reservoir areas.

The Miami Conservancy Basins have been in operation eight seasons. All the bottom-land above the dams continues to be farmed, and only a small fraction of 1% of the crops planted in them has been lost by the operation of the dams. The lands increase in fertility through the deposit of silt in early spring floods, and steadily increase in productiveness. The sweeping generalizations of members of the Commission on this point are unsound.

Repeatedly, the members of the Commission and Army Engineers condemn reservoirs because of the danger of failure of dams. This objection does not run against flood control alone, but against water supply, irrigation, and power development as well. Well-built dams are a permanent part of present civilization.

The disorganization of highways, railroads, and towns is repeatedly given as a conclusive objection to flood-control dams. Until definite studies are made these indefinite misgivings have little value in determining policies.

For the plans of the Miami Conservancy District, storage space was needed on the Mad River. The best dam site available was across a flat valley nearly a mile wide, with gravel and sand a hundred feet deep below the surface. Two important trunk-line railroads crossed the dam site and traversed the length of the valley almost at water level, with a ruling grade of only 0.2 per cent. An electric line paralleled the two railroads, although with more tolerance as to grades, and an old established town of 1 200 people was in the proposed basin. Main-line and branch highways crossed the site from end to end. Yet it paid to overcome all these difficulties and to build a dam on that site in order to supply only one of the seven major elements of a local improvement.

When one comes to face the Mississippi River problem in its entirety it may be found desirable to retard flood flows by the construction of dams under even greater difficulties and on a far larger scale.

Unsanitary conditions above dams are continually emphasized. The Miami Conservancy dams have not caused such conditions, and the storage areas in the Adirondacks are among the chief playgrounds of the nation. Floods have far more unsanitary effects in the low areas of Ohio River towns, and these conditions might be relieved by reservoirs.

It has been contended by Army Engineers that reservoirs would have to be paid for by the National Government, whereas flood control must be paid for locally. Their own policy on this point now seems to have changed.*

The dams of the Miami Conservancy District are repeatedly referred to as indicating the cost of reservoir flood control for the Mississippi. To secure the local benefits desired these dams could be built only above Dayton and Hamilton, Ohio, and mostly in a region thickly settled and traversed by many railroads and highways. More than a hundred public utilities were interfered with on that project. The President of the Mississippi River Commission† assumes that the whole cost of the Miami System was for dams and retarding basins, whereas a very considerable part was for channel control and levees. The high cost of channel improvement through the cities on that project could be used as an argument against levees and revetment as well as the cost of storing water can be used against reservoirs. For flood control on the Mississippi a much greater range of choice would exist. Even on the Miami River, a similar amount of storage for flood control on the Mississippi probably could have been secured at a far lower cost per acre-foot, and there would be a large amount of storage available. The writer is of the opinion that vast storage capacity is available well down on the Ohio and its main tributaries at a much lower cost than that of the Miami Conservancy District. Storage in the Miami Conservancy project cost about $18.00 per acre-ft., as compared with $2.65 per acre-ft., as an average for U. S. Reclamation Service projects.

The Miami dams were built for local flood control, and serve that purpose primarily. If they had been in operation during the 1913 flood they would scarcely have affected the flood stage exactly at the mouth of the Miami; but, because of the nature of the flood crest, due to increments lower down the Ohio, they would have reduced the crest stage at and below Louisville perhaps a foot. If the same dams with the same storage had been designed for Ohio River flood control they would have lowered the flood stage on the Ohio 3 to 5 ft. in a flood like that of 1913. The Miami Conservancy dams are more massive and more safely built than is customary, and would be adequate for any type of operation, so far as their strength is concerned.

The writer came to have an intimate acquaintance with the late General Chittenden and feels free to refer to his writings because he has known but few engineers for whose intelligence and intellectual integrity he has had such high regard, and because General Chittenden was recognized as an authority on this subject.

* *Engineering News*, Vol. 60, p. 378, October 8, 1908.
† *Engineering News-Record*, Vol. 94, p. 557.

In a paper delivered before the Society in 1908* he gave his reasons for disbelieving in the value of reservoirs for flood control. He refers to a system of "automatic reservoirs" proposed by the French Government on the Rhone about 1856. Evidently, he received his information from the previously mentioned paper by Gros, a translation of which had been published.† These reservoir dams were to have open outlets, not capable of being closed, and were intended to restrain only a part of the flow. General Chittenden apparently dismissed this type of reservoir on the authority of this article.

When exactly this same type of flood control was proposed for the Miami Valley in Ohio, General Chittenden was asked to review the plans, as he was the ranking authority in opposition to reservoir flood control. After long and intensive study, he approved the Miami Conservancy program unqualifiedly, and became one of its strongest public advocates. Either the proposed French dams were not properly designed, or their limitations did not apply to certain American conditions.

Seventy-five years ago European engineers did not think on the modern scale. Methods of earth dam construction that now are fully tested were then unknown, and some sites then rejected would now be looked upon as exceptionally desirable. Projects costing $10 000 000 or $20 000 000 are referred to as too vast for accomplishment by the French Government. It was the day of small undertakings.

Later, in the paper by General Chittenden, occur these statements:

"The best reservoir site is a natural lake. * * * A natural lake, wholly uncontrolled at its outlet, may have a more effective control of the outflow than an artificial reservoir of equal superficial area when full, although of far greater capacity between high and low water. * * * if the artificial reservoir has reached the limit of its allowable filling, the outflow must be made equal to the inflow. If this limit is reached before or at the time of maximum run-off, then a quantity equal to this run-off must be let out of the reservoir. This contingency can never happen in a natural lake."

At the time General (then Colonel) Chittenden read this paper, very little study had been made of flood-control reservoirs. It is now known that the limitations of artificial regulation, which he mentions as inherent, simply represent imperfect design. General Chittenden himself fully recognized this in his studies of the Miami River problem. No natural lake is ever so good as a medium of flood control as the same body of water would be with a properly designed outlet.

Further on, in the same paper, he states:

"Every reservoir built for the purpose of flood protection alone would mean the dedication of so much land to a condition of permanent overflow in order that three or four times as much might be redeemed from occasional overflow. * * * The cost, coupled with the loss of so much land to industrial uses, would be far greater than that of levees or other methods of flood protection. * * * The construction of reservoirs for flood protection is not, therefore, to be expected, except where the reservoirs are to serve some other purpose as well."

* *Transactions*, Am. Soc. C. E., Vol. LXII (1909), p. 287.
† *Engineering News*, Vol. 25, p. 258, March 14, 1891.

Here, again, the design of flood-control dams which General Chittenden had before him for criticism was inadequate and inefficient, and has been superseded by more suitable design.

Some of the faults and limitations pointed out by General Chittenden in the design and operation of the Mississippi reservoirs in Minnesota are not inherent, as he implies, but are due to improper design or operation, or to conflict of interest resulting from an effort to make them serve more than one purpose. In his discussion of proposed reservoirs on the Sacramento and Kaw Rivers, and in his quotations from other sources, incorrect design is assumed, which largely vitiates his argument.

At the time the Miami Conservancy flood-control dams were being planned, only two flood-control dams could be found in the United States. One of these controlled a local brook, and the design of the other was so primitive and inefficient that it must largely fail of its purpose. Such was the inadequate data on which General Chittenden and his contemporaries had to work.

That General Chittenden had been unconsciously indoctrinated by the standard creed of the Mississippi River Commission on flood control, and that he only gradually freed himself, is indicated by the following comment by him when he was criticizing the traditional position of the Commission on the matter of outlets: "The writer feels the more freedom in criticizing the Committee's treatment of this matter because he is at the same time criticizing his own previous utterances on the same subject."*

After his long study of the Miami Conservancy plans General Chittenden approved the methods he formerly had condemned, and his last professional effort was a contribution to the *Transactions* of the Society pleading for an open mind on the subject.

At the beginning of the Miami Conservancy studies the writer had the same convictions as those of the Mississippi River Commission. He was certain, on the authority of the Mississippi River Commission and the Army Engineers, that reservoirs were not feasible for flood control.

On the Miami Conservancy project the possibility of reservoirs was examined simply to carry out the sound engineering policy of examining into every possibility, no matter how remote. The writer had very vigorously expressed his disbelief in reservoir flood control to the Flood Prevention Committee at Dayton. When the evidence forced him to change his views, no one was more surprised than he. At the beginning of that project not more than two or three men in a large engineering force believed in the possibility of flood control by dams. At the end every one was convinced.

Even then the writer's faith in the doctrines of the Mississippi River Commission was only slightly shaken; reservoir control could be good only on small streams. Only recently he wrote an article on the Mississippi,† in which he criticized the Mississippi River Commission, but assumed it to be substantially right in the matter of reservoirs.

In the preparation of the present paper, however, he has hunted assiduously for those deep researches and critical studies so often referred to by the Mis-

* *Transactions*, Am. Soc. C. E., Vol. LXXXI (1917), p. 1269.

† *Atlantic Monthly*, November, 1927.

sissippi River Commission and by the Army Engineers. To his astonishment, he finds they never have been made. Repeatedly there is positive assertion and the attitude of great authority and always a complete lack of any adequate engineering analysis.

Following back to original sources one finds the obsolete French article before referred to, and the report of the Engineering Board of 1874 which led to the establishment of the Mississippi River Commission. In this report, so often referred to as authoritative, may be found expressed a fundamental misconception of the proper operation of flood-control dams, followed by the following conclusive remarks:*

"The question of absolute practicability [of flood control reservoirs] could only be decided by a series of extensive and elaborate surveys, for which neither funds nor time were available, nor in the opinion of this Commission are they needed. Here, as elsewhere in the valleys, this plan, as an efficient means of restraining the floods of the Mississippi, is chimerical."

(This was the Board which estimated the total cost of complete protection by levees at $46 000 000.)† A discussion by the late W. Milnor Roberts,‡ M. Am. Soc. C. E., to prove that reservoirs are not feasible is repeatedly referred to, and is mentioned as disposing once for all of the reservoir theory. Yet, on examining this article one finds no discussion and no conception of modern flood-control reservoirs. His discussion is obsolete. Coming down from that early date to recent years one of the last affirmations of the attitude of the Mississippi River Commission may be found in the report of the Special Committee on Floods and Flood Prevention of the Society. The Chairman of this Committee was President of the Mississippi River Commission, and the report presents the orthodox Mississippi River Commission attitude, with slight concessions and some caution. In deciding against reservoirs and in favor of levees this Committee states that for rivers like the Mississippi and the Colorado, levees "afford the only sure means of flood control."§ These are the only two streams particularly mentioned, and yet, to-day, only ten years later, engineers familiar with the situation generally recognize that to a considerable degree reservoirs do offer a sure means of flood control on the Colorado.

William Kelly, Colonel, Corps of Engineers, U. S. A., M. Am. Soc. C. E., in 1924, definitely recommended reservoir flood control for the Colorado River. He states that‖: "Storage for flood control is justified to a quantity that will reduce the maximum discharge for any year of record to 75 000 sec-ft."

The writer has not presented simply a few weak points from the arguments of the Mississippi River Commission. He has presented practically all the arguments it has offered. So far as work done before 1927 is concerned, the adequate scientific study of reservoirs, so often referred to by members of the Commission, in fact is entirely a myth.

In view of the great variety of topographic and other conditions over the drainage area, it seems probable that an exhaustive study may show this

* Report of Special Board of Engineers of 1874–75, Pt. I, p. 541.
† *Loc. cit.*, Pt. I, p. 563.
‡ "Practical Views on the Improvement of the Ohio River," *Journal*, Franklin Soc., 1857.

‖ *Loc. cit.*, Vol. LXXXVIII (1925), p. 323.

method of flood control to have some proper part, if only a very limited one, in a well-considered general plan. Dependable conclusions must come from thorough study of particular cases.

In discussing suggestions that have been made by the advocates of flood control on the Mississippi by means of reservoirs, the writer finds his attitude is not that of unqualified approval. There have been many suggestions for such control, but not many of them have been worked out in detail.

One of the most carefully planned projects is that of a proposed system of reservoirs above Pittsburgh, Pa. The writer has not kept informed of that situation since the publication of the voluminous report of the Pittsburgh Flood Commission about 1910. An examination of that report, together with numerous conferences with some of those most directly responsible for its preparation, led him to the opinion that in this case the difficulties in the way of combining storage for power, flood control, and navigation in the same space would be difficult to overcome, because of inability to foretell rainfall and run-off conditions, and from the impossibility of operating gates to harmonize the demands of flood control and power development.

The difficulty of knowing when to store water for power and when to reserve storage capacity for floods is illustrated in the case of the Miami River in Ohio. In March, 1913, there was an average rainfall of 10.4 in. over the Miami water-shed above Dayton; in March, 1915, only 1.4 in. Floods come too suddenly to provide storage capacity for them by emptying reservoirs after a heavy rain has fallen, and under such variable climatic conditions it would be impossible to tell when to keep the reservoirs full for power development, and when to keep them empty for flood control. There are many cases where the two purposes can be combined, such as the proposed Boulder Canyon Dam, but popular optimism in the matter is not well grounded.

One of the chief resources of the Mississippi River Commission in its battle against reservoirs has been this weakness with which the case in favor of reservoirs has been advocated, especially by other departments of the National Government. The case in favor of reservoir flood control sometimes has been presented with an irresponsible optimism, with an unconcern for the absence of dependable information, and with a disregard of difficulties, that is disconcerting. If one is planning a military campaign it is good strategy to exploit the enemy's weakness to the utmost. Where the aim is not to overcome an opponent, but to find the truth, a different course is indicated. One of the most valuable proposals the writer ever received was from an engineer who was so visionary and impractical that he could by no means be trusted with its execution. The Mississippi River Commission might profit in the same manner from the suggestions of its adversaries.

The matter of reservoir control is a technical one and cannot be mastered except by the same kind of skillful, thorough-going, and definitely directed study that is necessary for the mastery of any difficult technical problem. No happy inspiration, no casual sallies into the field, like those of enthusiastic advocates of reservoir flood control, and no blind loyalty to a traditional cause, like that of the Mississippi River Commission, can bring dependable results. The Mississippi River Commission seems to have trusted to the advocates of

reservoir flood control to make a sufficient presentation of the case for reservoirs. The Army and the Commission have practically controlled the purse strings for the Mississippi. An adequate analysis of the problem would require years of time and very considerable funds for the accumulation and analysis of data, and the Army Engineers or the Mississippi River Commission have been the only agencies with power to secure the necessary funds.

The Commission is to be criticized, not for failure to understand the issue quickly, but for ignoring it, and for letting the years of its stewardship pass without a definitive study of the entire Mississippi problem.

In case there should be opportunities for Mississippi flood control by means of reservoirs, where might the sites be found? In the writer's opinion they most probably would occur just above the mouths of the main tributaries, such as the Yazoo, the Red, and the Arkansas Rivers, where present back-water conditions probably should be continued, and on these main tributaries and their branches, probably not more than 200 or 300 miles from the Mississippi. The greatest benefit would be expected from a few large projects, rather than from many small ones.

The writer believes that there may be opportunity for very considerable storage, amounting to many millions of acre-feet, on the Lower Ohio itself, and near the outlets of its main tributaries, as well as farther toward the head-waters. If properly designed with low-water outlets, high dams could be built without undue interference with navigation.

The St. Francis and Yazoo Basins, which are among the very best of the Mississippi bottom-lands, and perhaps other parts of the overflow area along the river, must eventually receive protection from local flood water by dams in the hills. No one of the rivers entering these basins from the hills has a capacity equal to 5% of the extreme flood flow. The dams which are necessary for flood control on these streams may have a limited but significant effect on the main river.

Retarding basins of large capacity probably are feasible on the Red River, and on other large tributaries. No human being knows what the possibilities are, because the necessary investigations never have been made.

If the facts are faced, an heroic job appears ahead, one that will involve hundreds of millions of dollars of expense. Whatever type of protection is secured must be on an unprecedented scale. Under these conditions the whole aspect of the problem is changed. From time to time the problem of flood control on the Mississippi should be examined *de novo*, as if nothing were known about it, to discover how the new scale of thinking will affect the plans. The writer believes this to be desirable, regardless of the skill and standing of the men who have made previous studies, because the state of professional knowledge and the issues to be met change so greatly that old decisions cease to be authoritative. Dams on the Ohio have been dismissed as involving too many complications. The difficulties that formerly seemed insurmountable may now be only necessary incidents of the best plan.

What would the completion of Mississippi flood control by dams and retarding basins be worth as compared with completion by further raising the

levees? Only an exhaustive study can give an adequate answer, but a few items can be suggested. Assume that the present levee system is retained, and is supplemented by dams which will hold the river within its natural banks except during years of extreme run-off, at which time the levees will come into play.

First, there are reported to be about 3 000 000 acres along the Mississippi River that are not protected by levees. The writer has not personally checked this estimate. This is recognized as the most desirable agricultural land along the river, as for the most part it is sandy loam, and not the sticky gumbo of the lower land in the basins. To reclaim an equal amount of swamp land in the Yazoo, Arkansas, or Red River Basins would cost not less than $20 per acre. This land along the river-front is high, and needs little drainage. Assuming that the land between the river and the levees should be submerged in great floods once in 10 or 20 years, such flooding would tend to renew its fertility, and it would not lose its value. With the degree of protection just mentioned, this land along the river-front would be worth probably $50 per acre more than it is now, an increase in value of $150 000 000.

High water causes most of the caving of river banks. The reduction of floods would greatly decrease this caving, and might save levee replacements and revetment work ultimately running into hundreds of millions of dollars. A credit of $50 000 000 for this item is very conservative.

The completion of interior drainage and local flood control of the St. Francis, Yazoo, and other basins, except by means of dams and retarding basins on their own water-sheds, will cost more than $250 000 000, and possibly $500 000 000. Since the Morgan Engineering Company has made plans or superintended the reclamation of more than 1 000 000 acres of this land, the writer feels that he can make an estimate that is rough, but not without value. Flood control by dams and retarding basins on the streams entering these basins, in addition to value in reclaiming the low lands of the basins themselves, would help control the Mississippi, and might properly be credited with $50 000 000.

As to the cost of complete Mississippi flood control by levees, only a guess can be made. The estimates of the Mississippi River Commission have been totally inadequate, and there are no others. Rumors are rife that the new report of the Mississippi River Commission will indicate a cost of completion of $500 000 000. Perhaps, for the first time in the history of the Commission, the estimate will be adequate. Assume that completion of control by dams and retarding basins would save further levee construction, and so may be credited with that amount, in this comparison of costs and values.

Control by reservoirs would give protection to cities on the Ohio River and perhaps on other streams. In some cases, as at Cincinnati, Ohio, control by any other means than reservoirs seems remote or impossible. This item of local protection can safely be credited with $50 000 000.

Some advocates of reservoirs have gone far wrong in assuming that there is little difficulty in combining diverse uses, such as power development, flood control, and navigation. The writer has been insistent in drawing

attention to the limitations of such combinations of use, yet those difficulties are not absolute, but are a matter of degree. Some degree of combined use is possible and desirable. Only a wild guess can be made as to the value of such a system of dams for other purposes, but an item of $50 000 000 would seem to be well within safe limits.

Finally, there would be many incidental benefits, some of which would not be immediately apparent. The higher the water rises behind levees on the Lower Mississippi the farther will it back up the tributaries, flooding the lands and interfering with drainage. Reservoir control would very greatly reduce this damage. Probably three-fourths of the silt and sand carried by the river is caved from the banks, carried a short distance, and deposited again. A more uniform flow, by reducing caving, would relieve the river of this local burden of silt, and make its silt-carrying capacity available for the permanent deepening of its bed. Much land along tributary streams and below the upper dams would be saved from frequent flood damages. The construction of dams might reduce the need for outlets or spillways. Omitting such least measurable values of reservoir control, there is a value of more than $750 000 000 to offset the cost of further levee construction. It is probable that the value would reach $1 000 000 000.

In the practice of engineering there are two fundamental processes, both of them invaluable, which should supplement, and not compete with, each other. One method is that of perfecting and refining existing methods; of letting future policies grow gradually out of past experience. The other method is that of fundamental scientific analysis and engineering design.

The breeder of race horses followed the former method and with a remarkable degree of skill, but it required fundamental engineering design and a new synthesis of elements to create the automobile. The teacher of elocution may help the orator to reach a larger audience, and may use scientific principles in the details of his work, but it required a process of far more fundamental analysis and synthesis to produce the telephone and the radio.

The employees of the Mississippi River Commission, and the Army Engineers working under its direction, sometimes have used excellent scientific methods in their work, but in its larger aspects the whole policy has been that of the practical rule-of-thumb man, and has almost entirely lacked thoroughgoing scientific analysis of the larger engineering problems. The writer believes the major policies which have governed flood control on the Mississippi River justify the following remark of John R. Freeman, Past-President, Am. Soc. C. E.,

"That the steamboat pilot on the river and the scientist in his laboratory each has certain advantage in his point of view, and that much of the river training work in America has been of the quality that might be expected to be produced by a committee of steamboat pilots, without special training in exact science."

If the problem must of necessity be assigned to either type alone, it should be to the man of practical experience, but in the present instance the country sorely needs a combination of both types of service. A member of the Mississippi River Commission recently complained of the criticism that "no

adequate scientific study has been made of this important problem."* A study of the basis of the conviction of the Mississippi River Commission against reservoirs has completely confirmed the writer in this opinion.

The improvement of the Mississippi River is under the control of the Mississippi River Commission, which includes both Army and civilian engineers. The Army Engineers assigned to district offices carry out the policies of the Commission, and are not expected to originate policies. As the experience and the duties of Army Engineers are largely concerned with administration, rather than with technical engineering studies, and as these assignments to posts on the Mississippi River are usually for short periods, they do not have time or opportunity to become qualified as experts on Mississippi River control. Under the circumstances they generally reflect the attitude of the Commission. The civilian assistants in the district offices have worked under somewhat similar limitations, except as to tenure of assignments.

The orthodox attitude of the Mississippi River Commission is the traditional attitude of the engineers along the river. In general, the influence of the Army Engineers has been to raise the standards of the Commission. It is generally believed that such spirit of research and inquiry as has existed in the Commission has largely been due to the Army Engineers. It is generally understood, also, that they have prevented very serious blunders by the Commission, such as the closing of Old River.

It is impossible to separate the history of the Mississippi from the work of the Army Engineers but it should be realized that, in their short assignments on the river and in inheriting the old standards of engineering, they have largely been the victims of circumstance. The present administration of the river is not conducive to the type of engineering analysis that is imperative.

For nearly fifty years the Mississippi River Commission has held to an arbitrary dogma of "levees only" as the final solution of this great problem. Resting on the infallibility of that doctrine, it has discouraged a thorough scientific analysis of the problem as a whole. To-day, with the estimates of half a century discredited by events, and with the public ready to furnish the resources for protection, it finds the precious years largely wasted, so far as any comprehensive research on the problem as a whole is concerned.

When a good soldier finds himself in a hard position he determines to "fight it out on that line if it takes all summer." He knows that "many a battle has been won by a bad general, but that no battle ever was won by a debating society." The hard fighting qualities of the Army officers are praiseworthy. But when a scientist finds that he has taken a questionable position his method is to examine that position to discover whether it is justifiable. There are situations in which the attitude of the scientist is no less necessary to the nation than that of the soldier.

If there should be one chance in ten that reservoirs can play an economical part in the control of the Mississippi, then it is unscientific and unprofessional to adopt an engineering plan for the control of the great river without

* *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 1480.

having thoroughly examined into that possibility. The writer believes that there is in fact a much greater chance that control by dams and retarding basins has an economical, effective, significant, and necessary place in such a policy, even if it be a small place. No more definite opinion is justified in view of the limited data available.

During the preparation of this paper he has become convinced that the examination which is necessary to determine those possibilities never has been made. He strongly believes that for the National Congress to be committed to a permanent policy with reference to flood control on the Mississippi, without such inquiry, will be a mistake of historic magnitude.

The writer was much interested in Colonel Kelly's paper.* General Jadwin, Chief of Engineers, U. S. Army, and his associates, are attacking the problem of the Mississippi with an intelligence and a comprehensive view that are promising, and command the admiration of the profession. Had that outlook characterized the study of the river for thirty years past, the present dilemma as to plans would not exist.

Doubtless great pressure will be brought upon Congress to make appropriations for reservoirs on the distant head-waters of the Mississippi in the guise of helping Mississippi flood control. The writer thoroughly agrees with Colonel Kelly that no reservoirs on the distant head-waters of tributaries to the Mississippi can have any appreciable effect on Mississippi floods. He doubts whether there is a single irrigation project in the United States on which the building of reservoirs would have any markedly favorable effect on the lower river. The Army Engineers should have the full support of the Engineering Profession in their efforts to prevent the misuse of funds through appropriations for unsound reservoir projects. This statement is a necessary introduction to any criticism of the recent study of reservoirs described by Colonel Kelly.

A criticism of that study, however, seems necessary. If the analysis of the entire Mississippi problem, so intelligently outlined and undertaken in June, 1927, by the Chief of Engineers and his associates, could have been spread over a number of years, the country would be fortunate. To endeavor to crowd into six months the work of ten years is not productive of dependable results. The writer believes this is true of the recent study of reservoirs described by Colonel Kelly, for the following reasons.

Until recent years there has been little understanding in America of the principles of design and operation of flood-control dams. In the search by Army Engineers some years ago for flood-control reservoir sites in Ohio, not one of the sites used on the Miami Conservancy project was discovered. Every one of the most significant possibilities in the State was overlooked. In the development of the Miami Conservancy plans the writer found that widely experienced and competent hydraulic and power development engineers, who had not thought in terms of flood control, often had very erroneous conceptions of the problem. No hasty examination would have developed the reservoir possibilities of that project. The actual necessities and possi-

* See p. 724.

bilities could be discovered only by a process of thorough and fundamental analysis and design.

The control of the Mississippi by reservoirs or by any other means will require engineering imagination and creative design on an unprecedented scale, and only persons especially prepared, and having a clear understanding of the problem as a whole, would have a concept of the nature and functions of such reservoirs, or would recognize the existence of possible sites. The writer does not believe it is possible to send instructions to a miscellaneous group of division engineers, some of them burdened with flood-relief work, whose past duties have been largely administrative, few of whom have had any experience with flood-control reservoirs, or have given them any thought, and to get hastily prepared reports of very much value.

It is understood that instructions for the examination of reservoir sites were sent to the various division engineers about July 1, that preliminary reports were requested in about two weeks, and final reports about six weeks later, or about September 1. More than 400 000 sq. miles of territory had to be reported on in that time, only a minor part of which was covered with topographic maps. Under these conditions there was small chance that the significant sites would be recognized and properly appraised. To assume that errors would cancel each other is somewhat like giving a mathematical problem to several men who do not understand it, and taking the average of their answers as correct.

The writer believes that the rule adopted, namely, to consider that reservoir gates would be closed on February 1 for three months, is an arbitrary and improper assumption, made necessary by the great haste in which the work had to be done, and that this rule alone would largely prevent the recognition of favorable sites.

It is believed that this study will be worse than useless if it leaves the impression that an adequate investigation has been made, and if the possibility of a material degree of control by reservoirs is thereby dismissed without adequate examination. After reviewing Colonel Kelly's paper, the writer is of the opinion that an adequate study of this problem still remains to be made.

In his paper* Colonel Townsend, former President of the Mississippi River Commission, stated that in the further raising of the levees the cost would increase approximately as the square or the cube of the height. The last foot of raise is far the most expensive. Colonel Kelly, on the other hand, correctly states that, if reservoir control is sought, the top foot of water is most easily held back, because the most economical reservoir sites are first chosen. Thus, the work which can be done most economically by reservoirs is that which is most expensive if accomplished by levees. The writer believes it is very probable that at some point, to be determined only by very thorough-going analysis, the curves of economy will cross, and the balance will be in favor of reservoirs.

The confusion of counsel and the conflict of opinion running all through the present discussion of this subject is not due to absence of engineering

* See p. 666.

intelligence, but to a lack of the information necessary for sound judgment. If the Mississippi River Commission for the past thirty years had made the necessary studies, these controversies would already have been settled by the facts.

On the Miami Conservancy project there were at first the same conflicts of opinion, but the technical studies of the district settled nearly all mooted questions, and the technical design adopted has been generally approved by American engineers. Similar unity concerning the Mississippi problem will follow a proper study of the facts. No other policy than long-continued, thorough-going, comprehensive analysis will bring that unity. The country should not be committed to a far-reaching flood-control policy without such study. At some time, the fact of lack of information must be acknowledged, and this policy of thorough-going analysis adopted. It will then take years of such study to arrive at a dependable decision.

In conclusion, the writer would emphasize the fact that he is not an advocate of any specific degree of reservoir control as a proven method of flood control for the Mississippi. He does not know to what extent such control is feasible; but he does advocate a deliberate and conclusive study of the subject, which, he believes, never has been made.

LEVEES AS A MEANS OF FLOOD CONTROL FOR THE MISSISSIPPI RIVER

By J. F. Coleman,* M. Am. Soc. C. E.

The control of the floods of the Mississippi River is truly a great engineering problem. It involves uncertainties and difficulties to a greater extent than did the Panama Canal, or any other great work of which the writer has knowledge.

Control of these floods on a basis of any method which has been suggested would involve the expenditure of great sums of money which have not hitherto been available. For this reason the task of those who have been responsible has been to expend such funds as could be obtained in such manner as would afford the most protection. In the main, they have performed this task creditably. Political expediency and sectional jealousy have played their parts in impeding the appropriation of sufficient funds with which to accomplish the task.

By reason of the vast territory and large population whose interests are so greatly involved, the problem has received the attention of many men, both technical and non-technical, some at least of whom have not hesitated to proclaim full and final solution with little or none of the fundamental data on which a true solution must be based.

There can be no better forum than the Society before which to discuss this great engineering problem. The subject has been before it on past occasions and no doubt will be again until the true solution is found. The problem is far more complex than appears upon superficial examination and it is not to be expected that the ultimate solution will be attained without research, study, and analysis, such as would be applied to other engineering problems. It is unfortunately true that an enormous amount of misinformation is extant, which makes it necessary for the student to check carefully a great many of the data which he will assemble before reposing too much confidence therein.

As in the study of other problems in river hydraulics, one is soon brought to a realization of the vagaries and eccentricities of water flowing in open channels of the character of river channels, such, for example, that a given cross-sectional area and gauge reading does not always produce the same velocity and discharge; or that a given gauge reading at one point on the river does not always produce another given gauge reading at another point lower down; or that the flood-plane of the river along any given part of its length is a broken line, and that there is frequently an appreciable variation between the line showing the flood-plane at one time and that of another time when the river stage is approximately the same, etc.

The various formulas for the flow of water in open channels, which have served useful purposes in smaller streams and in canals, often serve to mislead when applied to so large a stream as the Mississippi River.

* (J. F. Coleman Eng. Co.), New Orleans, La.

Necessarily some of the factors to be dealt with may not be definitely known, and for practical purposes must be assumed. The most important of these is the volume of water for which provision must be made. The volume which has flowed down the main river channel during each of what may be called the high-water years for the last thirty or forty years is known with close approximation; but there has never been a time when all the tributaries of the main river have been in maximum freshet simultaneously, or rather at such time as to deliver their respective flows into the Mississippi River in synchronism with the wave crest of the flood in that river.

It is probable that there never will be such a time. It also seems probable that the flood of 1927 will never be exceeded. On the other hand, it is possible for the river to be called on to handle a greater flood than that of 1927. This flood problem is a very vital one to the residents and property owners of the Mississippi River Valley and to those of the valleys of many of its tributaries. Perhaps there has never before been a time when it has received the attention of as many engineers as are now concentrated upon it; and it is probably true that a greater amount of information is now, or soon will be, available than has heretofore existed.

All the methods proposed or suggested for controlling the floods of the Mississippi River include levees; and all of them also include revetment for the control of caving banks. The writer is among those who believe that levees and bank revetment, without the aid of reforestation, contour plowing, reservoirs, outlets, or spillways, will most surely provide the necessary control for the floods of the Mississippi River. This river, it will be remembered, is an alluvial stream flowing in a bed of its own creation. Its burden of silt is heavy and its need for energy with which to transport its silt-laden waters is great. The channel, as it now exists, is admittedly capable of carrying a volume of about 1 000 000 sec-ft. at a bank-full stage from Cairo, Ill., to the Gulf of Mexico. The maximum discharges recorded prior to 1927 were, as follows:

Place.	Year.	Second-feet.
Columbus, Ky.	1912	2 015 213
Helena, Ark.	1912	2 040 660
Arkansas City, Ark.	1912	2 006 601
Vicksburg, Miss.	1922	1 825 555
Red River Landing, La.	1912	1 499 402
New Orleans, La.	1922	1 358 311

The flood of 1927 is said to have been the greatest on record. There is, however, a divergence of opinion as to its volume. Estimates range from 2 000 000 sec-ft. to as much as 3 250 000 sec-ft. Whatever may have been the actual volume it would surely have been more than 2 000 000 sec-ft. if entirely confined within levees, which would have been more than double the capacity of the bank-full river. It is apparent, therefore, that the channel without levees is not large enough to carry the burden in time of freshets and must be enlarged.

A part of this necessary enlargement is taken care of by the leveed section above the bank-full stage. More may be provided by enlargement of the section below that stage.

The "Levees Only", or "Confinement", plan is based on the theory that, in an alluvial bed or channel, the energy and power required for channel enlargement may best be obtained by confining the flowing water so that its velocity will be increased and its scouring capacity will be put to the useful purpose of enlarging the channel.

According to the same theory, the removal or diversion of any part of the waters from the main stream reduces the velocity (and, consequently, the energy) of the main stream below the point of divergence and results in deposits of silt and the reduction of cross-section of the main channel, and hence reduces its carrying capacity; or, to state the proposition in the language of the first report (1880) of the Mississippi River Commission:

"If the normal volume of water in a silt bearing stream flowing in a bed of its own formation be permanently increased, there will result increase of velocity and consequently of the erosive and silt bearing power; an increase of depth, if the banks are held, and an ultimate lowering of the surface slope; and conversely if the normal flow be decreased in volume, there will ensue a decrease in velocity, silt transporting power, and mean sectional area, and an ultimate raising of the surface slope."

Let us examine how this theory fits the records of such streams of this character as are available.

In 1913, the late J. A. Ockerson, Past-President, Am. Soc. C. E., compiled experiences and conclusions of eminent authorities as to the utility of outlets,* from which the following excerpts are quoted:

"(1) Result of the diversion of the Adige into the Castagnaro, Italy.—Elevation of flood level by divided flow and conversely a lowering of flood level when waters were restored to one channel.

"M. R. C. 1890, p. 3106:—'About A. D. 1438 the Adige broke its levees and poured its waters south into the Castagnaro and Canal Bianco, which then formed a drainage stream parallel to the Po. In 1545 the break had so increased, that two-thirds of the low-water flow of the Adige, and three-fourths of the high-water flow, went through it. A low dam was built across the Castagnaro to check the flow into it, and both rivers raised their beds. In 1678 a new dam was built, as the old one was then buried in the deposit. The bed still rose. In 1791 a masonry dam, 39 feet high, with many arch ways through it, to allow floods to pass, was built across the Castagnaro. The bed continued to rise and the floods on the Adige were so high that in 1838 the Castagnaro was permanently closed. In the six years following the closure the floods in the Adige fell, and the more markedly the nearer the point considered was to the Castagnaro.'

"(2) Extracts from work of Frizi, an eminent Italian Engineer, published in 1762.

"Of the Rhine he says: 'The great multiplicity of channels, though productive of very great advantages to the navigation and commerce of Holland, draws after it very fatal consequences. The waters divided into so many branches lost the rapidity and strength which are required to sustain and push forward those heterogenous substances which they transport. The con-

* "Outlets for Reducing Flood Heights", p. 14, pub. by Mississippi River Comm., 1914.

stant rising of the bottom renders the drainage of the waters from the fields more difficult, increases the expense of the necessary embankments, and always augments the damage which these extensive lowlands suffer when the dikes break and threaten the whole country in ruin.'

"To remedy that trouble it was proposed in 1754 to provide still more channels and sluice ways. Gennette, however, maintained that this would not diminish the height of floods; that all of the several channels should be abandoned save one through which the waters should be carried to the sea by the shortest practicable route, and his advice was followed with satisfactory results.

"The effect of adding to or subtracting from the volume of a river is described as follows: 'We read in the collection of observations for 1728 that, having made the experiment of placing a mark (gage) in the Panaro (river) and of letting in and afterwards withdrawing the waters of the great drain of Burana, they observed in the Panaro no sensible rise in the first instance, nor any visible decrease in the second. These three facts have been particularly attested by Eustice Manfredi, whose testimony is worth that of all others. No objections can be made to these facts, for it cannot be said that the quantity of water in the affluent bore no sensible proportion to that of the recipient stream, nor that the sections of the recipient were not effective; neither can the variability of these very sections be attributed to any other cause than an increase of velocity in the united waters, proportioned to the increased quantity of water itself.'

"'* * * In diverting from the principal channel a considerable volume of water, that which is left behind is not visibly diminished either in height or in breadth.'

"Other early observations on the Po confirm this principle.

"'It is a hydrostatic paradox, commonly taught by Italian authors, and uniformly confirmed by experience, that you do not diminish the height of the waters in great floods by lessening the quantity of water.'

"Father Castelli, in the 13th Corollary of his first book on Running Waters, disapproved of the division formerly made of the Po at Buondens and which was afterwards abandoned. (In 1838).

"Guglielmini confirmed the opinion as to the little utility of spillways for reducing flood heights in streams.

"Eustice Manfredi proved the futility and danger of spillways proposed for the right bank of the Serchid River. Experience in like manner demonstrated the futility of a cut made in the right bank of the Arno to prevent the flooding of the City of Pisa. This cut was made in 1740 but no perceptible diminution of flood height at Pisa occurred. The cut was made anew in 1761 during a great flood but the waters continued to rise so high that the people 'could not be persuaded that the cut had been made.' In fact, the greatest flood within the memory of man was recorded.

"Cornelius Meyer, a celebrated Dutch engineer, disapproved of this method of dissipating the flood, and instead proposed confining the water to a single channel with ample embankments to carry the flood waters safely to the sea.

"'The canal made by order of the Emperor Nerva to draw off the superfluous waters of the Tiber at the times of its great freshets, did not contribute in the smallest degree to prevent inundations.'

"One may also inspect the discourse of the celebrated Lorgna on the inundations of the Adige, which sufficiently proves that all the derivations made in that river have only produced a heightening of its bed, and thereby rendered its floods more dangerous.

"The following rules, as set forth by Guglielmini, govern the regimen of alluvial streams:

"'The greater the ordinary body of water in a river the less will be the slope of its bed.

"'The greater the quantity of water which a river carries, the less will be its fall; and the greater the force of the stream, the less will be the slope of the bed.

"'These two rules resolve themselves into a single rule, viz., That the slope of the bottom in rivers will diminish in the same proportion in which the body of water is increased.'"

In the Annual Report of the Mississippi River Commission for 1881, page 128, occurs a statement to the effect that levee building on Red River below Shreveport, La., began about 1860; and that the bed of the river has been depressed and "lands have not been inundated for years."

The writer has not been able to obtain actual records of the surveys made of Red River since 1890, and, hence, is unable to give exact figures. Mr. Gervais Lombard, a member of the Board of Louisiana State Engineers, who has been in charge of levee work on Red River for many years, states that below Shreveport the size of the channel has increased about 300%; that the bed of the river is generally lower in elevation; and that a flood of given volume is carried out of that river now with a lower flood-plane than was possible prior to the completion of the levee system.

The Upper Yazoo River Levee District has enjoyed absolute protection from floods for a number of years. That District has been fortunate in having adequate funds with which to build superior permanent levees and auxiliary works. The levees have a free-board of about 5 ft.; are heavier than the standard; have a hard surface roadway on the banquette; and are systematically and effectively maintained by regularly employed section gangs. The writer is not able to furnish information in specific terms as to the size of the existing channel by comparison with the channel at the time of the completion of the levee system. It is understood that the channel has enlarged itself.

On the Mississippi River many opportunities have been lost for gathering and recording valuable data in precise terms. This has been due, no doubt, to a lack of sufficient funds, and perhaps, in part, to a failure to appreciate the value of such data.

Many outlets and spillways have been closed; many crevasses have occurred, some of which remained open for several years, but all of which were ultimately closed. Neither in the case of the closed outlets and spillways, nor in that of the crevasses, has there been available accurate surveys of the river before and after. It is known that just below each outlet and spillway the river contained shoals and sand-bars which were obliterated after the closure. It is also known that below each crevasse the river has been reduced in section and that, when the crevasse remained open over a period of years, this reduction has been progressive; also that upon the closure of the crevasse the reenlargement of the cross-section immediately began.

For lack of actual surveys, it is not possible to furnish precise figures of the reduction or of the enlargement resulting from any crevasse and its

closure. The only outlet which still remains open (other than the yet unclosed crevasses of 1927) is Old River (just above Red River Landing), through which large volumes of water leave the Mississippi River in high-water periods and pass through the Atchafalaya River to the Gulf. Surveys have been made of the Mississippi River in the vicinity of this outlet from time to time over a period of years.

Cross-sectional areas based on "low water" at Torras Landing and at Red River Landing, respectively, about ½ mile and 1 mile below the outlet, are given approximately in Table 28.

TABLE 28.—Cross-Sectional Areas, in Square Feet.

Place.	Year.				
	1884.	1908.	1918.	1922.	1924.
Torras Landing.....	61 300	21 150	21 300	19 900	23 600
Red River Landing.....	73 800	30 500	29 850	36 200	30 500

For some years past it has been necessary to dredge the channel in low-water seasons in the interests of navigation, and it is not known to the writer whether or not this dredging may have had the effect of maintaining a fairly constant sectional area from 1908 to 1924. Later surveys are not yet (1927) available. It is noteworthy, however, that the cross-sectional areas from 1908 to 1924 are only about 35 to 40% of the cross-sectional areas of 1884.

It seems safe to assert that a crevasse, a spillway, or an outlet will surely result in a progressive reduction in the main channel a short distance below the said crevasse, spillway, or outlet, and that this progressive reduction of channel will continue as long as the diversion of water from the main stream continues. There is also much evidence to support the belief that the crevasses and spillways have a tendency to silt themselves up gradually and, therefore, to grow less and less efficient as the years go by, although the evidence is not in the form of actual surveys.

If technically and practically the "Confinement" theory is right, as the writer believes it to be, it will be necessary either to close the mouth of Old River and confine all the waters of the Mississippi River within the channel of that stream, or to close the Mississippi River just below the mouth of Old River and divert the waters to the Gulf of Mexico through the Atchafalaya River. The latter route is shorter by about 150 miles, but the volume to be provided for would be greater than in the former case by the addition of waters from Red River and its tributaries.

It is not the purpose of this paper to select the channel, or to enter into questions of details of levee construction or bank protection. It seems to the writer that the first step to take in a study of this great problem is to determine, with as much certainty as possible, whether it is better to concentrate the flood waters in one channel, or split these waters into two or more channels by maintaining the Old River outlet and by creating other outlets

and spillways. When the broad general principle is settled, it will be time enough to attempt the determinations of other points.

The unquestioned fact that the stream of large sectional area will attain greater velocities and consequently greater discharge capacities with a given hydraulic slope than would be possible with smaller streams of equal total sectional area is a strong point in favor of the "Confinement" theory. The increased velocities resulting from confinement of the flood waters and the increase in silt-bearing capacity and in scouring capacity, which follow such increase in velocity, hold forth promise of the enlargement of the channel by the erosive forces of the contained waters, and an enlarged channel is needed to carry the excess burden of freshet waters.

The knowledge that the diversion of waters by outlet, spillway, or crevasse will surely check velocities and cause deposits of silt, and hence will reduce the cross-section of the main channel, foreshadows ultimate reduction of carrying capacity as a natural sequence.

It cannot be questioned that a crevasse affords an immediate relief when the river is surcharged and the containing levees are water-soaked or insufficient in elevation or stability; but every crevasse also results in a depletion of the capacity of the main channel, which needs to be enlarged rather than reduced.

If the problem were merely to deal with the control of floods for a few years, perhaps spillways or outlets would serve; but the problem is to provide for all posterity, and it appears to the writer that the advantages which may be gained by spillways are not only temporary, but that they are at so enormous a cost for the future that it would be an engineering mistake to formulate designs of flood control based upon a system of spillways.

For the reasons stated, the writer is of the earnest conviction that levees, with auxiliary works for the protection of banks from caving, will afford the only certain method of controlling the floods of the Mississippi River.

IMPROVEMENT OF NAVIGATION IN RELATION TO FLOOD CONTROL

By Stuart C. Godfrey,* M. Am. Soc. C. E.

I.—Navigation and Flood Control

"And the waters prevailed, and increased greatly upon the earth; and the ark went upon the face of the waters." This passage from Genesis is the earliest record that the writer finds of the relationship of floods and navigation. In the modern parallel that occurred in April, 1927, Noah's one ark had increased to a hundred, freely and instantly made available by the Army, the Navy, the Coast Guard, the Lighthouse Bureau, and the various commercial boat lines. In place of the dove, fortunately, the seaplane and the radio were available. And the outcome proved anew, if proof were needed, that these boats cannot be spared from the rivers.

To-day, on the Lower Mississippi, navigation is overshadowed in importance by flood control. The latter, like a modern prodigal son, after a season of wildness and dissipation, comes back to be the center of popular attention. Navigation is the elder brother who once enjoyed pre-eminence on the river, but who now finds himself relegated, at least for the present, to a subordinate place at the feast. All this is natural enough; a wild animal must be tamed before he can become a useful beast of burden. And the elder brother may accept his position the more gracefully, inasmuch as his brother's salvation will bring to him also great benefits.

II.—Present Extent of Navigation

Indeed, navigation on the Mississippi River does not lack encouraging developments. The present volume of this navigation is not generally appreciated. Consider the giant steamer, *Sprague*—so useful in April, 1927, in rescue activities—at her usual task, supplying the Standard Oil Refinery, at Baton Rouge, La., with crude oil from the Smackover Fields. On March 21, 1926, the *Sprague* finished a 300-mile tow at Baton Rouge with a cargo of petroleum (224 000 bbl. of crude oil) contained in 19 steel barges. (See Fig. 4.)

This tow, the size of four city blocks, contained more than could be carried in the largest tank steamer; the equivalent of no less than 28 full train loads of 40 cars each, or one solid train 9 miles long. It would have taken about thirty of the largest old-time packet-boats to carry this one cargo. No wonder the rivers do not appear so busy in this era of barges and towboats! Yet the Secretary of War was able to state in his Annual Report for 1926 that the tonnage now handled on the Mississippi River System is twice what it ever was in the "good old days" of river steamboating.

* Maj., Corps of Engrs., U. S. A.; Instr., Command and Gen. Staff School, Fort Leavenworth, Kans.

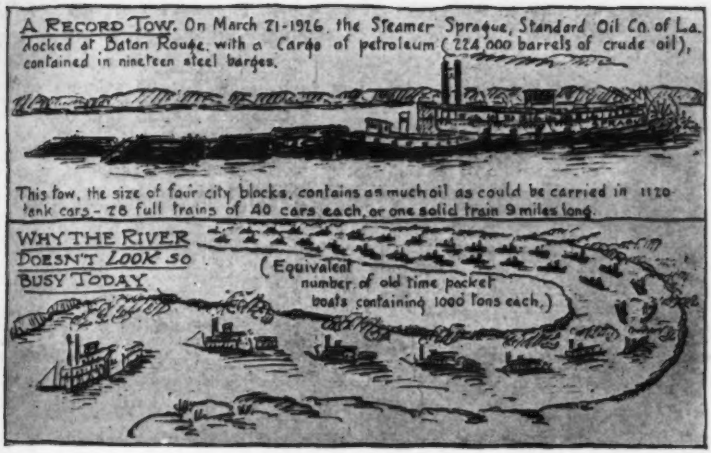

FIG. 4.—VISUAL COMPARISON OF PRESENT AND FORMER TRAFFIC HANDLING.

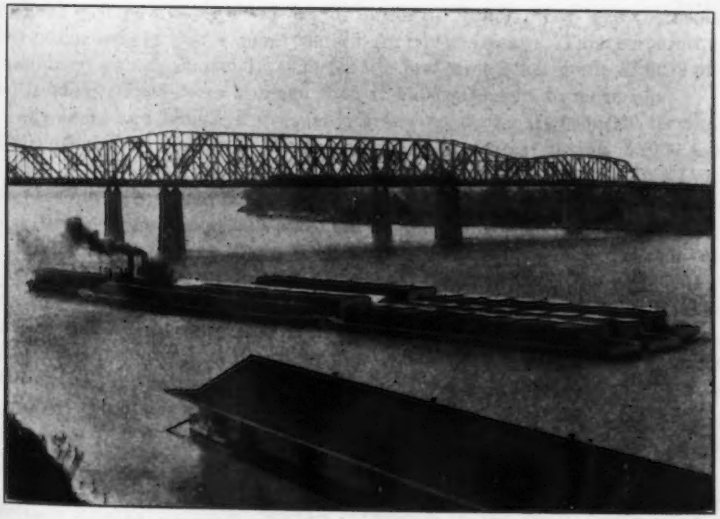

FIG. 5.—TYPICAL FEDERAL BARGE LINE TOW.

The single traffic in crude oil referred to, handled by the *Sprague* and half a dozen other towboats, amounted in 1926 to 2 500 000 tons, about the equal of the entire foreign commerce of Boston, Mass., Newport News, Va., or Galveston, Tex.

The tonnage on the Mississippi and Ohio Rivers has increased greatly since 1920, as shown by Table 29.

TABLE 29.—SOME COMMERCIAL STATISTICS.

	ANNUAL TONNAGE.		
	1920.	1923.	1926.
Cairo, Ill., to Memphis, Tenn.	1 044 945	1 048 322	1 660 188
Memphis, Tenn., to Vicksburg, Miss.	925 763	1 452 837	4 792 780
Vicksburg, Miss., to New Orleans, La.	2 874 190	5 493 297	11 074 488
Ohio River	9 869 325	9 245 647	19 700 000*

* Approximately.

The Inland Waterways Corporation, in its Mississippi-Warrior Service (operating on the Lower Mississippi and Warrior Rivers), charging a rate which is 80% of the rail rate, carried 1 341 000 tons of freight in 1926, an increase of 18% over the preceding year, with a direct saving in rates to shippers of more than $2 000 000. (See Fig. 5.) This season (1927) the Service has been extended to the Upper Mississippi, with three new towboats of lighter draft now in commission. Promising experiments in the use of powdered coal now being tried on the towboat, *Illinois*, may lead to revolutionary changes in power plant design for river vessels. This corporation, Government-owned, showed in 1926 for the first time a net profit of $219 512, and is being offered more tonnage than it has equipment to move.

The Jones and Laughlin Company is now enlarging its $350 000 terminal at Memphis, Tenn., where it handles annually, at a great saving, 50 000 tons or more of steel products shipped by river from the Upper Ohio. This Company has not only issued an attractive and illuminating pamphlet, "Our Runaway Rivers—Put Them to Work", but is practicing what it preaches.

The Carnegie Steel Company is one of several concerns that are making an increasing use of the Ohio and Mississippi for the shipment of heavy tows of steel from the Pittsburgh District by water to the Gulf. This through traffic can be expected to increase greatly with the completion of the Ohio River improvement project by 1929. The W. C. Kelly Barge Line has built and is putting into operation a fleet of modern Diesel towboats of great capacity. Even the old packet-boats, in general an outgrown type, have in some cases found a successor in such fine modern passenger boats as the *Cincinnati*, plying between Cincinnati, Ohio, and Louisville, Ky.

As for terminals, there is a growing appreciation of the vital need of adequate terminal facilities, finding expression in the rapid development at numerous sites of such structures as the river and rail terminal at Memphis, representing an investment by the City of more than $2 000 000.

The economics of transportation on these rivers, especially the Ohio, has been discussed* before the Society, and will not be here reviewed. However, the symptoms referred to, relating to navigation at present, are not those of a languishing patient. Rather do they give encouragement to President Hoover's vision of a 9 000-mile consolidated system of inland waterways serving twenty States, developed to keep pace with the vast expansion of transportation facilities that will be required in the next twenty-five years.

III.—Improvement of Navigation on the Lower Mississippi

The scope of this paper precludes more than a brief discussion of some of the practical aspects of maintaining a navigable channel on the Lower Mississippi. The Mississippi from Cairo to the Gulf is about 1 060 miles in length; the lower 290 miles, below the mouth of the Red River, has ample depth for river craft at all times.

Among the factors which make the Lower Mississippi difficult for navigation are the instability of its channel, the swiftness of its current in places, its easily eroded banks, and the constantly shifting bars. The bar-forming material is supplied from the eroded banks, which give up annually to the river nearly 1 000 000 000 cu. yd. The most favorable factor, as compared with other rivers, is the large low-water discharge, which seldom falls below 100 000 sec-ft.

The general formation of the river is not essentially different from that of other alluvial streams, with abundant water in the bends, which are separated, however, by long bars stretching obliquely across the river. At the broad "crossings" over many of these bars, the same river that at flood stages measures 60 ft. or more on the gauge, fails by its own efforts to maintain a low-water channel more than 4 or 5 ft. deep. The location of these bars shifts from season to season, and even from day to day. The one unchanging thing about the river is its changeableness.

The first comprehensive plan for improving the Mississippi River was by means of regulation. In 1880, when the Mississippi River Commission made its preliminary report, river navigation was a controlling factor, and the plan of improvement comprised the contraction of the waterway and the protection of caving banks, in order to scour out and maintain a channel through the shoals and to build up new banks and establish a fixed regimen. It was then the general belief, based upon experience with other rivers, that such results might be secured largely through the instrumentality of light flexible structures of poles and brush.

The initial works of river regulation undertaken by the Commission, and those most often referred to, were located in the Plum Point Reach, and the Lake Providence Reach, where low-water navigation was particularly difficult. On these works there was expended over a period of several years between $4 000 000 and $5 000 000, more than two-thirds of which went into contraction works.

* *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 1105.

These works improved navigable conditions, and confirmed the soundness of the general theory of improvement. The frail structures of poles and brush, however, proved too light to withstand long the ravages of the floods. Too little attention relatively was paid at that time to bank protection, and most of the contraction works, lacking continuity and completeness, failed sooner or later through changes in the river resulting in "flanking," if not by direct attack. (See Fig. 6.)

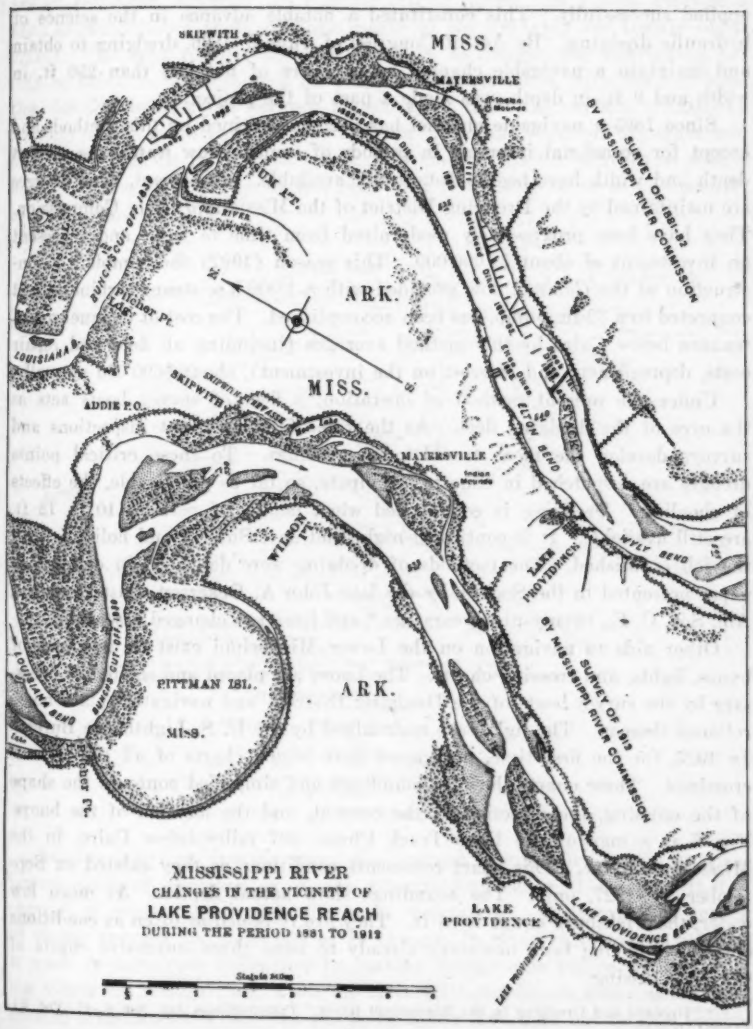

FIG. 6.

Channel Maintenance by Dredging.—When it became apparent that channel improvement by contraction works, as then conceived, could not meet the pressing needs of commerce within a reasonable time limit, the Commission began experiments with hydraulic dredges of large capacity. After extended study and experiment, such dredges adapted to this peculiar service were developed, and the plan for the temporary improvement of low-water navigation by opening and maintaining channels across the obstructing bars, was applied successfully. This constituted a notable advance in the science of hydraulic dredging. By Act of Congress of June 3, 1896, dredging to obtain and maintain a navigable channel below Cairo of not less than 250 ft. in width and 9 ft. in depth, was made a part of the project.

Since 1895 a navigable channel has been maintained by this method, and except for occasional intervals in periods of unusual low water, the project depth and width have been substantially available. At present, nine dredges are maintained by the Dredging District of the Mississippi River Commission. They have been progressively modernized from time to time, and represent an investment of about $2 000 000. This season (1927) the complete reconstruction of the *Gamma,* now provided with a 1 000-h.p. steam turbine, direct connected to a 32-in. pump, has been accomplished. The cost of channel maintenance below Cairo by this method averages (including all field and repair costs, depreciation, and interest on the investment), about $600 000 annually.

Under the present method of operation, a fleet of survey boats acts as the eyes of the dredging fleet. As the river falls, frequent inspections and surveys develop the more troublesome crossings. To these critical points dredges are despatched in time to anticipate, so far as practicable, the effects of shoaling. Dredging is commenced when depths of perhaps 10 to 12 ft. are still available. It is continued night and day, Sunday and holiday, until the job is finished. The methods of dredging were described in detail in a paper presented to the Society by the late John A. Ockerson, Past-President, Am. Soc. C. E., twenty-nine years ago,* and have not changed essentially.

Other aids to navigation on the Lower Mississippi exist in the form of buoys, lights, and crossing charts. The buoys are placed and shifted as necessary by the survey-boats of the Dredging District, and navigators place much reliance thereon. The lights are maintained by the U. S. Lighthouse Bureau. In 1927, for the first time, navigators were issued charts of all troublesome crossings. These charts show by soundings and simplified contours the shape of the crossing, the direction of the current, and the location of the buoys. Fig. 7 is a map of the Race Track Chute, 607 miles below Cairo, in the Mississippi River. This chart represents conditions as they existed on September 24, 1927, only. The soundings show actual depths. At mean low water, the Vicksburg gauge is 3½ ft. They are re-issued as often as conditions change, it having been necessary already to issue three successive charts of Corona Crossing.

* "Dredges and Dredging in the Mississippi River," *Transactions,* Am. Soc. C. E., Vol. XL (1898), p. 215.

Limitations of Dredging.—In this connection, it should be understood that the dredging done for channel maintenance is purely temporary in nature. The excavated material is not removed from the river, but deposited a few hundred feet down stream from the channel limits. If the location of the dredged cut has been skillfully chosen, the channel will maintain itself during the remainder of that particular low-water period. At the first considerable rise of the river, however, the channel fills up much like a path through a bank of wind-driven snow, and the marks of the dredging are largely obliterated. The next time it becomes necessary to dredge, the obstructing bar may be found to have assumed an entirely different shape, with the new location for the dredged cut perhaps a mile away from the old site. Thus, no stability exists as to channel location, nor as to the location of lights and buoys. So difficult is the pilot's task that one will hardly venture to take a boat down the river unless he has been over it recently so as to be "posted" as to its changes.

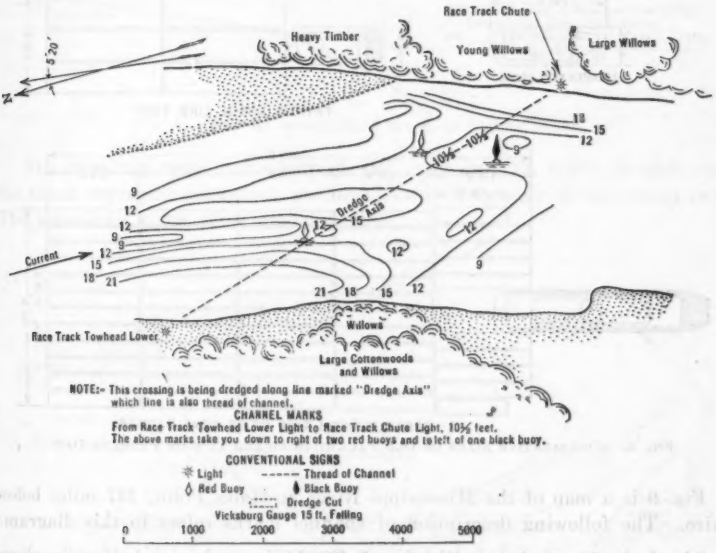

FIG. 7.—RACE TRACK CHUTE.

Another inherent disadvantage of a dredged channel lies in the physical impossibility of ensuring, with any reasonable number of dredges, that a channel of project depth will always be maintained. Ordinarily, by means of timely surveys and forecasts as to changes in river regimen, an attempt is made to anticipate difficulties by making dredge cuts before the critically low stages are reached; but when the river falls rapidly, so many shoals may develop simultaneously that the entire dredging fleet may not be able to give timely assistance at all needed points.

Another serious objection to the present project lies in the restricted width of channel. For the old-time packet-boats a channel width of 250 ft. was perhaps sufficient. The situation has entirely changed with the advent of the present type of towboat and barges. (See Fig. 8.) The normal tow for a Federal Barge Line towboat, for example, is six barges, three abreast, with outside dimensions of 135 by 750 ft. The Standard Oil tows are even larger. Only when such a channel is straight and parallel with the current can it be regarded as affording adequate width. In the occasional sharp bends (see Fig. 9), curved channels (Fig. 10), or those with the current running obliquely to the channel, so as to require "flanking" on the part of navigators, the channel becomes hazardous in the extreme. In such cases, the pilots of large tows usually resort to "double tripping," involving great loss of time.

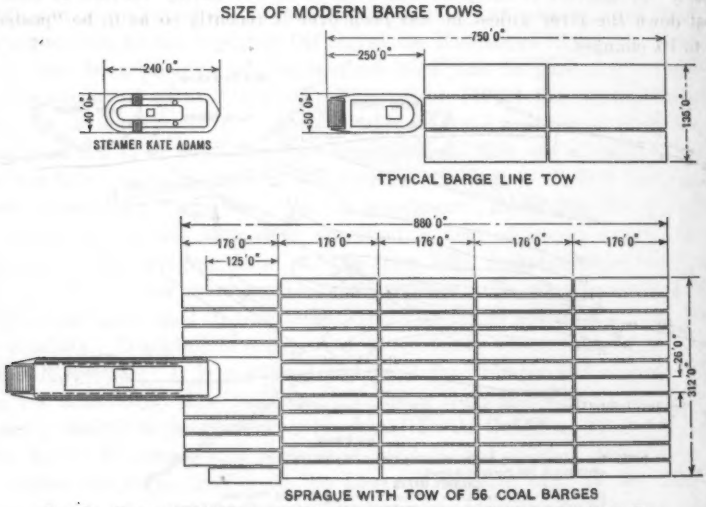

FIG. 8.—COMPARATIVE SIZES OF OLD PACKET-BOAT AND TOW OF PRESENT DAY.

Fig. 9 is a map of the Mississippi River at Hales Point, 137 miles below Cairo. The following description of channel marks refers to this diagram:

"At from 50 yd. below Wrights Point Light to target half mile above Hales Point Light. This takes you 75 yd. to right of red buoy and 100 yd. to left of first black buoy and 25 yd. to left of second black buoy, 13 ft., one cast until from Tennessee Point opposite Island 21 to tin roof barn 250 yd. below target, 15 ft. This takes you to left of third black buoy."

Fig. 10 is a map of the Mississippi at Corona, 204 miles below Cairo. The corresponding channel marks are described as follows:

"From head of white sand below Massey light to 150 yd. below Corona upper light, 13½ ft. Down this way till from 150 yd. below Corona Bar light to Corona lower light, 15 ft. The above marks take you down to right of two red and left of four black buoys, favoring the red buoys."

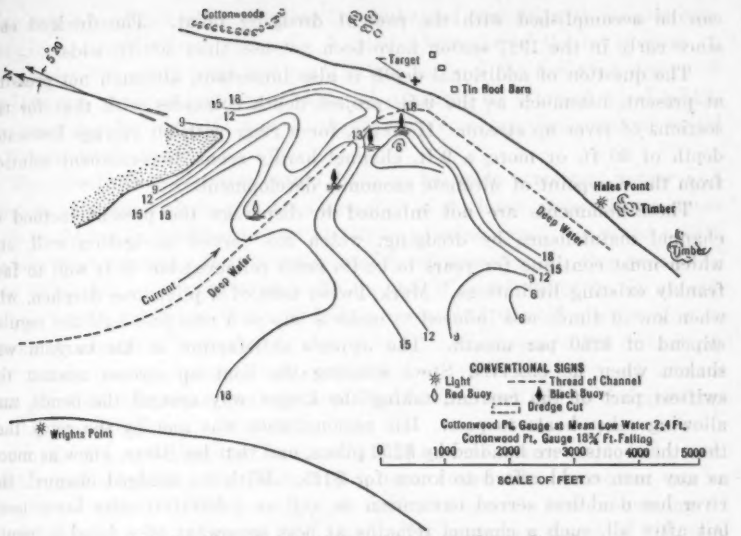

FIG. 9.—MAP OF MISSISSIPPI RIVER AT HALES POINT.

The soundings were taken July 26, 1927, and July 23, 1927. In each case, the charts represent conditions as they existed on the day of the survey only. The soundings given show actual depths.

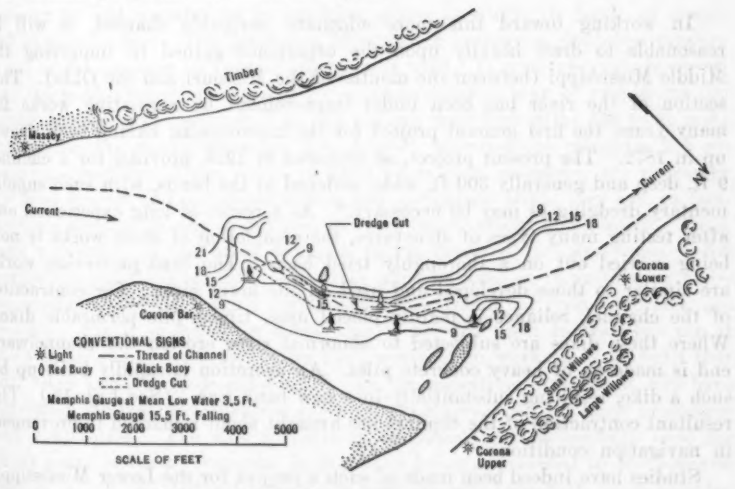

FIG. 10.—MAP OF MISSISSIPPI RIVER AT CORONA.

This need of additional channel width has already been recognized by the Commission, and approval has been given for a moderate increase, which

can be accomplished with the present dredging plant. The dredged cuts since early in the 1927 season have been not less than 300 ft. wide.

The question of additional depth is also important, although not pressing at present, inasmuch as the 9-ft. project depth coincides with that for the sections of river up stream. However, for a river with an average low-water depth of 30 ft. or more, a 9-ft. channel hardly seems a permanent solution from the viewpoint of ultimate economic development.

These comments are not intended to disparage the present method of channel maintenance by dredging, which has served navigation well, and which must continue for years to be its main reliance; but it is well to face frankly existing limitations. Mark Twain tells of a pilot, one Stephen, who when low of funds was induced to make a trip at a rate just half the regular stipend of $250 per month. The owner's satisfaction at his bargain was shaken when he observed Steve steering the boat up stream against the swiftest part of the current, taking the longer way around the bends, and allowing other boats to pass. His remonstrance was met by the reply that the other boats were handled by $250 pilots, and that he, Steve, knew as much as any man could afford to know for $125. With its dredged channel, the river has doubtless served navigation as well as a $600 000 river knew how; but after all, such a channel remains at best somewhat of a hand-to-mouth solution, a precarious foundation for a substantial commerce. Some day the growing needs of navigation are likely to demand a better solution.

IV.—As to Regulating the Lower Mississippi

In working toward this more adequate navigable channel, it will be reasonable to draw heavily upon the experience gained in improving the Middle Mississippi (between the mouths of the Missouri and the Ohio). This section of the river has been under improvement by regulating works for many years, the first general project for its improvement having been drawn up in 1872. The present project, as reviewed in 1926, provides for a channel 9 ft. deep and generally 300 ft. wide, widened at the bends, with such supplementary dredging as may be necessary.* As a result of long experience, and after testing many types of structures, the completion of these works is now being carried out on a thoroughly tried basis. The bank-protection works are similar to those developed and used on the lower river. For contraction of the channel, reliance is mainly placed upon timber-pile permeable dikes. Where these dikes are subjected to abnormal river erosion the channelward end is made up of heavy concrete piles. An accretion is rapidly built up by such a dike, resulting substantially in a new bank line. (See Fig. 11.) The resultant contraction of the channel has brought about a marked improvement in navigation conditions.

Studies have indeed been made of such a project for the Lower Mississippi, which is believed to be entirely feasible, given sufficient time and funds. This would involve a progressive treatment over a long period, regarding the

* See H. R. Doc. No. 9, 69th Cong., 2d Session, "Review of the Project for Improving the Middle Mississippi River."

river as a consecutive whole, shaping its banks and channel with infinite care and giving time for it to respond. A great advantage of the lower river in this respect lies in its large minimum discharge, and the moderate degree of amelioration required, compared with what might be attained (and which may some day be desired); that is, the degree of contraction required would be comparatively small.

The structures themselves would have to be made somewhat larger and sturdier, on account of the greater dimensions of the lower river. These structures would not be confined to any particular existing types, but would utilize the best types emerging from experimental development work. One promising type which has been used extensively on the Missouri River is the retard, similar to the Brownlow Weed of Indian rivers and the old abattis type on American streams. It consists generally of a series of spur dikes of built-up tree trunks deeply anchored by concrete piles. (See Fig. 12.) It is used both for bank protection and channel contraction, and is now being tested on the Mississippi.

On the Upper Mississippi, with an abundance of coarse sand and gravel readily available along the banks, it has been found that spur-dikes can be constructed effectively and cheaply of sand and gravel, with a capping of brush mattress weighed down with stone. Their success suggested the trial of this type of dike on the lower river, where on account of different soil and conditions it is of far more limited application.

Such a plan of regulation (which would be in fact a return to the Mississippi River Commission's early policy) would provide a channel distinctly superior to that maintained by dredging alone, in width, in depth, in shape, and in permanence. The great cost of complete regulation doubtless renders it out of the question in view of any present need. It is noteworthy, however, that the bank protection required for a comprehensive plan of regulating the Lower Mississippi is estimated to cost no less than four-fifths the total cost; the contraction works necessary for channel improvement comprise the remaining one-fifth. These works of bank protection, moreover, are necessary for flood control and soil conservation and navigation alike; they are, in fact, the basic element in any sound plan of river improvement and control. Thus, bank protection is the great common factor involved in improvements for navigation and flood control. The river must be fixed at its critical points—the caving bends—before any permanent works, including river terminals, are possible. Fix it in whatever shape that is decided upon as best, but pin it down somehow, somewhere. After that, contraction works may be built that will "stay put", if made substantial. In the meantime experiment will have developed the best and cheapest types of structures, both for bank protection and contraction. The willow mattress developed and successfully used for many years in bank revetment, is gradually being superseded by the concrete mat, of which two distinct types have been evolved, both with much promise. (See Fig. 13.) Other types of structures being tested for various purposes of bank protection or channel contraction include the retard and the sand-dike, both mentioned previously.

V.—Relationship of Improvements for Navigation to Flood Control

Navigation and Bank Protection.—As has already been suggested, it can be confidently expected that a complete system of bank protection, whether or not followed by contraction, will materially improve the navigability of the Lower Mississippi. This will be due partly to the exclusion of much of the enormous mass of eroded material from the caving banks, and partly to the greater stabilization of regimen, resulting from fixing the river in the concave bends.

Under the present program of operations, only about 6 miles of bank was protected by new work during the fiscal year of 1927. This is less than 2% of the total amount of bank that will need protection within the next decade. In view of the fundamental importance of this work from every viewpoint, it is reasonable to suppose that with more adequate funds the present program of operations will be largely expanded.

In this important and extensive program of bank stabilization, there will be need for the most careful planning to forward the interests of navigation as well as to meet the pressing demands of flood control. In the relatively small amount of bank protection that has been completed, much of it of an emergency nature, it has not always been possible to locate the work so as to serve these various purposes. In laying out a complete system, however, the opportunity surely will not be lost to utilize to the maximum the beneficient effect of bank revetment upon the regimen of the stream. This will mean that some banks will be permitted to wear away before protecting them, that others will be re-shaped to a flatter curvature, that, in short, all work done will be in conformity with, and contributory to, such a plan of complete regulation as may some day be warranted.

Influence of Floods on Navigable Channel.—It is noteworthy that the worst flood-years are also the most difficult years for navigation. Thus, the most troublesome seasons for the last ten years have been in 1922 and 1927, both flood-years. The obvious reason is that the abnormally high stages result in building up the bars to an unusual height (the rate of bar-building being often one-half as great as the rise of the river itself). When the river eventually falls, and especially if that fall be rapid, the river does not immediately "cut out" a new channel through the bars, but leaves them at higher than ordinary levels. In 1927 it was necessary to commence dredging operations at some crossings when the river stages were still 15 to 20 ft. above mean low water, or about 5 ft. higher than for the average year.

Moreover, the occurrence of crevasses naturally tends to cause deterioration in the channel below the crevasse. Instances of this are numerous, the most obvious evidence of this kind noted during the present year, 1927, being at James Bayou Crossing, about 10 miles below the Dorena crevasse. Whereas no dredging has been required over this entire reach for many years, already this season it has been necessary to dredge twice at this point. The more complete control and alleviation of floods would diminish such navigation difficulties.

Influence of Regulating Works upon Flood Heights.—It might be advanced, as an argument against regulation, that contraction works, being in

FIG. 11.—PERMEABLE DIKE AS USED ON THE MISSISSIPPI RIVER.

FIG. 12.—RETARD AS USED ON THE MISSOURI RIVER.

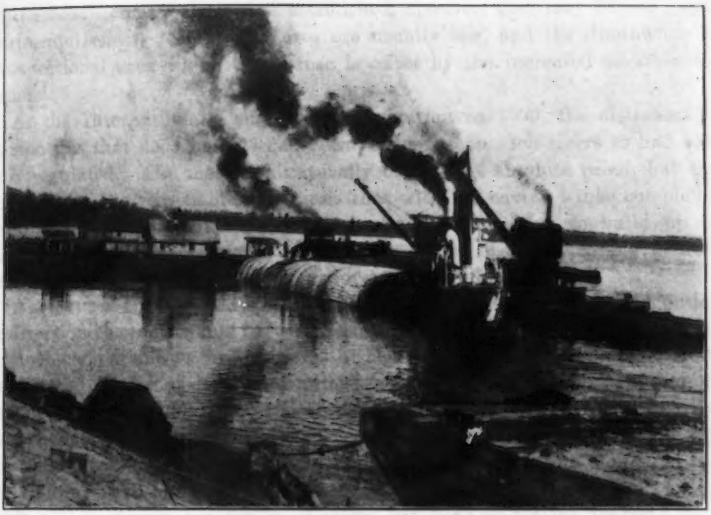

FIG. 13.—VIEW SHOWING THE LAYING OF AN ARTICULATED CONCRETE MATTRESS.

FIG. 14.—DREDGES ASSIST IN CLOSING THE MOUND CREVASSE.

one sense an obstruction in the bed of the river, would have the effect of raising flood heights. It is well established, however, that they have no such detrimental effect. Such structures are usually low, and the diminution in cross-sectional area which they cause is offset by the increased scour in the channel.

At the International Congress of Navigation in 1900, the consensus of opinion was that flood heights had been reduced upon such rivers as had been fully regulated. The matter is naturally difficult of absolute proof, but this accords with the reasonable hypothesis that with the caving banks completely protected, the rising river finds less material with which to build up its bars, and, therefore, maintains a better high-water channel, tending to draw off the floods more rapidly and to reduce flood heights.

Navigation and Spillways.—It is doubtless true that uncontrolled outlets or diversion channels would be very harmful in their effect upon the navigable channel, comparable to that of crevasses just mentioned. From this viewpoint the general theory as to the advantages of contracting the flow in a single channel is unassailable; but it is significant that the spillways or diversions proposed for the Lower Mississippi contemplate long overflow weirs, with their sills fixed at a level which will not affect low or medium stages, so that the spillways will operate only when relief is needed from excess flood waters. With such spillways, navigation, it seems, can have no serious quarrel.

Navigation and Reservoirs.—The potential capacity of reservoirs to serve navigation is well known, but the practical limitations as to cost and as to the difficulty of utilizing reservoirs for more than one purpose are also generally appreciated. Each case must stand on its own merits.

The studies as to possible reservoir effect now under way are being made primarily from the viewpoint of flood control, and navigation could probably expect only such incidental benefits therefrom as would be in the nature of a by-product. The writer has no data relative thereto, in addition to what have been given, except the statement that if all the reservoirs above Cairo thus far studied were built, they would increase the low-water flow below that point by an amount estimated at 150 000 sec-ft. for a period of 6 months, which would about double the low-water flow, and greatly diminish the dredging required. The great cost of such a system of reservoirs, however, would probably exceed any economic benefit to be derived therefrom.

Navigation in Relation to River Shortening.—In reviewing the report of the Special Committee of the Society on Floods and Flood Prevention,* the writer has been interested in noting the remarks by Messrs. Chittenden, Grunsky, and Townsend, as to shortening the Mississippi. The late General Chittenden thought that the river below Cairo might advantageously be shortened from 125 to 150 miles, or about one-eighth of its length; that the real difficulty in shortening lay in the damage to riparian interests rather than in the disturbance to the regimen of the river. More radical programs of shortening and straightening have also been proposed, some of which go so far as to visualize a mammoth straight ditch with concrete sides. The effect

* *Transactions*, Am. Soc. C. E., Vol. LXXXI (1917), p. 1218.

of "improving" in the sense of thus straightening a stream for drainage purposes, was also discussed in a paper presented by L. K. Sherman, M. Am. Soc. C. E., to the Western Society of Engineers, in 1923.*

With the effect of such a program of shortening on flood control this paper is not concerned. However, among the weighty objections advanced against shortening is that of interference with navigation. It appears to the writer that this danger has been exaggerated.

Thirty miles above Memphis is situated Island 35, which divides the river almost equally in two. Of late years the main current, which has long gone the more devious way around the bend, has been tending more and more to take the route through the chute, shorter by 4 or 5 miles. Early in the season of 1927, the Dredging District dredged as hitherto in the bend, with little success as to securing a channel which would remain open. Later, when that channel was plainly playing out, a dredged cut was made in the chute, supplemented by snagging operations. With some initial difficulty this channel has been maintained, and the boats are running there now with increased facility. The criticism that the river had been shortened by causing a cut-off was of course unjustified. The river itself had gradually selected and improved the chute way, and the dredging was merely a recognition at the proper time of that fact.

In this case navigation readily adapted itself to the mildly shortened channel. The pilots of the big river tows, in fact, usually prefer (where there is any choice) the shorter and straighter way; nor do the straighter reaches, on the whole, give greater maintenance difficulty than the crooked ones. A similar case in point is that of Racetrack Chute and Reid Bedford Bend, south of Vicksburg, Miss. The preferable channel, from the navigation viewpoint, is *via* Racetrack, the straight path through the chute, which is a mile or two shorter than around Reid Bedford Bend. It is worthy of note that the swiftest current in this vicinity is found in the point of the bend where the channel is quite narrow. It is not the average current that hinders navigation, but the swift current at some particular spot, as in climbing a reef or negotiating a sharp turn. The average slope below Cairo is less than two-thirds that for the St. Louis-Cairo Section, and, in the writer's opinion, both slope and average velocity might be somewhat increased without detriment to navigation, if attention were paid to the critical points.

Suppose, for example, that by encouraging every tendency of the main channel of the river to take the shorter way, as in the two cases mentioned, it proved feasible to gain as much as 1 mile in every 20 miles, or a total of 50 miles. Of course, other critical points would have to be strongly held to prevent a corresponding lengthening of the channel elsewhere; this should be feasible with an expanded program of bank revetment, with which program the shortening would go hand in hand. Such a moderate program of shortening would have better chance of success than a radical one, and would not require the same sweeping and difficult adjustments. Naturally, at flood stages

* "Experiments on the Effect of Upper Channel Improvements upon the Downstream Flood Heights," by L. K. Sherman, *Journal*, Western Soc. of Engrs., Vol. 28, 1923, p. 293.

the river would continue to use both channels, but a greater proportion of the discharge would go the shorter way.

The writer's point is not to contend that shortening is advantageous, but to suggest that the treatment of the navigable channel, which in general departs from the natural regimen as little as practicable, would probably adapt itself without detriment and perhaps with benefit to whatever moderate program of shortening might prove beneficial from a flood-control and drainage viewpoint.

Dredging and Flood Control.—In addition to their normal tasks connected with the navigable channel, the dredges of the Mississippi River Commission have served more directly the cause of flood control. During the past several years the cutter-head dredges have been occasionally useful in filling land-side pits and "blue-holes" (thus making levees more secure) and in constructing levees of sand, naturally on a somewhat flatter slope than the standard cross-section. The task of closing the great Mound crevasse is about one-half a dredging proposition, and the dredges there have now completed three-fourths of their work ahead of the original schedule and at a cost greatly below the bids received in response to advertising. (See Fig. 14.) Thus, for any program of levee enlargement or reconstruction, the plant designed to benefit navigation has proved its ability to serve as well the needs of flood control.

VI.—Conclusion

Improvement of navigation and flood control are quite different problems. The former is chiefly concerned with the stream at its lowest stages. The latter has to do with flood discharges thirty to forty times the minimum discharge, and a materially different channel. Flood control seeks to prevent the river from being a destructive enemy; navigation wants it improved in order to make it a useful friend.

Yet, despite these differences, navigation and flood control have much in common, and few if any conflicting interests. A comprehensive plan of bank stabilization is urgently needed for flood control and will greatly benefit the navigability of the river. In this and other ways, by finding a solution to this vast flood-control problem, it will be feasible at the same time to advance the cause of navigation on America's largest inland waterway.

THE FLOOD PROBLEM OF NEW ORLEANS, LOUISIANA

By Marcel Garsaud,* M. Am. Soc. C. E.

The flood problem of New Orleans, La., and of the Mississippi Valley below the mouth of Red River, is unique because of the special treatment to which it is susceptible. In order to have a comprehensive understanding of the situation one should be familiar with the topography of the city, and should have an intimate knowledge of the present status of New Orleans as a city, and of its commercial importance as a seaport.

Topography of New Orleans

The City of New Orleans is co-extensive with Orleans Parish, having an area of 196.2 sq. miles, of which 19.7 sq. miles are on the right bank of the Mississippi River. The densely populated and highly developed portion of the city has an area of about 40 sq. miles, and lies in a great crescent-shaped bend in the river. Lake Pontchartrain lies north of the city, the distance from lake to river ranging from 4½ to 7 miles. Lake Borgne, an arm of the Gulf of Mexico, lies to the east of the city. Fig. 15 shows the relation of New Orleans to the water about it. Several canals extend into the city from Lake Pontchartrain. The Inner-Harbor Navigation Canal, with a lock near the river end, connects the river with Lake Pontchartrain.

Except for a narrow strip of high ground along the river bank the ground surface in New Orleans varies in elevation from about 2 ft. below to 8 ft. above Gulf level. Fig. 16 shows the topography of the principal part of the city. (The contours are referred to Cairo Datum. The mean Gulf level is equal to 20.43 ft., Cairo Datum.)

The river at the Carrollton, La., gauge, located at the upper limit of New Orleans, fluctuates from slightly below, to about 21 ft. above, Gulf level. The range of fluctuation would have been increased by the 1927 flood had not the levee been breached at Caernarvon, a few miles below the city. The normal elevation of Lake Pontchartrain is about 0.3 ft. above mean Gulf level, but during windstorms it sometimes rises to a height 5 or 6 ft. above that level. It is necessary, therefore, that the city be protected against flooding from both the river and the lake.

Protection against the tides in Lake Pontchartrain presents no unusual difficulty. During the storm of 1915 the lake attained a record height of 6 ft. above Gulf level. Levees of very liberal section, with top elevations of 10 ft. above Gulf level, should provide ample protection against flooding from the lake.

The protection of the City of New Orleans against floods of the Mississippi River, however, presents an entirely different problem, toward the solution of which years of study and effort have been devoted and large sums of money have been spent. The river at New Orleans has a width of from 1 800 to

3 400 ft. and a depth at high water of from 86 to 194 ft. The maximum discharge measured at Carrollton prior to the flood of 1927 was 1 358 000 sec-ft. and occurred during 1922. The velocity of the current at the minimum section for that discharge was about 7.8 ft. per sec.

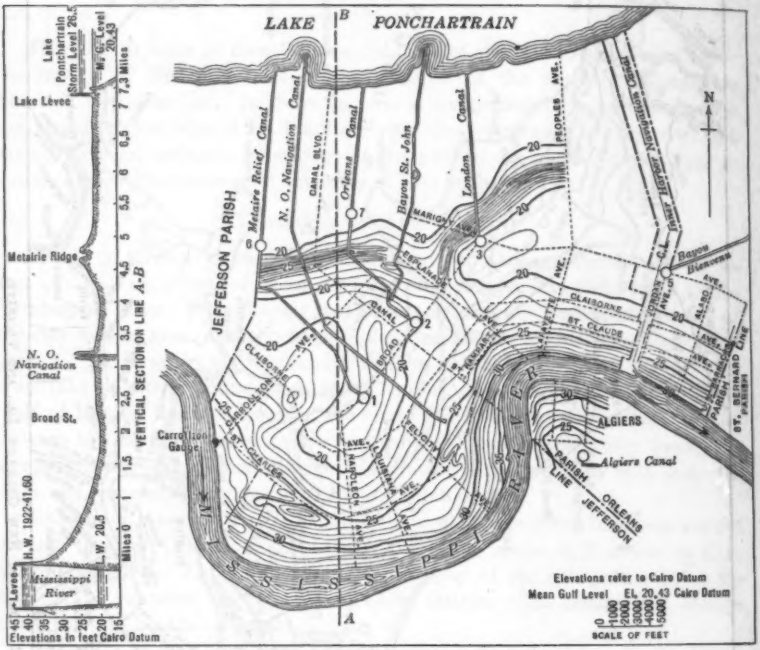

FIG. 16.—CONTOUR MAP OF NEW ORLEANS, LA.

Until 1924 the protection provided for the City of New Orleans against floods consisted of levees built to a grade established by the Mississippi River Commission, and of such section as would not only be adequate for flood protection, but which would have a land-side slope sufficiently flat to permit of easy access to traffic serving the wharves. In 1924 the Point à la Hache Relief Outlet, which will be described later, was authorized.

The levee grade established by the Mississippi River Commission in 1914 was 25.2 on the Carrollton gauge, or about 4 ft. above the highest water of record. The section adopted for the City of New Orleans and followed, except in particular instances where expediency requires modifications, has a crown width of 50 ft., river-side slope of 1 on 3, and a land-side slope of 1 on 10.

PORT DEVELOPMENT

The river banks of the City of New Orleans have been given over to commerce and are lined with modern, up-to-date wharves, docks, sheds, and warehouses. On the east bank of the river, of 12 miles of river bank, 7½ miles

are covered over by these structures. A great majority of these structures have been erected to conform to the Mississippi River Commission grade as established in 1914, and the State agency known as the Dock Board, which is charged with the construction and operation of the port facilities, is undertaking the reconstruction of its obsolete wharves to Commission grade as its budget will permit.

The value of the port facilities of New Orleans is estimated at about $100 000 000, with outstanding bond issues of more than $43 000 000. The Port of New Orleans is second to the Port of New York in foreign commerce. Steamship lines have sailings from New Orleans to almost every port of the world; and with the completion of the inland waterways, and particularly of the proposed 9-ft. channel from New Orleans to Chicago, Ill., the Port of New Orleans is destined to become one of the great ports of the world and the terminus of all the commerce and traffic of the Mississippi Valley.

Record Floods

The three greatest floods of record passing New Orleans in point of volume were those of 1882, 1912, and 1927. These floods can be classed as "super-floods". The floods of 1897, 1903, 1908, 1913, 1916, 1920, and 1922 were large floods; and many floods of ordinary magnitude have occurred.

Flood heights have been increasing at New Orleans for a great many years, due to the building of levees and the consequent closing off of the delta basins. The 1922 flood reached 21.3 at the Carrollton gauge, as against 14.95 for the flood of 1882. This quite naturally brought up the question of raising the levee grade on the lower river, and of the limit of height to which levees can be built on the soils in the vicinity of New Orleans. It has been observed in several localities, and particularly in the territory in and adjacent to New Orleans, that levees have settled or subsided, and that there is a certain point of equilibrium beyond which height it is not safe to construct a levee. An examination of the levees that have settled brought some engineers to the conclusion that a grade of 25 ft. at Carrollton is about the limit to which the levee grade can be set in this section if a reasonable margin of safety as to load limit is insisted upon.

Relief Spillways

A study of the 1922 flood indicated that much greater floods might occur. It was clearly seen that higher stages would occur at New Orleans in the future. This gave added impetus to the consideration of spillways as a means of lowering flood heights and thereby limiting the height of levees. The lowering effect of crevasses that had occurred during previous floods was closely studied, and a conclusion was reached by a large number of technical men that spillways in the vicinity of New Orleans would give the desired relief. About that time a committee of New Orleans engineers recommended the construction of a spillway a few miles below the city to discharge into Lake Borgne. Diversion of 250 000 sec-ft. was proposed. Due largely to the difference of opinion then obtaining among engineers regarding the effect of spillways, the recommendation was not carried into effect.

In 1924 the Louisiana Legislature passed an Act authorizing the Orleans Levee Board to construct a relief outlet on the left bank of the river below Point a la Hache, Louisiana. The writer was then Chief Engineer of the Orleans Levee District and was charged with the responsibility of reporting on this project. A favorable recommendation suggesting a justifiable expenditure of about $1 000 000 was made. It was estimated that by completely removing 11 miles of levee about 60 miles below New Orleans, flood heights would be lowered approximately 1 ft. at the Carrollton gauge.[8] The writer further stated that the discharge through the outlet at the crest of a flood like that of 1922 would exceed 250 000 sec-ft.

The Point a la Hache Spillway was constructed at a cost of $800 000; and observations taken during the flood of 1927 substantially confirmed the ideas of the writer as expressed in his report to the Orleans Levee Board. The curve in Fig. 17, indicates that the stage at Carrollton was 0.8 ft. lower than it would have been without the Point a la Hache outlet. The writer advocated the construction of this spillway not only to relieve flood heights at New Orleans, but also to provide an opportunity to make observations and to study the effect of spillways.

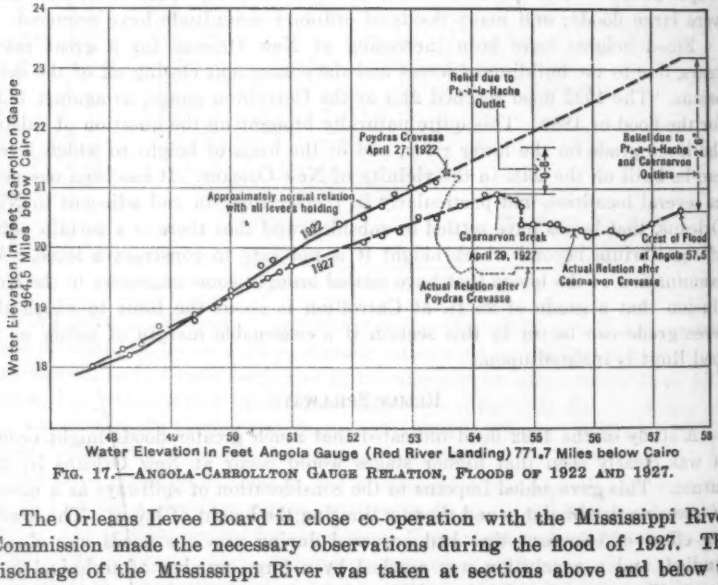

FIG. 17.—ANGOLA-CARROLLTON GAUGE RELATION, FLOODS OF 1922 AND 1927.

The Orleans Levee Board in close co-operation with the Mississippi River Commission made the necessary observations during the flood of 1927. The discharge of the Mississippi River was taken at sections above and below to determine the discharge through the gap. This work was done by the forces of the Mississippi River Commission. The Orleans Levee Board established gauges in the bays at the Gulf end of the outlet and observed them throughout the flood. All these data were furnished to the Federal Spillway Board.

About the middle of April, 1927, when the storms that produced the great flood were occurring, the U. S. Weather Bureau predicted a stage of 24 ft. at

the Carrollton gauge. This was nearly 3 ft. higher than any previous stage. The engineers and business men of New Orleans were confronted with an imminently dangerous condition. It was fully realized that, unless relief should come through a natural crevasse, such as occurred in 1922, emergency action would be necessary. As a result, the left bank levee was breached at Caernarvon about 22 miles down stream from the Carrollton gauge. The discharge through this gap was approximately 270 000 sec-ft. and the lowering effect at Carrollton about 2½ ft. The Caernarvon break not only gave effective protection to the City of New Orleans, but restored faith in the security of the city as well. In addition, it gave another opportunity to make observations and collect more data on mooted points. These observations were also furnished to the Federal Spillway Board.

Permanent Relief Measures

The writer has thus far attempted to sketch briefly the history of the flood question in the lower valley in order that the solution proposed by New Orleans may be more readily understood when presented. The flood problem of the lower valley consists of the necessity for flood-protection works of permanence, adequate not only to protect this part of the valley but also to preserve the integrity of New Orleans as a city and as a port. New Orleans has a population of more than 400 000 and property values of about $1 300 000 000.

It is estimated that the maximum rate of inflow at the latitude of Old River (mouth of Red River) during a flood like that of 1927 would be about 2 500 000 sec-ft. under confined conditions. As the Ohio River System was only in moderate flood at the time it is possible for a flood to occur that would be considerably larger than that of 1927. For this reason the greatest possible inflow is assumed at 3 000 000 sec-ft. at the latitude of Old River. The Lower Tensas Basin forms a reservoir just above Old River in which a large quantity of water is stored during floods. For this reason the maximum outflow below Old River may be taken as somewhat less than the inflow, or, say, 2 900 000 sec-ft.

Even to the casual engineer observer it is obvious that the Atchafalaya Basin is the logical place through which to discharge a large part of the excess flood waters. It is suggested, therefore, that this basin be converted into a floodway by removing the levees at its upper end and building side levees to control the flow throughout the full length of the basin. For the maximum assumed flood the Atchafalaya floodway would carry 1 100 000 sec-ft. A controlled spillway of 350 000 sec-ft. capacity would be built on the left bank at Bonnet Carre to discharge through Lake Pontchartrain. This would leave 1 450 000 sec-ft. to pass New Orleans.

Under present conditions, and with levees holding, this flow would produce a stage of not less than 22.5 ft. on the Carrollton gauge. Such a stage would not only endanger the city, but would seriously interfere with the commerce of the port. A third spillway should be built therefore at the Caernarvon site, a few miles below New Orleans. This spillway would be given a capacity

of 250 000 sec-ft. and would lower flood heights at New Orleans about 2½ ft. With such a system of spillways the stage at the Carrollton gauge could be held to 20 ft. under the extreme conditions assumed.

Operation of Proposed Spillways

The Atchafalaya floodway would be uncontrolled and would operate during all floods rising above bank-full stage. In addition to lowering flood heights at and below Old River, it would give a corresponding relief in the Lower Tensas Basin, and would afford a gradually diminishing relief in the main river for a considerable distance up stream.

The other two spillways would be of the controlled type and would be operated only when necessary to prevent unsafe or undesirable conditions. It would be necessary to raise the levees moderately as far down stream as College Point. However, no increase in levee heights would be necessary between College Point and the Passes. The free-board at New Orleans would be 5 ft. for the assumed maximum flood and somewhat more than 5 ft. for such large floods as have occurred in the past.

The spillway at the Caernarvon site will increase velocities along the New Orleans front by reason of the water passing the city at a lower elevation. Too great a diversion at this site might produce scour and caving, and for this reason the capacity of the spillway is limited to 250 000 sec-ft., and the spillway built as a controlled type so that the amount of diversion may be regulated at all times. Velocities of about 8.5 ft. per sec. occurred at the smallest sections of the channel through the city during the flood of 1927. Higher velocities should not be permitted in the future. Recent soundings taken along the harbor front show some scour, which is sufficient indication that greater velocities than those that occurred during the 1927 flood should never be permitted.

In constructing the spillways, auxiliary works of drainage, railway, and highway re-adjustments, and various other works would have to be done, of course, none of which presents unusual difficulties. Fig. 18 shows tentative details of a spillway suitable for both the Caernarvon and Bonnet Carre sites as designed by Roger B. McWhorter, M. Am. Soc. C. E., Special Engineer of the New Orleans Levee District.

Expense Involved

The probable cost of the flood protection project outlined would be about as follows:

Atchafalaya floodway	$50 000 000
Bonnet Carre spillway	12 000 000
Caernarvon spillway	9 000 000
Levee work between Point Breeze and College Point	35 000 000
Total	$106 000 000

Although the writer has not made estimates of the cost of raising levees on the lower river for a project that does not include spillways, it is believed that an expenditure of more than $100 000 000 would be required for all levee work below Point Breeze, exclusive of that in the City of New Orleans. An estimate has been made to determine the probable cost of raising the levees and the wharves in the city to conform to the levee grade necessary if spillways are not used. The estimated cost of this work is $40 000 000. The writer thinks it is clear that spillways are not only necessary and desirable, but that they will effect a large saving in cost as well.

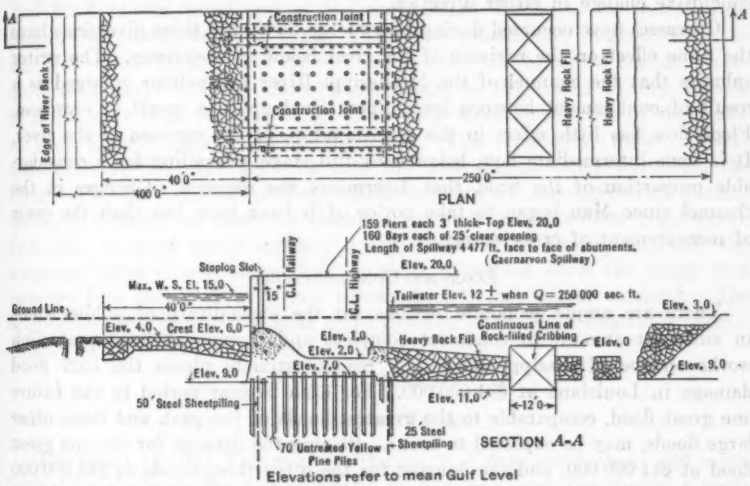

FIG. 18.—TENTATIVE SPILLWAY DESIGN, CAERNARVON SITE. SAME TYPE OF STRUCTURE SUITABLE FOR BONNET CARRE SITE.

The solution that has been given contemplates, of course, that the revetting of the river banks will not only continue, but will be carried forward at a more rapid rate in the future.

HISTORIC BASIS FOR SPILLWAYS

The writer has said little as yet in the line of argument for spillways, and little space will be devoted to the subject. To the best of his knowledge and belief there is not an engineer in the country who does not admit that spillways will effectively reduce flood heights. There are a few who believe the main river channel below a spillway will deteriorate as a result of silting. Fig. 17 plainly shows the effect produced by the Point a la Hache outlet and the Caernarvon break on the flood height at Carrollton. The Poydras crevasse of 1922, a mile or so up stream from Caernarvon, produced practically the same effect on the Carrollton gauge as the Caernarvon crevasse of 1927.

Originally, in its natural state, the channel of the Mississippi River was not nearly large enough to carry the flood flow and the excess water was stored temporarily in the delta basins and much of it carried over-bank down

the valley. Then, beginning at New Orleans in 1718, the levee system was built, most of this work having been done during the last fifty years. The delta basins were closed off and the river was confined between levees.

Those who favored "levees only" as a means of flood protection on the Lower Mississippi, as against levees supplemented by spillways, claimed that the confinement of the river would cause the channel to be scoured larger and deeper, and that flood heights would be lowered as a result; but such has not been the case. Cross-sections of the river have been taken from time to time since the Mississippi River Commission was formed, but they show no conclusive change in either direction.

Crevasses have occurred during every large flood, and these diversions have the same effect on the regimen of the river below as a spillway. The writer submits that the channel of the Mississippi River has neither enlarged as a result of confinement between levees, nor silted up as a result of crevasses. Flood flow has little effect in the determination of the regimen of the river. It is some intermediate flow, below bank-full stage, prevailing for a considerable proportion of the time, that determines the regimen. Changes in the channel since Man began to take notice of it have been less than the error of measurement of cross-section.

Economic Considerations

There are ample economic reasons for the expenditure of public funds in sufficient amount to construct complete and permanent flood protection works on the Mississippi River. A recent estimate places the 1927 flood damage in Louisiana at $81 000 000. For each 20-year period in the future one great flood, comparable to the greatest floods of the past, and three other large floods, may be expected to occur. Placing the damage for the one great flood at $81 000 000, and the damage for the other three floods at $15 000 000 each, the calculable loss in Louisiana during a 20-year period would be $126 000 000.

The loss to Louisiana, due to the fact that investment capital would certainly lose faith in the lower valley, would probably be several times that amount. There can be no doubt of ample justification for the expenditure of more than $100 000 000 for flood protection on the 300-mile stretch of river below Point Breeze. There is a broader view, however, than that based solely on economic returns. The flood problem of New Orleans and the lower valley involves the preservation of human life, as well as billions of dollars of property values.

The spillways suggested herein, especially the Atchafalaya Basin floodway, will restore to the river some of the characteristics it possessed when it flowed unmolested and unhampered in its natural state, prior to the time of levees which Man found necessary to build to reclaim valuable lands.

THE RELIEF OUTLETS AND BY-PASSES OF THE SACRAMENTO VALLEY FLOOD-CONTROL PROJECT

By C. E. Grunsky,* Past-President, Am. Soc. C. E.

Synopsis

The Sacramento River, throughout a large portion of its course from Red Bluff at the upper end of the Sacramento Valley to its outfall into Suisun Bay, flows between banks which are considerably higher than the adjacent valley land. The channel dimensions of the river are in places quite inadequate to carry the extreme floods, as illustrated by one stretch of river, more than 60 miles long, where only about one-eighth of the water at such a flood stage flows in the river. The remainder, under natural conditions, spilled over the bank into the flood basins which paralleled the river. The flood-control project, taking account of these physical characteristics, includes as essential features, not only relief outlets (spillways), but, also, selected areas between levees, so-called by-passes, to which the outgoing water is confined and in which it is carried down the valley to a re-entry into the river at points below which it has larger capacity. The application of such relief outlets and by-passes to the flood control in Sacramento Valley is here described.

Sacramento Valley

The Great Central Valley of California is a depression about 400 miles long, lying between the Coast Range on the west and the Sierra Nevada Mountains on the east. The northerly portion of this valley is known as Sacramento Valley. The northerly apex of the Sacramento Valley is at Red Bluff, at which point the valley begins at once to widen out, attaining and holding a width of about 30 to 40 miles throughout the lower half of its north and south extent. The Sacramento River enters the valley at its northern apex coursing down a little west of its center and discharging into the waters of San Francisco Bay. (See Fig. 19.)

In its meandering course through the valley the river has a total length of about 250 miles. Its fall from Red Bluff to the Bay is about 240 ft. at its low-water stage and a few feet more at its high-water stage, because the rise at flood is about 10 to 15 ft. more at the head of the valley than at points near the Bay.

The Sacramento Valley has a total surface extent of about 4 250 sq. miles (2 720 000 acres) of which the lands, that under natural conditions were subject to flooding and to occasional overflow during freshets, comprise about 1 000 000 acres, or nearly 40 per cent. Three-fourths of the lands which were thus subject to periodical and to occasional submersion by river and

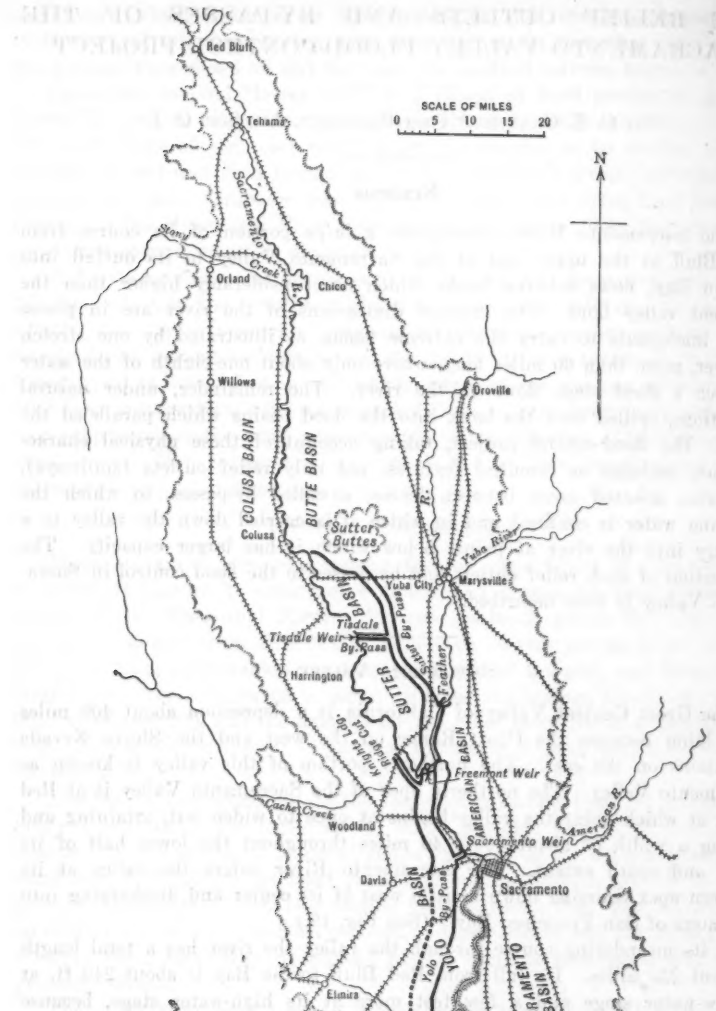

FIG. 19.—FLOOD-CONTROL PROJECT, SACRAMENTO VALLEY, SHOWING SACRAMENTO RIVER RELIEF OUTLETS AND THE BY-PASS SYSTEM.

freshet waters, lie in depressions or basins which flank the river. At times of high water there was an over-bank spill from the river into these basins and on a falling stream water returned therefrom to the stream at a number of points through natural drainage channels. The basins had thus become natural flood-flow retarding basins and had the effect of prolonging the high or flood stages of the river, thereby effectively and very materially holding down the river's peak discharge during flood conditions.

Sacramento River

This will be better understood from a brief description of the original condition of Sacramento River in its course through the Sacramento Valley. At the head of the valley the river has an apparent aggregate drainage area, as indicated by topographic features, of about 9 900 sq. miles. This area does not include about 1 500 sq. miles of territory in the northeastern portion of California and in Southern Oregon, to the northward of the river's visible drainage basin, from which there is supposed to be an underground flow southward, with discharge through springs into tributaries of the Sacramento River. However, it does include the secondary Goose Lake Drainage Basin with a water-shed of about 1 300 sq. miles, of which a portion is in Southern Oregon and the remainder in the extreme northeastern part of California. Pit River, as the main upper branch of the Sacramento River is called, received the occasional output of water from the Goose Lake Drainage Basin. This basin almost takes rank as an interior basin, because a long period has intervened since there was any outflow from Goose Lake into Pit River. The last notable outflow of which there is any definite record occurred in 1868. The rainfall in the water-shed of Sacramento River above Red Bluff varies from an average yearly minimum of about 15 in. on the northeastern plateau of California to upward of 60 in. in the vicinity of Mount Shasta. In high portions of the water-shed of Feather River, a Sierra Nevada tributary, the mean annual precipitation of rain and snow reaches 80 to 90 in. A large portion of the water-shed of the Sacramento River is composed of porous volcanic material into which rain and melting snows sink rapidly, feeding extensive natural and underground storage reservoirs from which there is at many points a large outflow in springs. These springs have a fairly constant flow throughout the year and, in consequence, are the principal source of the large low-water flow of the Sacramento River. This, under natural conditions, was about 4 000 sec-ft. at Red Bluff.

The flood stages of the Sacramento River result from winter rains. There is practically no precipitation from May to September, inclusive, which would produce material run-off. Rain in the winter months, however, and particularly a warm rain falling upon snow, may cause in a few days the river at Red Bluff to rise quite rapidly from very low stages to the highest. The ordinary winter flood stage at that point is about 22 ft. above low water. The peak discharge at an ordinary high stage of the river at Red Bluff is about 200 000 sec-ft.; at the river's extreme high stage its peak discharge may be as great as 270 000 sec-ft. When the river is in flood the extreme discharge at the head of Sacramento Valley does not persist for any great

length of time. The river ordinarily rises rapidly to maximum conditions and then its flow decreases in a comparatively short time to a moderate discharge. Over a period of a week or two the discharge at Red Bluff may be only one-fourth, or even less, of that at the extreme high stage of the river.

From the head of Sacramento Valley to Stony Creek, in a length of 58 miles, the river has an average fall of a little more than 2.5 ft. per mile. In this portion of the Sacramento Valley the slope of the land on both sides of the river is from the hills which encompass the valley toward the river. A number of small streams both from the east and west discharge their waters directly into the main stream. There are no extensive depressions or flood basins such as are found in the valley farther south. The channel capacity of the river is here sufficient to pass ordinary floods within the natural river banks, and the waters of larger floods which overtop portions of bank lands return to the river channel at points above Stony Creek.

This characteristic of the valley topography does not persist toward the south. The river in its farther course, as far as its delta, has built up high bank lands beyond which are the valley depressions, or so-called flood basins. The bottoms of these basins are here and there quite near to, but at other places several miles from, the river. The valley surface has ordinarily a quite uniform gentle slope toward the lowest points of these depressions, giving a smooth appearance to the valley floor.

The stream from Stony Creek to Butte Slough, a distance by river of 53 miles, flows on a lighter grade than in the more northerly portions of Sacramento Valley. Its fall in this stretch is about 1.3 ft. per mile, and the river cannot carry all the water which comes down in times of flood from the north. Some escapes over the banks into the depressions referred to previously. The river's original channel capacity in this stretch decreased gradually with distance down stream from about 150 000 sec-ft. to about 50 000 sec-ft.

From Butte Slough to Feather River, the Sacramento River has a very deficient capacity. Its gradient is here about 0.34 ft. per mile. Under natural conditions the river in this stretch could carry only about 20 000 sec-ft. All the remainder of the flood flow entering the valley from the north, east, and west, above Feather River, found its way into the flood basins and drained from them back into the river lower down. In this stretch the high bank lands are close to the river and there is a rapid fall, in places 15 to 20 ft. into the depressions on either side, making it impracticable to construct river levees far apart.

Below Feather River the Sacramento River in its original condition had a discharge capacity between 75 000 and 100 000 sec-ft., depending on the unknown channel dimensions now modified materially by human agencies, notably by the deposit in the river channel of great quantities of sand which originated in large part in the mountains in the days of hydraulic mining activity. The river gradient from Feather River to the first large partition of water in the river delta, at the head of Steamboat Slough, a distance of 48 miles, is

about 0.30 ft. per mile and somewhat less thence for 18 miles to the point where the water from the great lower west side depression, Yolo Basin, returns to the river and where the capacity of the original river channel increased to upward of 200 000 sec-ft.

Sacramento Valley Flood Basins

For an understanding of the flood-control project on this river it is necessary to say a few words about the Sacramento Valley flood basins which under natural conditions were very effective agents in decreasing the peak of the river's flood discharge. These basins are here very briefly described as they were and as they functioned before the flow of the river had been materially modified by human activities. (See Fig. 18.)

On the east side, in their order down stream, are Butte Basin, Sutter Basin, American Basin, and Sacramento Basin. On the west side are the Colusa Basin (frequently described as consisting of the Upper and the Lower Colusa Basins) and Yolo Basin.

Butte Basin, the uppermost east side depression, extends down stream as far as the contraction between the river's high bank lands on the west and the Sutter Buttes on the east. At this contraction, Butte Slough, a break through river bank lands, forms an interconnection between the river and the basin. The water which flows over the east bank of the river above Butte Slough flowing in a network of channels and uniting with water from a number of streams which drain outlying portions of the Sierra Nevada region, reaches and fills the Butte Basin, the drainage from which, during river flood stages, goes south through the contracted low area between the river and Sutter Buttes already referred to. During a general flood stage of the river this basin holds a slow moving sea of water, 30 to 150 sq. miles in area, depending on the magnitude and origin of the flood waters. The volumetric contents of the basin cannot be given with precision because in times of flood the surface of the water in the basin has more or less slope depending upon the source from which it receives its greatest accession of water.

The second flood basin on the east side of the river is Sutter Basin. This basin has a length from north to south of about 30 miles and an average width of 6 miles. The upper 10 miles thereof, however, has so much surface slope and lies so much higher than the more southerly portion, that, as soon as the inflow of water from the north ceases, there is rapid drainage into the more depressed southerly portion, and submersion of basin lands does not there continue long. The unwatering of the more southerly basin lands being by drainage into Sacramento River near its confluence with the Feather is a slow process. When the flood stage at the mouth of Feather River is at Elevation 30 (above mean sea level), and the basin is full to this height (which is about 8 ft. below the flood-control project high-water stage), its surface has an area of nearly 140 sq. miles and its contents range from 25 000 000 000 to nearly 40 000 000 000 cu. ft., according to the momentary volume of inflow from the north. When, for example, in December, 1889, at its highest stage of the winter, the water in Sutter Basin amounted to

39 000 000 000 cu. ft., or four times the quantity which would fill the Sacramento River channel below Iron Canyon from a low-water to a high-water plane. The general elevation of the lowest portion of this basin is 19 to 20 ft. This is but little above the elevation of the low-water plane of Sacramento River at the mouth of Feather River. Complete drainage of Sutter Basin as it was originally, was therefore a slow process.

The river does not fall to its seasonal lowest stage until in the autumn months, and drain-ways to it which Nature had provided, did not everywhere connect with the lowest spots. Drainage, therefore, was imperfect and water stood in some portions of the flood basin throughout the entire year. It is to be noted that by reason of its position between two rivers, this basin, before its reclamation, received water not only from the Sacramento, but also from the Feather River. While being filled and while discharging its contents, it had a pronounced effect on the flow of the Sacramento River below the Feather.

American Basin is the third east side basin. Its southerly or down-stream end is at the American River. Its northerly apex extends along the east side of Feather River for some miles above its mouth. The basin has a surface extent, if measured by such a flood as that of December, 1889, of 110 sq. miles and, at that time, at its highest stage it contained about 25 000 000 000 cu. ft. of water. Its water stage at its southerly end was controlled by the stage of Sacramento River at the mouth of the American. It is interesting to note that a change of 1 ft. in its elevation at a full stage represents as much water as goes by Sacramento City at a flood stage of Sacramento River in 10 hours.

Sacramento Basin is a name sometimes applied to the depressed area on the east side of the Sacramento River below Sacramento City. This depression is long and narrow. It has been so well protected by levees—although there have been occasional floodings—that its having ever had any material effect on the river discharge is generally ignored. About 35 sq. miles of the lowest portion of this depression are only 6 to 7 ft. above mean sea level, and, therefore, about 10 to 15 ft. lower than the original high-water stages in the Sacramento River opposite the upper end of the basin.

Colusa Basin lies on the west side of Sacramento River, being separated from the Yolo Basin by a ridge of relatively high ground built out from the Coast Range to Sacramento River at Knights Landing (Grafton), by Cache Creek. This basin is long and comparatively narrow. Before the water was held back by levees, any general river flood stage converted the entire west side valley trough from a point in the latitude of Princeton to the ridge at Knights Landing into an inland sea nearly 50 miles long and 2 to 7 miles wide. Its water came from the west side over-bank flow of the river and from numerous small creeks which descend from the Coast Range. During flood conditions, when this basin was full, and water was flowing in it from north to south, its contents may at times have reached 45 000 000 000 cu. ft.

Yolo Basin is the largest of the several flood basins along the Sacramento River. It extends from the ridge described at Knights Landing to Cache

Slough at the lower end of Grand Island on the south. It has a length of more than 40 miles and an average width of 7 miles. At times of general inundation when water was flowing down the basin, its volumetric capacity, before being reduced by reclamation works, was about 50 000 000 000 cu. ft. Its surface extent may be noted at nearly 300 sq. miles. During the high water of 1889 (this being a flood for which the records permit approximation), the discharge from the lower end of this basin back into Sacramento River through Cache Slough, its outlet channel, was more than twice the quantity of water which the river was carrying. In other words the natural capacity of the river at and below Sacramento was only one-third of the combined flow in the river and in the Yolo Basin and yet this combined flow was not as great as the discharge would have been, at the peak, if there had been no retarding influence by flood basins.

The Flood Control Project*

In view of the situation on the Sacramento River in the Sacramento Valley, as explained, the adopted project was based on the following basic principles:

1.—The river must be forced to carry the maximum amount of the flood flow which can be held between properly placed levees of reasonable height.

2.—The water presented at any time in excess of maximum river capacity must be allowed to escape from the river at selected points under control and only for such length of time as is necessary to keep the river below an adopted flood-plane elevation.

3.—The flooding of lands by the water which is allowed to escape from the river must be restricted to definite areas set apart for the purpose.

In the application of these principles to the Sacramento River, the engineers who advised the State and Federal authorities found it desirable to use river discharges as determined from the flood conditions of March, 1907,* as a general guide and to plan control works with some allowance for safety under similar conditions. Studies made in great detail under the direction of Capt. (now Col.) T. H. Jackson, Corps of Engineers, U. S. A., by the Civilian Assistant, H. H. Wadsworth, M. Am. Soc. C. E., and further amplified by E. A. Bailey, Flood Control Engineer of the California State Reclamation Board, led to an adoption of channel, relief outlet, and by-pass capacities in the main, as follows:

From the head of the valley to a relief outlet weir constructed in 1891, and known as Tisdale Weir, the channel capacity will decrease from about 260 000 sec-ft. to about 72 000 sec-ft. The excess over what the river just above Tisdale Weir can carry goes over the east bank of the river flowing as already described into Butte Basin and thence into Sutter Basin. Tisdale Weir has a fixed crest 1 100 ft. long, over which the discharge at flood stage is to be 38 500 sec-ft. (See Fig. 20.)

* *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), pp. 1488–1495.

Below the Tisdale Weir the river is to have a capacity of 33 500 sec-ft. between high levees and the remainder of the flood flow of this part of Sacramento Valley, estimated at 216 500 sec-ft. for a flood such as that of 1907, will be carried in the Sutter By-Pass. To this there will be added the flow of Feather River, 200 000 sec-ft., some miles above the lower or south end of Sutter Basin.

The total flood flow from the north, which will reach the vicinity of the confluence of Feather and Sacramento Rivers, is estimated at 450 000 sec-ft. being the 33 500 sec-ft. in Sacramento River and 416 500 sec-ft. by-pass flow, including Feather River. Of this quantity the Lower Sacramento is expected to take away 107 000 sec-ft., leaving 343 000 sec-ft. to be otherwise cared for. As there is no room for this in the lower river channel, it must be allowed to escape into Yolo Basin. For this purpose a relief outlet controlled by the Fremont Weir has been constructed on the right, or west, bank of Sacramento River a few miles up stream from the confluence of the two rivers. (See Figs. 21 and 22.)

At the City of Sacramento, 20 miles below the mouth of Feather River, the Sacramento receives its last tributary, the American River. It is estimated that this river at a general flood stage similar to that of 1907, will discharge 128 000 sec-ft. into the Sacramento River. This discharge alone, without regard to the water already in Sacramento River, would overtax the contemplated river capacity (110 000 sec-ft.) below Sacramento. To meet this situation a relief outlet has been constructed near the mouth of American River. It is known as Sacramento Weir. (See Figs. 23 and 24.) For economic reasons this has been placed about two miles up stream. Under this arrangement there will be, at times, an up-river current from American River to the relief outlet, but this will be so rare and will continue for such a short time that no bad effects, such as channel obstruction by silt, are feared. It is anticipated that under recurrence of a 1907 flood considerably more than 100 000 sec-ft. of water would go out of the Sacramento through this relief outlet.

At each relief outlet there is a permanent structure replacing a section of levee, through or over which the outgoing water flows. There is thus a Tisdale Weir on the left or east side bank of Sacramento River at the upper end of Sutter Basin; a Fremont Weir on the west bank of the river a few miles above the mouth of Feather River; and a Sacramento Weir also on the west bank of Sacramento River 2 miles above its mouth. The crest of the Tisdale Weir is at an elevation about 2 ft. above the general level of bank lands and about 9 ft. below the extreme flood height in Sacramento River. Whenever water reaches the crest height of the weir the outflow from the river begins and continues during flood stages until the water in the river again drops to below the height of the crest of the weir.

The Fremont Weir also has a fixed crest which is at the general level of bank lands. A trench was excavated to receive this structure. The length of its crest is 9 000 ft. Here, as in the case of the Tisdale Weir, flood water flows freely over the weir whenever the flood stage is higher than the crest. When

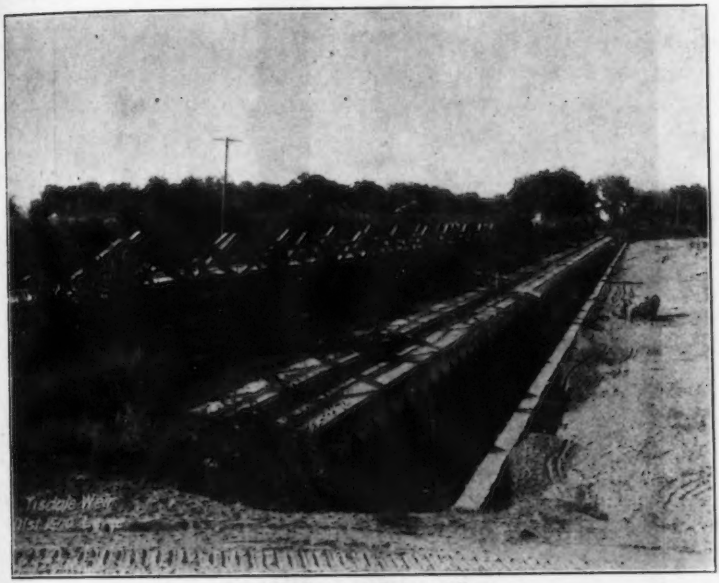

FIG. 20.—VIEW OF TISDALE WEIR.

FIG. 21.—VIEW OF FREMONT WEIR.

FIG. 22.—FREMONT WEIR, FEBRUARY 15, 1925.

flood conditions are similar to those of 1907 the depth of water on the weir will be about 7.5 ft.

The Sacramento Weir has a length of 2 000 ft. and is provided with a movable crest. The top of the fixed structure is about 10 ft. below the river flood stage and the movable crest adds 6 ft. to the effective height of the weir.

At all three weirs the force of the over-falling water is broken by a stilling device, a box-like depression constructed of concrete. In the case of the Fremont Weir, on account of the slight elevation of the crest above the land over which the weir discharges, the stilling-box is shallow and a down-stream apron of rock has been added for additional protection.

The water which flows from the river, through the various relief outlets is not allowed to spread out at random over the basin lands. (See Figs. 25 and 26.) It is confined to comparatively narrow channels by levees. The water which reaches Sutter Basin through the Tisdale relief outlet, together with the water that flows out of Butte Basin, is thus forced by levees, 4 000 ft. apart, over toward the east or Feather River side of Sutter Basin (see Fig. 25) and, as already stated, unites with the water of Feather River a few miles above the mouth of that river. By means of this arrangement the river's over-bank waters are carried around the main portion of Sutter Basin and about 55 000 acres thereof are afforded protection against the floods of both the Sacramento and the Feather Rivers. The water which flows through the Fremont relief outlet (Fig. 22), and that which flows through the Sacramento relief outlet, is likewise confined between levees, making it practical to prevent inundation of a strip of land on the west bank of the river and of considerable areas along the western margin of Yolo Basin.

It would go beyond the purpose of this paper to describe in detail the various areas which have thus received protection against river floods, or to discuss the economic aspects of the Sacramento River flood-control problem. It will suffice to add to the foregoing description that the location of the various by-pass areas necessitated the construction of some quite high levees. Thus, for example, in the case of the Sutter By-Pass there are long stretches of levee from 20 to 25 ft. in height. At times of flood the water of the by-pass stands against these levees for days at a time and subjects them to the usual danger in such circumstances of being attacked by wave action or threatened by seepage waters.

The by-passes have considerable width. The one through the Sutter Basin, as noted, is 4 000 ft. and more in width. That through Yolo Basin ranges from 7 000 to 14 000 ft. When they are filled with water this great width gives the wind a free sweep and subjects the by-pass levees to attack at exposed points by wave action, making their protection with facing of rip-rap or concrete at exposed points necessary.

The fact that high levees are vulnerable is generally recognized. This is particularly true where as in the case of the California by-pass levees there is a long period each year in which there is no rainfall, and in which, therefore, the levees become very dry and subject to cracking where clay enters into their composition. Absolute assurance of protection behind high levees can-

not, therefore, be given. (See Fig. 27.) When this is taken into account, together with the additional fact that volumes of water to be handled at the extreme flood cannot be known, because any flood stage of the past may be surpassed in the matter of volume of flow sometime in the future, then it appears quite questionable whether attempts to protect completely such areas as Sutter Basin should ever be made. This basin might well have been acquired by the State of California and held for all time as an overflow recipient functioning as a retarding basin. Had this been done much of it would have been free of overflow in May or early in June of most years and could have been farmed to summer crops. There would have been little or no economic loss to the State. Furthermore, the flow into this basin and the discharge from it would have prolonged the duration of floods and would have cut down the peak discharge of the lower river, thereby simplifying and rendering safer the protection works on the lower river.

The Sacramento Valley flood-control works have thus far functioned under moderate tests only. There has been no flood stage comparable with that of 1907, nor even with that of 1909, since the completion of the two lower relief outlets. There has, however, been water in the by-passes, notably in February, 1927, when it reached an elevation 10 ft. below the levee tops in the Sutter By-Pass. All that can be said at this time of the relief outlets on the Sacramento and of the by-passes is that their introduction as features of the flood-control works was based on sound principles, but that it is still questionable as to whether these principles have been throughout properly applied to the existing situation.

That the flood-control problem in the Mississippi Valley is comparable with that in the Sacramento Valley seems to be established by recent events. When such volumes of water are presented as was the case during the 1927 floods in the Mississippi Valley, the peak discharge would demand a waterway far in excess of what can everywhere be provided between river levees of reasonable height. Moreover, no one can give assurance that some time in the future there may not be even a worse combination of discharges from tributaries and still greater demand for capacity. It is apparent, therefore, that the present program of levee building should be approved and accepted as a first step in the execution of a comprehensive project, to be, however, supplemented with relief outlets—always preferably in the nature of spillways with a high crest level—through which the river can unload its surplus water.

At such relief outlets no water should go out except when the river rises above a predetermined danger stage, and the discharge through them should cease as soon as the river is again below the danger line. The outgoing volume of water and the flooding of lands will thus be kept at a minimum as will also the number of days or hours during which the outflow continues. Moreover, the areas that will be flooded should be selected in advance, as in the case of the Sacramento River by-pass areas, and they should be held in public ownership in order that farming activities thereon can be kept under control and erection of improvements that would be too greatly damaged by occasional floods can be prevented. It will readily be seen that under such

a plan great stretches of levee, perhaps miles in length, can be held relatively low and converted into overflow weirs or spillways by being covered with concrete, and yet will serve as effectively as the remainder of the river levee in confining the river at a reasonably high stage to its channel. When an extreme flood flow is then presented, the outgoing water will not be discharged through deep accidental breaches in excessive volume (see Fig. 27), but will go out at selected points over high barriers and will be held at the minimum amount which will afford the desired relief.

Cost of the Project

This project is not merely for flood control. The lower end of Sacramento River below Cache Slough is being widened and deepened and navigation conditions there and elsewhere along the river are being protected and improved. The cost of the project falls upon the United States, the State of California, and the land owners, as indicated by the following figures taken from the report of the State Engineer under date of February 10, 1925:

Total Federal appropriations to June 30, 1924		$3 749 900
State Appropriations:		
Co-operative work	$3 500 000	
Lands, cut-off, and channel enlargement	248 600	
For Sutter By-Pass	3 000 000	
Total by State		6 998 600
Land owners' expenditures and obligations		20 497 804
Total appropriations, expenditures, and obligations		$31 246 304
Estimated cost to complete		20 000 000
Estimated total project cost (since 1910)		$51 246 304
Expended by land owners on works useful in the project prior to 1910		$7 272 526
Expended by land owners within the area protected by this project, on back levees, drainage, and other works necessary for land reclamation, since 1850 to December 31, 1924		$41 344 445
The cost of levying assessments from time to time, interest, discounts, and other costs of financing, is estimated by the State Engineer at		$7 657 148
The land owners' expenditures for maintenance of flood control and reclamation works to December 31, 1924, are estimated by the State Engineer at		$8 561 643

Infrequency of Extreme Flood Flow

It is now generally recognized that records of precipitation do not cover long enough time periods to show with positiveness any tendency toward permanent change in the amount thereof or in its intensity. Moreover, the combination of circumstances which produce extreme flood conditions are not of frequent occurrence. Abundant evidence can be found to show that greater floods than any of which there is record are still occurring from time to time and that the possibility of such greater floods should not be lost sight of when flood-control works are being planned.

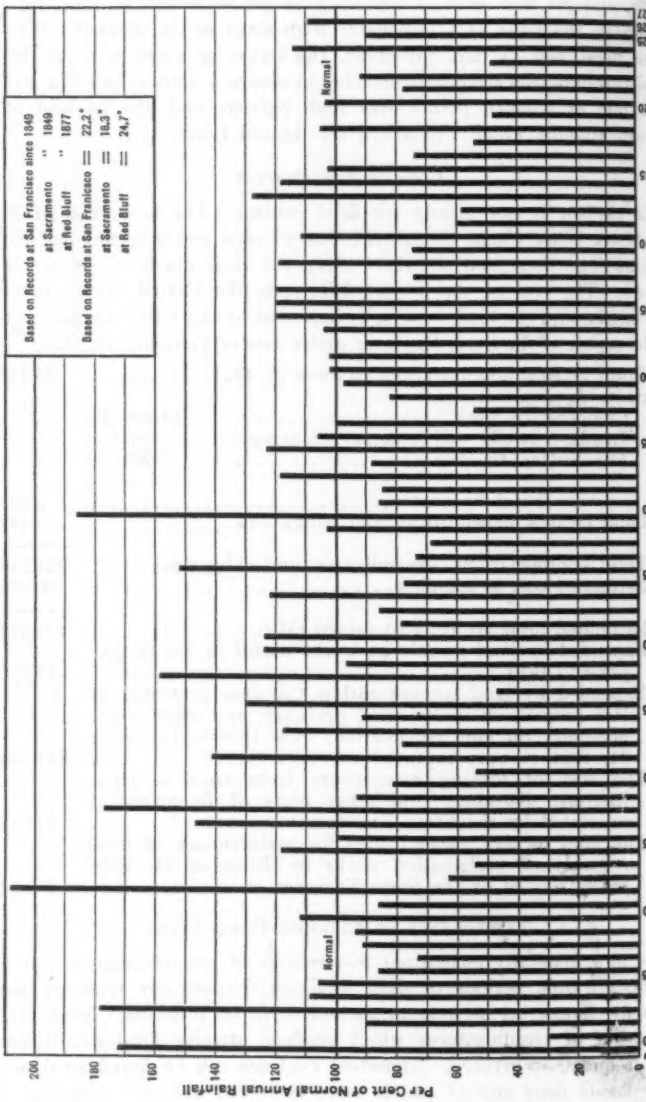

FIG. 28.—RAINFALL IN CENTRAL CALIFORNIA, 1849 TO 1926.

The following facts are cited by way of illustration:

The City of Szegedin, Hungary, on a tributary of the Danube, had been protected by levees for about 100 years when, in 1879, water overtopped the levees and great disaster resulted.

Salt Lake, Utah, which has no outlet, was low in 1843.* It was high 20 to 30 years later, then fell to a low stage (culminating about 1896) comparable with that of the Forties. The claim was then freely made that consumption of water from tributary streams for irrigation had been the cause of the lowering and would keep the lake low. Despite such depletion the lake rose again to a high stage and has remained comparatively high since 1908.

Tulare Lake, California, according to Indian tradition, was once dry. It was certainly very low for a long period preceding the arrival of the white man. This is evidenced by tree stumps uncovered about 1881 by its receding waters. It was filled to overflowing in 1861-62; again to its highest stage in 1867-68. It has been dry for a number of years in recent times, but will surely be temporarily restored to a sizeable area sometime in the future.

On the Danube, in 1897 and 1899, high waters at Vienna rose to within an inch or two of the levee crest; and, yet the river discharge at the peak of the flood conditions was only about three-fourths of the discharge, estimated from high-water marks, of the flood of 1501.

In California, the last winter of the type most likely to produce extreme flood stages in the Sacramento River was that of 1889-90. (See Fig. 28.) Similar winters, earlier in the history of the State were those of 1849-50, 1852-53, 1861-62, and 1867-68. Their absence since 1890 gives no assurance that there has been a change of climatic conditions. Such winters will occur again. No one can tell how soon.

It is possible, and should be regarded as probable, that floods in such winters will surpass those of 1907, 1909, 1911, and 1914, which have served as recent object lessons to the flood-control engineers of the State.

* See Fremont's Reports.

RECLAMATION AS AFFECTING FLOOD CONTROL

By Elwood Mead,* M. Am. Soc. C. E.

According to the 1920 Census figures, there are in the United States a total of 7 538 irrigation reservoirs with an aggregate storage capacity of 21 246 436 acre-ft. Of these, 1 601 reservoirs with an aggregate capacity of 6 023 922 acre-ft. are located within the Mississippi River Drainage Basin. All these reservoirs would be filled with about 4½ days' average discharge of 1 375 000 acre-ft. per day, and amounts to less than 2 days' flow of the Mississippi at maximum flood, maximum discharge being estimated at 1 806 000 sec-ft. It is apparent, therefore, that the flood-reducing effect of the irrigation reservoirs now in existence is negligible.

Approaching the problem from another angle, the total irrigated area in the Mississippi Basin (1920 Census figures) is about 5 000 000 acres. Assuming an average diversion of at least 2 acre-ft. per acre, there would be roughly 10 000 000 acre-ft. by which the discharge of the river during the irrigation season has been reduced by reclamation development; and this reduction is effected during the period of the great Mississippi floods, as the return flow arising from the irrigation diversion dam does not reach the stream until after the flood period.

According to the same Census figures, the total irrigable area included in existing irrigation enterprises in the Mississippi Basin is about 10 000 000 acres, and there is, therefore, an apparent opportunity by the extension of these projects to reduce the flow of the river by another 10 000 000 acre-ft. Assuming that this is spread out uniformly over an irrigation season of 180 days, it would effect an average reduction in flow amounting to 28 000 sec-ft.; or about 4% of the average flow of the stream.

On the Mississippi itself, the serious floods arise elsewhere than in the irrigated regions. The effect of reclamation on the control of its floods appears, therefore, to be negligible; its effect on those tributaries lying within the arid regions is, however, a controlling factor. On the North Platte River former destructive floods have been practically eliminated by the construction by the U. S. Bureau of Reclamation of the Pathfinder and Guernsey Reservoirs. These two reservoirs provide 1 140 000 acre-ft. out of the total storage on this stream of 1 800 000 acre-ft. On the South Platte, 338 reservoirs are in operation with a storage capacity of nearly 1 000 000 acre-ft. On the Arkansas, 367 reservoirs provide 1 155 000 acre-ft. of storage, and the effect within the valleys of these streams, as well as other tributaries on which storage has been provided, has been highly beneficial.

Farther west are regions where flood protection by irrigation reservoirs has been most marked. One of the U. S. Bureau of Reclamation reservoirs, namely, the Elephant Butte, on the Rio Grande, was designed with the purpose of setting aside a definite portion of its capacity for flood control. Its total

* Commr. of Reclamation, U. S. Dept. of the Interior, Washington, D. C.

capacity is 2 638 000 acre-ft., of which the upper 400 000 acre-ft. is reserved for this purpose. The rapidly alternating conditions of extreme shortage and devastating flood characteristic of many streams in the arid region, are graphically portrayed in the following excerpt from a report made in 1921 by L. M. Lawson, M. Am. Soc. C. E., at that time Superintendent of the Rio Grande Project:

"In the relatively short time of five years since the completion of the Elephant Butte Dam, it has served the two extreme requirements, namely, that of storage and that of flood control. The crop produced during the period of 1917 and 1918, when practically all the water used for irrigation was drawn from storage, had a value in excess of the cost of the dam. The flood damage which would have resulted from the uncontrolled discharge of the flood of 1920, through the valleys of the Rio Grande above and below El Paso, would have reached an amount also largely in excess of the cost of the structure."

On the other hand, the fact that flood protection cannot in every case be expected to be provided by the reservoirs necessary for irrigation, is demonstrated by conditions on the Middle Rio Grande Conservancy District. This District comprises lands in the Rio Grande Valley between the upper end of the Elephant Butte Reservoir and the Colorado-New Mexico State line, and has been organized in order to determine in a proper and co-ordinated manner the particularly acute problems of flood control, drainage, and irrigation, which must be solved to permit the fullest development of that part of the Rio Grande Valley. Here, the engineers have reached the tentative conclusion that dependence will have to be placed largely, if not exclusively, on levees for flood protection.

The construction of the Roosevelt Dam on the Salt River, in Arizona, has greatly improved flood conditions down stream, and the completion by the U. S. Bureau of Reclamation of the American Falls Reservoir on Snake River, Idaho, with a storage capacity of 1 700 000 acre-ft., has put an end to floods lower down.

An outstanding example of the possibilities of combining flood control and irrigation in streams of the arid region is the proposed Boulder Canyon Reservoir on the Colorado River. Here, the investigations of the Bureau of Reclamation engineers have demonstrated that by the construction of a dam in a narrow canyon raising the water surface 550 ft., a reservoir with a capacity of 26 000 000 acre-ft. may be formed, which would permit the utilization of the entire flow of the stream for irrigation and, in addition, would provide ample reserve capacity to regulate its floods to any desired extent. This would furnish flood protection for a number of irrigated valleys in the river bottoms between Needles, Calif., and Yuma, Ariz., and definitely remove the ever-present threat of disaster now hanging over Imperial Valley. This river is kept out of this basin by means of levees along its north bank, which turn it south into the Pacific Ocean, but water is carried from it by a canal which runs through Mexico into the Valley, where 400 000 acres are now irrigated and 700 000 acres can be irrigated. Sixty thousand people live on the irrigated lands of this Valley, watered from the Colorado, with all their homes

below sea level and from 100 to 200 ft. below the level of the river where it crosses the International Boundary.

The Valley has once been threatened by destruction through inundation. For a year the whole volume of the Colorado poured into this basin, flooding farms, washing away houses, and doing millions of dollars of damage. With the growing use of water along tributary streams, and the extension of its use in Mexico, further extension of irrigation is stopped, and the farms of the Valley are menaced by irreparable loss through drought. In September, 1924, less than one-third of the water needed by irrigators came down the river. There had been dangerous floods a few months before, followed by this devastating drought, that in two weeks caused a loss of $6 000 000 to the farmers.

The average flow of the Colorado River for a whole calendar year is about 16 000 000 acre-ft. This reservoir will hold, therefore, the entire discharge of the river for a year and a half. The great floods which now come down in the spring when the snows are melting will be caught here and held back, to be released later when water is needed to irrigate parched fields. No water will flow over the dam; all that goes down the stream will be discharged through its regulating gates which will open into tunnels that pass around the end of the dam.

POWER AS AFFECTING FLOOD CONTROL

F. W. SCHEIDENHELM,* M. AM. SOC. C. E.

Power development and flood control are so often incompatible that, from the standpoint of power development, one more readily states the subject of this paper in the inverted order, namely, flood control as affecting power development.

As a practical matter, consideration of power development in connection with flood control presupposes the use of reservoirs for such purposes. Some proponents of flood control conceive of benefits to power development as one of the economic justifications for control of floods by means of reservoirs. Proponents of water power development, on the other hand, are disposed to have misgivings whenever it is proposed to couple the use of storage capacity for flood control with that for power development. However, the two uses are not intrinsically, even if frequently, antagonistic, and it behooves one to analyze more deeply in order properly to appraise the effect of the one on the other.

For the purposes of this paper, the term, "floods", is assumed to include only those high waters which necessitate control in order to prevent damage. Further, the writer assumes that the control of Mississippi River floods solely by means of reservoirs is impracticable. This subject has been discussed in some detail in certain other papers of this Symposium.

To the extent that reservoir sites may be available below Cairo, Ill., such reservoirs are not likely to be of great value for power development. The reservoirs could be filled safely only if and when important floods required the temporary storage of flood-crest water and as soon as practicable thereafter would have to be emptied so as to be ready to receive the water of the next flood crest, which might occur during the very same season or might not occur for several years.

The heads, where sufficiently great, are likely to be so variable and the water supply so intermittent that the possibilities for power installations in connection with Lower Mississippi flood-control reservoirs in general do not seem attractive. Certainly one could not reasonably expect power developments to contribute toward the cost of such reservoirs.

In connection with the use of levees, spillways, or by-passes for Mississippi flood control, power development is not a consideration. Here, too, heads would not be sufficient, nor is any head available for a time sufficiently long.

This paper, therefore, must be concerned mainly with reservoirs located on the tributaries of the Mississippi River and particularly in the upper portions of the drainage areas of those tributaries, for it is primarily at the headwaters that the fall occurs and power must be developed. Unfortunately, it is in those very areas that storage reservoirs are least effective as regards the control of floods on the Mississippi proper.

* Cons. Engr. (Mead & Scheidenhelm), New York, N. Y.

The relationship existing between power development and flood control in respect to such reservoirs will be considered in the following categories:

I.—Complete Regulation by Storage.
II.—Partial Regulation by Storage.
(1) Reservoirs Solely for Power Development.
(2) Reservoirs Solely for Flood Control.
(3) Reservoirs for Joint Power Development and Flood Control.

I.—Complete Regulation by Storage

At the extreme of favorable relationship between power and flood control is the situation existing when a stream is under complete regulation or control by storage. By "complete regulation", from the standpoints of power development and flood control, is herein meant approximate equalization of run-off as of a given point on a given stream, for instance, to the extent of causing approximately the same aggregate run-off to occur month after month, but with variation in flow, for power purposes, within the months. Such regulation may be the work of Man or of Nature. However, on any stream with as much as several thousand square miles of drainage area, complete regulation by artificial storage is not likely to be attempted for power purposes alone.

Whether the regulation be artificial or natural, and despite any utilization of the regulated run-off for power development, there can be practically no high stages of importance on such a stream save those due to ice gorges. This is true even if the stream flow be artificially regulated so as to yield little or no power at certain hours of the day, or days of a week, or weeks or seasons of a year, and correspondingly greater power during other hours, days, weeks, or seasons. In general, it is economically impracticable to install machinery of a capacity sufficient to utilize power from stream flow at such a rate as to produce a damaging flood wave.

The outstanding example of practically complete regulation is, of course, the St. Lawrence River, with its flow regulated by the Great Lakes. If one eliminates from consideration the "high water" caused by ice gorges, the St. Lawrence simply has no flood problem. The status would not be materially different were there artificial regulation for power purposes located, say, at the head of Niagara River, and were such regulation to release at times materially more than the normal flow.

The effect of the complete regulation of a tributary on a larger stream into which it discharges, constitutes a separate story. Generally, as regards flood control, that effect is favorable. Thus, the storing of water, especially of local flood run-off, cannot be otherwise than beneficial. Again, stored water on completely regulated head-waters of tributaries of the Mississippi would normally be released to offset the deficiencies in natural flow occurring either in mid-winter (for example, in the North), or in late summer or autumn (say, in the West, or in western regions of milder climate). In neither event can the water thus released from storage aggravate any major floods of the Mississippi, for apparently without exception these occur in the spring.

Whether complete regulation is feasible, whether it is economically warranted, and, if warranted, what proportions of cost should be borne by the respective beneficiaries thereof, are questions to be determined for each case, in the light of the facts of that case.

II.—Partial Regulation by Storage

Since the very question of the extent to which flood control is affected by power development implies some regulation by reservoirs, the category of partial regulation includes all pertinent cases other than those involving complete regulation.

(1) *Reservoirs Solely for Power Purposes.*—From the short-range standpoint, that is, as concerns areas down stream from the reservoirs, but not too far (say, within several hundred miles), such power reservoirs can only be beneficial in respect to flood control. This benefit, however, may be negligible and certainly is not to be relied on as adequate protection against floods.

If the storage capacity of a reservoir is utilized, then, axiomatically, the storage is drawn upon either when the natural stream flow is relatively low, or in advance and in anticipation of a flood. Conversely, the reservoir is usually refilled when the stream flow is above normal, preferably when the stream is in flood. The result can only be a tendency to reduce flood crests in near-by down-stream areas; certainly, no harm can result.

Such beneficial effect is increased if the storage capacity is sufficient to absorb the entire flood and if, at the same time, other power capacity is available for supplying market demands, so that during the flood the power use at the reservoir may be temporarily suspended in whole or in part. Indeed, if such other power capacity is "hydro" and is located at power stations on streams simultaneously in flood, the benefit from the standpoint of flood control would be accompanied by benefit from the standpoint of power development as well.

Even if the storage capacity of a reservoir be not utilized by drawing upon it, there is generally an absorption of flood peaks. Such absorption is not necessarily important in quantity, but is bound to be beneficial in quality. The absorption takes place without exception wherever the dam or spillway is not controlled by gates or siphons. It results from the fact that, as the flood discharge increases, the depth of flow over the spillway crest increases. This, in turn, necessitates the storing of water over the reservoir surface area to a depth corresponding to the increase in depth of over-flow. The water thus stored must necessarily include the run-off at the very peak of the flood. The result is to decrease the peak of the flood flow from the dam as compared with the peak of the flow into the reservoir.

The smaller the drainage area above the dam and the larger the surface of the reservoir, the greater is such flood-peak absorption. As an extreme there may be cited a drainage area of about 58 sq. miles proposed to be controlled by a storage dam for a power project in West Virginia. There

the reservoir area of about 6 450 acres will be relatively so great that, even assuming the reservoir to be filled at the beginning of the probable maximum flood, the actual flood peak passing over a spillway only 100 ft. long, would be hardly 5% of the natural peak at that point. A case applying to a larger drainage area, namely, 1 044 sq. miles, is that cited* by E. H. Sargent, M. Am. Soc. C. E., for the Sacandaga Reservoir with an area of about 26 000 acres. A flood of the same unit intensity and graph as the Miami River flood of 1913 apparently would have its peak reduced by one-half in passing through the Sacandaga Reservoir and over a spillway assumed to be 600 ft. long. In this case, too, the reservoir was assumed to have been full at the beginning of the flood.

The flood-peak water thus absorbed is retained only temporarily and upon subsidence of the flood is released gradually, but with the result of prolonging the period of high water.

From the long-range standpoint, that is, as concerns 1 000, or more, miles down stream from the reservoir, the effect may be beneficial, or it may be quite the contrary. If one considers the Mississippi River, and the fact that its flood peaks are due to varying coincidences of flood peaks from its several principal tributaries, it is clear that the retardation of flood-peak run-off from a given tributary might prevent the arrival of that peak run-off at a critical junction point, such as Cairo, at a time when it would aggravate a situation arising from synchronous arrivals of floods from other tributaries.

Conversely, the tremendous drainage area of the Mississippi and the long distances of flood travel on its tributaries make equally possible the circumstance that if a given head-water flood peak had not been disturbed or retarded, its water would have reached the critical junction head of the main coincident flood flows, whereas the retardation in fact aggravates the synchronism and hence the resultant Mississippi flood peak.

As regards the Mississippi, therefore, it seems fair to state that over a long period of time the beneficial and the harmful effects of local flood-peak absorption would offset each other. Ample evidence is available to show that the magnitude of effect in either direction can only be negligible.

Finally, it is well to bear in mind that an operating procedure which would involve drawing down a power reservoir in advance of the flood season, so as to afford some additional flood control, is likely to be detrimental to power development. It would involve reduction in head and, hence, in power and, should the anticipated flood not occur, there might be no opportunity to refill the depleted reservoir.

(2) *Reservoirs Solely for Flood Control.*—As to method of operation or purpose these may be classified, as follows:

(*a*) Reservoirs intended to prevent completely any flow past the dam until the reservoirs overflow.

The object is to postpone, completely if possible, the discharge of flood waters until after the flood flows from drainage areas farther down stream have passed the region to be protected. Such a reservoir may be intended

* *Transactions*, Am. Soc. C. E., Vol. 90 (June, 1927), p. 973.

to protect areas at considerable distances down stream, for instance, for the protection of Pittsburgh, at the junction of the Monongahela and Allegheny Rivers to form the Ohio River, in Western Pennsylvania, there has been proposed a system of reservoirs which, among others, would include reservoirs in West Virginia on the head-waters of the Monongahela River.

(*b*) Reservoirs or basins intended to detain the flood discharge, or, more accurately, to lessen the rate of flood discharge to such as may be carried safely by the stream channels through the areas to be protected.

Detention reservoirs are intended to protect areas relatively close to the reservoirs. The outstanding example is the system of the Miami Conservancy District, intended to protect the Cities of Dayton and Hamilton, Ohio, and certain smaller towns.

A reservoir of either type intended solely for flood control in general cannot reliably fulfill its function unless it be emptied as soon as practicable after a flood and thus made ready for the next flood. (Detention reservoirs cause this to take place automatically.) The result is that the flood flows completely withheld, or merely retarded, as the case may be, are released long before the natural stream flow reaches a stage materially below normal. In other words, the flood flows can not, must not, be utilized to increase natural flows during low-water periods. Consequently, benefits to power developments are necessarily incidental and, generally, are minor in amount.
